Chapter 1: Introduction to Flex 4.6

Adobe® Flex® 4.6 introduces new features and continues to build upon the major architectural changes in Flex 4.

If you are a new Flex developer, and have not previously developed applications in Flex, you can use the many available resources to learn more about Flex. For more information on the resources available for new Flex developers, see "Getting started with Flex 4.6" on page 1 and What's new in Flex 4.6 SDK.

If you are an existing Flex developer, you can use the information in "Migration" on page 2 to decide how best to upgrade your applications to the newest SDK.

Getting started with Flex 4.6

Adobe and the Flex developer community provide many resources that you can use to get started with Flex development. These resources are helpful for new users, and for experienced users seeking to increase their knowledge of Flex.

The Flex Developer Center contains many resources that you can help you start using Flex 4.6, including:

- Getting Started articles, links and tutorials
- Samples of real applications built in Flex
- The Flex Cookbook, which contains answers to common coding problems
- Links to the Flex community and to other sites devoted to Flex

As a new Flex user, there are other Adobe sites that you can also use to get familiar with Flex, including the following:

- Adobe Flex in a Week at http://www.adobe.com/devnet/flex/videotraining/
- Flex Test Drive at http://www.adobe.com/devnet/flex/testdrive.html
- Flex video training at Adobe Flex TV

Features new for Flex 4.6

Flex 4.6 contains several new features, including:

- More Spark mobile components including: SplitViewNavigator, CalloutButton, Callout, SpinnerList, DateSpinner, and ToggleSwitch
- Better performance
- Updated platform support
- Enhanced Tooling – Flash Builder 4.6
- Text Enhancements

For more information on additional features, see What's new in Flex 4.6 SDK and What's New in Flash Builder 4.6.

Features new for Flex 4.5

Flex 4.5 contains several new features, including:

- Support for mobile applications
- More Spark UI components including: Image, DataGrid, and Form
- Integration with Flash Player’s globalization classes
- RSL enhancements
- TLF 2.0
- OSMF 1.0 integration
- Spark validators and formatters

This list is a subset of the new features in Flex 4.5 SDK. For more information on additional features, see What's New in Flex 4.5 SDK. You can get more information about productivity enhancements in Flash Builder 4.5 at What's New in Flash Builder 4.5.

Development tools for Flex 4.6

Flex developers typically use two development tools:

- Adobe® Flash® Builder™

  Flash Builderis an integrated development environment (IDE) for building cross-platform, rich Internet applications (RIAs). Using Flash Builder, you build applications that use the Adobe Flex framework, MXML, Adobe Flash Player, Adobe AIR, ActionScript 3.0, Adobe® LiveCycle® Data Services ES, and the Adobe Flex Charting components. Flash Builder also includes testing, debugging, and profiling tools that lead to increased levels of productivity and effectiveness.

  For more information on Flash Builder, see About Flash Builder.

- Adobe® Flash® Catalyst™

  Catalyst makes it easy for designers to create Flex-based RIA UI's from artwork imported from Adobe® Creative Suite® tools, and to define interactions and behaviors within Catalyst. The applications created in Catalyst are Flex applications. Flash Builder provides a simple workflow for importing these applications, which allows designers to collaborate with developers more easily than ever before.

  For more information on Flash Catalyst, see About Flash Catalyst.

Migration

If you are an existing Flex customer, you might migrate your existing applications from Flex 4 to Flex 4.6, or even from Flex 3.

For Flex 4 users, migrating to Flex 4.6 is relatively simple. The differences are largely cosmetic and are summarized in Flex Backwards Compatibility.

For Flex 3 users, before starting the migration process, you should be aware of all new Flex 4 and 4.6 features, and be familiar with changes to existing features. The greatest differences are from Flex 3 to Flex 4. For information on migrating applications from Flex 3 to Flex 4, see the *Adobe Flex 4 Features and Migration Guide*at http://www.adobe.com/go/learn_flex4_featuremigrate_en.

If you upgrade to a new version of Flash Builder to take advantage of new features in the IDE but do not want to use the new compiler features, you can downgrade the output application. You do this by setting the `player-version` compiler option. You can also select an older SDK to compile against. For more information, see “Backward compatibility” on page 2239.

Chapter 2: Getting started

Developing applications in MXML

MXML is an XML language that you use to lay out user interface components for applications built in Adobe® Flex®. You also use MXML to declaratively define nonvisual aspects of an application, such as access to server-side data sources and data bindings between user interface components and server-side data sources.

For information on MXML syntax, see "MXML syntax" on page 21.

About MXML

You use two languages to write applications in Flex: MXML and ActionScript. MXML is an XML markup language that you use to lay out user interface components. You also use MXML to declaratively define nonvisual aspects of an application, such as access to data sources on the server and data bindings between user interface components and data sources on the server.

Like HTML, MXML provides tags that define user interfaces. MXML will seem very familiar if you have worked with HTML. However, MXML is more structured than HTML, and it provides a much richer tag set. For example, MXML includes tags for visual components such as data grids, trees, tab navigators, accordions, and menus, as well as nonvisual components that provide web service connections, data binding, and animation effects. You can also extend MXML with custom components that you reference as MXML tags.

One of the biggest differences between MXML and HTML is that MXML-defined applications are compiled into SWF files and rendered by Adobe® Flash® Player or Adobe® AIR™, which provides a richer and more dynamic user interface than page-based HTML applications.

You can write an MXML application in a single file or in multiple files. MXML also supports custom components written in MXML and ActionScript files.

Using Spark and MX component sets

Flex defines two sets of components: MX and Spark. The MX component set was included in previous releases of Flex, and is defined in the mx.* packages. The Spark component set is new for Flex 4 and is defined in the spark.* packages. The Spark components use a new architecture for skinning and have other advantages over the MX components.

The MX and Spark component sets contain many of the same components. For example, both component sets defines a Button control, TextInput control, and List control. However, while you can use MX components to perform most of the same actions that you can perform by using the Spark components, Adobe recommends that you use the Spark components when possible.

Writing a simple application in MXML

Because MXML files are ordinary XML files, you have a wide choice of development environments. You can write MXML code in a simple text editor, a dedicated XML editor, or an integrated development environment (IDE) that supports text editing. Flex supplies a dedicated IDE, called Adobe® Flash™ Builder™, that you can use to develop your applications.

The following example shows a simple “Hello World” application that contains just an `<s:Application>` tag and three child tags, the `<s:Panel>` tag and the `<s:Label>` tags, plus a `<s:layout>` tag. The `<s:Application>` tag defines the Application container that is always the root tag of an application. The `<s:Panel>` tag defines a Panel container that includes a title bar, a title, a status message, a border, and a content area for its children. The `<s:Label>` tag represents a Label control, a very simple user interface component that displays text.

```
<?xml version="1.0"?>
<!-- mxml\HellowWorld.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:Panel title="My Application">
        <s:Label text="Hello World" fontWeight="bold" fontSize="24"/>
    </s:Panel>
</s:Application>
```

Save this code to a file named hello.mxml. MXML filenames must end in a lowercase .mxml file extension.

About XML encoding

The first line of the document specifies an optional declaration of the XML version. It is good practice to include encoding information that specifies how the MXML file is encoded. Many editors let you select from a range of file encoding options. On North American operating systems, ISO-8859-1 is the dominant encoding format, and most programs use that format by default. You can use the UTF-8 encoding format to ensure maximum platform compatibility. UTF-8 provides a unique number for every character in a file, and it is platform-, program-, and language-independent.

If you specify an encoding format, it must match the file encoding you use. The following example shows an XML declaration tag that specifies the UTF-8 encoding format:

```
<?xml version="1.0" encoding="utf-8"?>
```

About the <s:Application> tag

In addition to being the root tag of an application, the `<s:Application>` tag represents a Spark Application container. A *container* is a user-interface component that contains other component sets, and uses layout rules for positioning its child components. By default, the Spark Application container lets that you set the position of its children. In the previous example, you set the layout of the container to VerticalLayout so that the Application container automatically lays out its children in a vertical column.

You can nest other types of containers inside an Application container, such as the Panel container shown above, to position user interface components according to other rules. For more information, see “Visual components” on page 280.

About namespaces

In an XML document, tags are associated with a namespace. XML namespaces let you refer to more than one set of XML tags in the same XML document. The `xmlns` property in an MXML tag specifies an XML namespace.

In Flex, you typically define three namespaces:

- `xmlns:fx="http://ns.adobe.com/mxml/2009"` The namespace for top-level ActionScript elements, such as Object and Array, and for tags built into the MXML compiler, such as `<fx:Script>`.
- `xmlns:mx="library://ns.adobe.com/flex/mx"` The namespace for the MX component set.

- `xmlns:s="library://ns.adobe.com/flex/spark"` The namespace for the Spark component set.

In general, you include the Spark and MX component namespaces so that you can use any components from those sets. Where possible, use the Spark components. However, not all MX components have Spark counterparts, so the components in the MX namespace are also sometimes necessary.

You can define additional namespaces for your custom component libraries. For more information on namespaces, see “Using XML namespaces” on page 10.

About MXML tag properties

The properties of an MXML tag, such as the `text`, `fontWeight`, and `fontSize` properties of the `<s:Label>` tag, let you declaratively configure the initial state of the component. You can use ActionScript code in an `<fx:Script>` tag to change the state of a component at run time. For more information, see “Using ActionScript” on page 32.

Compiling MXML to SWF Files

If you are using Flash Builder, you compile and run the compiled SWF file from within Flash Builder. After your application executes correctly, you deploy it by copying it to a directory on your web server or application server.

You can deploy your application as a compiled SWF file, as a SWF file included in an AIR application or, if you have Adobe LiveCycle Data Services ES, you can deploy your application as a set of MXML and AS files.

End users of the application do not typically reference the SWF file directly in an HTTP request. Instead, you embed the application SWF file in an HTML page. The HTML page then uses a script to load the SWF file. Collectively, the HTML page and the script are known as the *wrapper*.

When the SWF file is embedded in the HTML page, users then access the deployed SWF file by making an HTTP request to the HTML page, in the form:

```
http://hostname/path/filename.html
```

For more information on wrappers, see “Creating a wrapper” on page 2552.

Flex also provides a command-line MXML compiler, mxmlc, that lets you compile MXML files. You can use mxmlc to compile hello.mxml from a command line, as the following example shows:

```
cd flex_install_dir/bin
mxmlc --show-actionscript-warnings=true --strict=true c:/app_dir/hello.mxml
```

In this example, *flex_install_dir* is the Flex installation directory, and *app_dir* is the directory containing hello.mxml. The resultant SWF file, hello.swf, is written to the same directory as hello.mxml.

For more information about mxmlc, see “Flex compilers” on page 2164.

The relationship of MXML tags to ActionScript classes

Adobe implemented Flex as an ActionScript class library. That class library contains components (containers and controls), manager classes, data-service classes, and classes for all other features. You develop applications by using the MXML and ActionScript languages with the class library.

MXML tags correspond to ActionScript classes or properties of classes. Flex parses MXML tags and compiles a SWF file that contains the corresponding ActionScript objects. For example, Flex provides the ActionScript Button class that defines the Flex Button control. In MXML, you create a Button control by using the following MXML statement:

```
<s:Button label="Submit"/>
```

When you declare a control using an MXML tag, you create an instance of that class. This MXML statement creates a Button object, and initializes the `label` property of the Button object to the string `"Submit"`.

An MXML tag that corresponds to an ActionScript class uses the same naming conventions as the ActionScript class. Class names begin with an uppercase letter, and uppercase letters separate the words in class names. Every MXML tag attribute corresponds to a property of the ActionScript object, a style applied to the object, or an event listener for the object. For a complete description of the Flex class library and MXML tag syntax, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Understanding the structure of an application built with Flex

You can write an MXML application in a single file or in multiple files. You typically define a main file that contains the `<s:Application>` tag. From within your main file, you can then reference additional files written in MXML, ActionScript, or a combination of the two languages.

A common coding practice is to divide your Flex application into functional units, or modules, where each module performs a discrete task. In Flex, you can divide your application into separate MXML files and ActionScript files, where each file corresponds to a different module. By dividing your application into modules, you provide many benefits, including the following:

Ease of development Different developers or development groups can develop and debug modules independently of each other.

Reusability You can reuse modules in different applications so that you do not have to duplicate your work.

Maintainability You can isolate and debug errors faster than if your application is developed in a single file.

In Flex, a module corresponds to a custom component implemented either in MXML or in ActionScript. These custom components can reference other custom components. There is no restriction on the level of nesting of component references in Flex. You define your components as required by your application.

You can also use sub-applications rather than modules to develop applications that are not monolithic.

Developing applications

MXML development is based on the same iterative process used for other types of web application files such as HTML, JavaServer Pages (JSP), Active Server Pages (ASP), and ColdFusion Markup Language (CFML). Developing a useful Flex application is as easy as opening your favorite text editor, typing some XML tags, saving the file, requesting the file's URL in a web browser, and then repeating the same process.

Flex also provides tools for code debugging. For more information, see "Command-line debugger" on page 2209.

Laying out a user interface using containers

In the Flex model-view design pattern, user interface components represent the view. The MXML language supports two types of user interface components: controls and containers. Controls are form elements, such as buttons, text fields, and list boxes. Containers are rectangular regions of the screen that contain controls and other containers.

You use container components for laying out a user interface, and for controlling user navigation through the application. Examples of layout containers include the HGroup container for laying out child components horizontally and the VGroup container for laying out child components vertically. Examples of navigator containers include the MX TabNavigator container for creating tabbed panels and the MX Accordion navigator container for creating collapsible panels. Typical properties of a container tag include `id`, `width`, and `height`. For more information about the standard Flex containers, see "Introduction to containers" on page 326.

The following example application contains a Spark List control on the left side of the user interface and an MX TabNavigator container on the right side. Both controls are enclosed in a Spark Panel container:

```
<?xml version="1.0"?>
<!-- mxml/LayoutExample.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:Panel title="My Application">
        <s:HGroup>
            <!-- List with three items -->
            <s:List>
                <s:dataProvider>
                    <mx:ArrayCollection>
                        <fx:String>Item 1</fx:String>
                        <fx:String>Item 2</fx:String>
                        <fx:String>Item 3</fx:String>
                    </mx:ArrayCollection>
                </s:dataProvider>
            </s:List>
            <!-- First pane of TabNavigator -->
            <mx:TabNavigator borderStyle="solid">
                <s:NavigatorContent label="Pane1" width="300">
                    <s:layout>
                        <s:VerticalLayout/>
                    </s:layout>
                    <s:TextArea text="Hello World"/>
                    <s:Button label="Submit"/>
                </s:NavigatorContent>
                <!-- Second pane of TabNavigator -->
                <s:NavigatorContent label="Pane2" width="300" height="150">
                    <!-- Stock view goes here -->
                </s:NavigatorContent>
            </mx:TabNavigator>
        </s:HGroup>
    </s:Panel>
</s:Application>
```

The List control and TabNavigator container are laid out side by side because they are in an HGroup container. The controls in the TabNavigator container are laid out from top to bottom because they are in a NavigatorContent containers that use the VerticalLayout class.

For more information about laying out user interface components, see “Visual components” on page 280.

Adding user interface controls

Flex includes a large selection of user interface components, such as Button, TextInput, and ComboBox controls. After you define the layout and navigation of your application by using container components, you add the user interface controls.

The following example contains an HGroup (horizontal group) container with two child controls, a TextInput control and a Button control. An HGroup container lays out its children horizontally.

```
<?xml version="1.0"?>
<!-- mxml/AddUIControls.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <fx:Script>
        <![CDATA[
            private function storeZipInDatabase(s:String):void {
                // event handler code here
            }
        ]]>
    </fx:Script>
    <s:HGroup>
        <s:TextInput id="myText"/>
        <s:Button click="storeZipInDatabase(myText.text);"/>
    </s:HGroup>
</s:Application>
```

Typical properties of a control tag include `id`, `width`, `height`, `fontSize`, `color`, event listeners for events such as `click` and `change`, and effect triggers such as `showEffect` and `rollOverEffect`. For information about the standard Flex controls, see "UI Controls" on page 643.

Using the id property with MXML tags

With a few exceptions (see "MXML tag rules" on page 32), an MXML tag has an optional `id` property, which must be unique within the MXML file. If a tag has an `id` property, you can reference the corresponding object in ActionScript.

The following example uses the `trace()` function to write the value of the `text` property of a TextInput control to the log file:

```
<?xml version="1.0"?>
<!-- mxml/UseIDProperty.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <fx:Script>
        <![CDATA[
            private function writeToLog():void {
                trace(myText.text);
            }
        ]]>
    </fx:Script>
    <s:VGroup id="myVGroup">
        <s:TextInput id="myText"
            text="Hello World!" />
        <s:Button id="mybutton"
            label="Get Weather"
            click="writeToLog();"/>
    </s:VGroup>
</s:Application>
```

This code causes the MXML compiler to generate a public variable named `myText` that contains a reference to the TextInput instance. This variable lets you access the component instance in ActionScript. You can explicitly refer to the TextInput control's instance with its `id` instance reference in any ActionScript class or script block. By referring to a component's instance, you can modify its properties and call its methods.

Because each id value in an MXML file is unique, all objects in a file are part of the same flat namespace. You do not qualify an object by referencing its parent with dot notation, as in myVGroup.myText.text.

For more information, see "Referring to components" on page 36.

Using XML namespaces

The xmlns property in an MXML tag specifies an XML namespace. To use the default namespace, specify no prefix. Typically, you specify a tag prefix and a namespace.

For example, the xmlns properties in the following <s:Application> tag indicates that tags corresponding to the Spark component set use the prefix *s:*.

```
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark" >
```

Flex defines the following Universal Resource Identifiers (URI) for the Flex namespaces:

- xmlns:fx="http://ns.adobe.com/mxml/2009"

  The MXML language namespace URI. This namespace includes the top-level ActionScript language elements, such as Object, Number, Boolean, and Array. For a complete list of the top-level elements, see the Top Level package in the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

  This namespace also includes the tags built in to the MXML compiler, such as <fx:Script>, <fx:Declarations>, and <fx:Style> tags. For a list of the compiler elements, see the MXML Only Tags appendix in the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

  This namespace does not include the MX or Spark component sets.

  The complete list of top-level ActionScript language elements included in this namespace is defined by the frameworks\mxml-2009-manifest.xml manifest file in your Flex SDK installation directory. Note that this file does not list the MXML compiler tags because they are built in to the MXML compiler.

- xmlns:mx="library://ns.adobe.com/flex/mx"

  The MX component set namespace URI. This namespace includes all of the components in the Flex mx.* packages, the Flex charting components, and the Flex data visualization components.

  The complete list of elements included in this namespace is defined by the frameworks\mx-manifest.xml manifest file in your Flex SDK installation directory.

- xmlns:s="library://ns.adobe.com/flex/spark"

  The Spark component set namespace URI. This namespace includes all of the components in the Flex spark.* packages and the text framework classes in the flashx.* packages.

  This namespace includes the RPC classes for the WebService, HTTPService, and RemoteObject components and additional classes to support the RPC components. These classes are included in the mx: namespace, but are provided as a convenience so that you can also reference them by using the s: namespace.

  This namespace also includes several graphics, effect, and state classes from the mx.* packages. These classes are included in the mx: namespace, but are provided as a convenience so that you can also reference them by using the s: namespace.

  The complete list of elements included in this namespace is defined by the frameworks\spark-manifest.xml manifest file in your Flex SDK installation directory.

  The following table lists the classes from the mx.* packages included in this namespace:

Category	Class
RPC classes	mx.messaging.channels.AMFChannel mx.rpc.CallResponder mx.messaging.ChannelSet mx.messaging.Consumer mx.messaging.channels.HTTPChannel mx.rpc.http.mxml.HTTPService mx.messaging.Producer mx.rpc.remoting.mxml.RemoteObject mx.rpc.remoting.mxml.Operation mx.messaging.channels.RTMPChannel mx.messaging.channels.SecureAMFChannel mx.messaging.channels.SecureStreamingAMFChannel mx.messaging.channels.SecureHTTPChannel mx.messaging.channels.SecureStreamingHTTPChannel mx.messaging.channels.SecureRTMPChannel mx.messaging.channels.StreamingAMFChannel mx.messaging.channels.StreamingHTTPChannel mx.rpc.soap.mxml.WebService mx.rpc.soap.mxml.Operation mx.data.mxml.DataService
Graphics classes	mx.graphics.BitmapFill mx.geom.CompoundTransform mx.graphics.GradientEntry mx.graphics.LinearGradient mx.graphics.LinearGradientStroke mx.graphics.RadialGradient mx.graphics.RadialGradientStroke mx.graphics.SolidColor mx.graphics.SolidColorStroke mx.graphics.Stroke mx.geom.Transform

Category	Class
Effect classes	mx.effects.Parallel mx.effects.Sequence mx.states.Transition mx.effects.Wait
States classes	mx.states.State mx.states.AddItems
Component classes	mx.controls.Spacer mx.controls.SWFLoader

XML namespaces give you the ability to use classes in custom packages that are not in the Flex namespaces. The following example shows an application that contains a custom component called CustomBox. The namespace value `myComponents.boxes.*` indicates that an MXML component called CustomBox is in the myComponents/boxes directory.

```
<?xml version="1.0"?>
<!-- mxml/XMLNamespaces.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:MyComps="myComponents.boxes.*">

    <s:Panel title="My Application"
        height="150">
        <MyComps:CustomBox/>
    </s:Panel>
</s:Application>
```

The myComponents/boxes directory can be a subdirectory of the directory that contains the application file, or it can be a subdirectory of one of the ActionScript source path directories assigned in the flex-config.xml file. If copies of the same file exist in both places, Flex uses the file in the application file directory. The prefix name is arbitrary, but it must be used as declared.

When using a component contained in a SWC file, the package name and the namespace must match, even though the SWC file is in the same directory as the MXML file that uses it. A SWC file is an archive file for Flex components. SWC files make it easy to exchange components among Flex developers. You exchange only a single file, rather than the MXML or ActionScript files and images, along with other resource files. Also, the SWF file inside a SWC file is compiled, which means that the source code is obfuscated from casual view.

For more information on SWC files, see “Flex compilers” on page 2164.

Using MXML to trigger run-time code

Flex applications are driven by run-time events, such as when a user selects a Button control. You can specify *event listeners*, which consist of code for handling run-time events, in the event properties of MXML tags. For example, the `<s:Button>` tag has a `click` event property in which you can specify ActionScript code that executes when the Button control is clicked at run time. You can specify simple event listener code directly in event properties. To use more complex code, you can specify the name of an ActionScript function defined in an `<fx:Script>` tag.

The following example shows an application that contains a Button control and a TextArea control. The `click` property of the Button control contains a simple event listener that sets the value of the TextArea control’s `text` property to the text `Hello World`.

```
<?xml version="1.0"?>
<!-- mxml/TriggerCodeExample.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:Panel title="My Application">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <s:TextArea id="textarea1"/>
        <s:Button label="Submit"
            click="textarea1.text='Hello World';"/>
    </s:Panel>
</s:Application>
```

The following example shows the code for a version of the application in which the event listener is contained in an ActionScript function in an `<fx:Script>` tag:

```
<?xml version="1.0"?>
<!-- mxml/TriggerCodeExample2.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <fx:Script>
        <![CDATA[
            private function hello():void {
                textarea1.text="Hello World";
            }
        ]]>
    </fx:Script>

    <s:Panel title="My Application">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <s:TextArea id="textarea1"/>
        <s:Button label="Submit"
            click="hello();"/>
    </s:Panel>
</s:Application>
```

For more information about using ActionScript with MXML, see “Using ActionScript” on page 32.

Binding data between components

Flex provides simple syntax for binding the properties of components to each other. In the following example, the value inside the curly braces ({ }) binds the `text` property of a TextArea control to the `text` property of a TextInput control. When the application initializes, both controls display the text `Hello`. When the user clicks the Button control, both controls display the text `Goodbye`.

```
<?xml version="1.0"?>
<!-- mxml/BindingExample.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:Panel title="My Application">
        <s:VGroup left="10" right="10" top="10" bottom="10">
            <s:Label text="Enter Text:"/>
            <s:TextInput id="textinput1"
                text="Hello"/>
            <s:Label text="Bind Text to the TextArea control:"/>
            <s:TextArea id="textarea1"
                text="{textinput1.text}"/>
            <s:Button label="Submit"
                click="textinput1.text='Goodbye';"/>
        </s:VGroup>
    </s:Panel>
</s:Application>
```

As an alternative to the curly braces ({ }) syntax, you can use the `<fx:Binding>` tag, in which you specify the source and destination of a binding. For more information about data binding, see “Data binding” on page 299.

Using RPC services

Remote-procedure-call (RPC) services let your application interact with remote servers to provide data to your applications, or for your application to send data to a server.

Flex is designed to interact with several types of RPC services that provide access to local and remote server-side logic. For example, a Flex application can connect to a web service that uses the Simple Object Access Protocol (SOAP), a Java object residing on the same application server as Flex using AMF, or an HTTP URL that returns XML.

The MXML components that provide data access are called RPC components. MXML includes the following types of RPC components:

- WebService provides access to SOAP-based web services.
- HTTPService provides access to HTTP URLs that return data.
- RemoteObject provides access to Java objects using the AMF protocol (Adobe LiveCycle Data Services ES only).

In MXML, define the RPC components in an `<fx:Declarations>` tag. You use the `<fx:Declarations>` tag to declare non-visual components an MXML file.

The following example shows an application that calls a web service that provides weather information, and displays the current temperature for a given ZIP code. The application binds the ZIP code that a user enters in a TextInput control to a web service input parameter. It binds the current temperature value contained in the web service result to a TextArea control.

```
<?xml version="1.0"?>
<!-- mxml/RPCExample.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <fx:Declarations>
        <!-- Define the web service connection
            (the specified WSDL URL is not functional). -->
        <s:WebService id="WeatherService"
            wsdl="http:/example.com/ws/WeatherService?wsdl"
            useProxy="false">
            <!-- Bind the value of the ZIP code entered in the TextInput control
                to the ZipCode parameter of the GetWeather operation. -->
            <s:operation name="GetWeather">
                <s:request>
                    <ZipCode>{zip.text}</ZipCode>
                </s:request>
            </s:operation>
        </s:WebService>
    </fx:Declarations>

    <s:Panel title="My Application">
        <s:VGroup left="10" right="10" top="10" bottom="10">
            <!-- Provide a ZIP code in a TextInput control. -->
            <s:TextInput id="zip" width="200" text="Zipcode please?"/>
            <!-- Call the web service operation with a Button click. -->
            <s:Button width="60" label="Get Weather"
                click="WeatherService.GetWeather.send();"/>
            <!-- Display the location for the specified ZIP code. -->
            <s:Label text="Location:"/>
            <s:TextArea text="{WeatherService.GetWeather.lastResult.Location}"/>
            <!-- Display the current temperature for the specified ZIP code. -->
            <s:Label text="Temperature:"/>
            <s:TextArea
                text="{WeatherService.GetWeather.lastResult.CurrentTemp}"/>
        </s:VGroup>
    </s:Panel>
</s:Application>
```

For more information about using RPC services, see Accessing Server-Side Data with Flex.

Storing data in a data model

You can use a data model to store application-specific data. A *data model* is an ActionScript object that provides properties for storing data, and optionally contains methods for additional functionality. Data models provide a way to store data in the Flex application before it is sent to the server, or to store data sent from the server before using it in the application.

You can declare a simple data model that does not require methods in an `<fx:Model>`, `<fx:XML>`, or `<fx:XMLList>` tag. In MXML, define a data model in an `<fx:Declarations>` tag. You use the `<fx:Declarations>` tag to declare non-visual components an MXML file.

The following example shows an application that contains TextInput controls for entering personal contact information and a data model, represented by the `<fx:Model>` tag, for storing the contact information:

```
<?xml version="1.0"?>
<!-- mxml/StoringData.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Declarations>
        <!-- A data model called "contact" stores contact information.
            The text property of each TextInput control shown above
            is passed to a field of the data model by using data binding. -->
        <fx:Model id="contact">
            <info>
                <homePhone>{homePhoneInput.text}</homePhone>
                <cellPhone>{cellPhoneInput.text}</cellPhone>
                <email>{emailInput.text}</email>
            </info>
        </fx:Model>
    </fx:Declarations>
    <s:Panel title="My Application">
        <s:VGroup left="10" right="10" top="10" bottom="10">
            <!-- The user enters contact information in TextInput controls. -->
            <s:TextInput id="homePhoneInput"
                text="This isn't a valid phone number."/>
            <s:TextInput id="cellPhoneInput"
                text="(999)999-999"/>
            <s:TextInput id="emailInput"
                text="me@somewhere.net"/>
        </s:VGroup>
    </s:Panel>
</s:Application>
```

This example uses data binding in the model definition to automatically copy data from the UI controls to the data model.

Validating data

Flex includes a set of standard validator components for data such as phone numbers, social security numbers, and ZIP codes. You can also create your own custom validator.

In MXML, define validators in an `<fx:Declarations>` tag. You use the `<fx:Declarations>` tag to declare non-visual components an MXML file.

The following example uses validator components for validating that the expected type of data is entered in the TextInput fields. In this example, you validate a phone number by using the PhoneNumberValidator class and an e-mail address by using the EmailValidator class. Validation is triggered automatically when the user edits a TextInput control. If validation fails, the user receives immediate visual feedback.

```
<?xml version="1.0"?>
<!-- mxml/ValidatingExample.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <fx:Declarations>
        <!-- Validator components validate data entered into the TextInput controls. -->
        <mx:PhoneNumberValidator id="pnV"
            source="{homePhoneInput}" property="text"/>
        <mx:EmailValidator id="emV"
            source="{emailInput}" property="text" />
    </fx:Declarations>
    <s:Panel title="My Application">
        <s:VGroup left="10" right="10" top="10" bottom="10">
            <s:Label text="Enter phone number:"/>
            <s:TextInput id="homePhoneInput"/>
            <s:Label text="Enter email address:"/>
            <s:TextInput id="emailInput"/>
        </s:VGroup>
    </s:Panel>
</s:Application>
```

A component with a validation failure displays a red border. If the component has focus, it also displays a validation error message. Set the component to a valid value to remove the error indication.

For more information about using data models, see “Storing data” on page 889. For more information on validators, see “Validating Data” on page 1964.

Formatting data

Formatter components are ActionScript components that perform a one-way conversion of raw data to a formatted string. They are triggered just before data is displayed in a text field. Flex includes a set of standard formatters. You can also create your own formatters.

In MXML, define formatters in an `<fx:Declarations>` tag. You use the `<fx:Declarations>` tag to declare non-visual components an MXML file.

The following example shows an application that uses the standard ZipCodeFormatter component to format the value of a variable:

```
<?xml version="1.0"?>
<!-- mxml/FormatterExample.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
            [Bindable]
            private var storedZipCode:Number=123456789;
        ]]>
    </fx:Script>
    <fx:Declarations>
        <!-- Declare a ZipCodeFormatter and define parameters. -->
        <mx:ZipCodeFormatter id="ZipCodeDisplay" formatString="#####-####"/>
    </fx:Declarations>
    <s:Panel title="My Application">
        <!-- Trigger the formatter while populating a string with data. -->
        <s:TextInput text="{ZipCodeDisplay.format(storedZipCode)}"/>
    </s:Panel>
</s:Application>
```

For more information about formatter components, see “Formatting Data” on page 2004.

Using Cascading Style Sheets (CSS)

You can use style sheets based on the CSS standard to declare styles to Flex components. The MXML `<fx:Style>` tag contains inline style definitions or a reference to an external file that contains style definitions.

The `<fx:Style>` tag must be an immediate child of the root tag of the MXML file. You can apply styles to an individual component using a class selector, or to all components of a certain type using a type selector.

Namespace qualification is required for type selectors in the `<fx:Style>` tag. Prefix the namespace qualification with the `@namespace` tag.

The following example defines a class selector and a type selector in the `<fx:Style>` tag. Both the class selector and the type selector are applied to the Button control.

```
<?xml version="1.0"?>
<!-- mxml/CSSExample.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <fx:Style>
        @namespace s "library://ns.adobe.com/flex/spark";
        @namespace mx "library://ns.adobe.com/flex/mx";

        /* class selector */
        .myClass {
            color: Red
        }

        /* type selector */
        s|Button {
            font-size: 18pt
        }
    </fx:Style>
    <s:Panel title="My Application">
        <s:Button styleName="myClass" label="This is red 18 point text."/>
    </s:Panel>
</s:Application>
```

A class selector in a style definition, defined as a label preceded by a period, defines a new named style, such as `myClass` in the preceding example. After you define it, you can apply the style to any component by using the `styleName` property. In the preceding example, you apply the style to the Button control to set the font color to red.

A type selector applies a style to all instances of a particular component type. In the preceding example, you set the font size for all Spark Button controls to 18 points.

For more information about using Cascading Style Sheets, see “Styles and themes” on page 1492.

Using skins

Skinning is the process of changing the appearance of a component by modifying or replacing its visual elements. These elements can be made up of bitmap images, SWF files, or class files that contain drawing methods that define vector images. Skins can define the entire appearance, or only a part of the appearance, of a component in various states.

One of the big differences between Spark and MX components is that Spark components rely on the component skin to define its layout and appearance. When working with Spark components, you often define a custom skin to modify the component appearance.

MX components use a combination of CSS styles and skins to control their appearance. With MX components, you can use styles to modify much of the appearance of the component without having to define a custom skin.

For more information about using Spark skins, see “Spark Skinning” on page 1602. For more information about using MX skins, see “Skinning MX components” on page 1655.

Using effects

An *effect* is a change to a component that occurs over a brief period of time. Examples of effects are fading, resizing, and moving a component. In MXML, you apply effects as properties of a control or container. Flex provides a set of built-in effects with default properties.

In MXML, define effects in an `<fx:Declarations>` tag. You use the `<fx:Declarations>` tag to declare non-visual components an MXML file.

The following example shows an application that contains a Button control with its `click` property set to use the Resize effect when the user moves the mouse over it:

```
<?xml version="1.0"?>
<!-- behaviors\TargetProp.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <fx:Declarations>
        <s:Resize id="myResize"
            heightBy="25"
            widthBy="50"
            target="{myButton}"/>
    </fx:Declarations>

    <s:Button id="myButton"
        label="Resize target"
        click="myResize.end();myResize.play();"/>
</s:Application>
```

For more information about effects, see “Introduction to effects” on page 1784.

Defining custom MXML components

Custom MXML components are MXML files that you create and use as custom MXML tags in other MXML files. They encapsulate and extend the functionality of existing Flex components. Just like MXML application files, MXML component files can contain a mix of MXML tags and ActionScript code. The name of the MXML file becomes the class name with which you refer to the component in another MXML file.

The following example shows a custom ComboBox control that is prepopulated with list items:

```
<?xml version="1.0"?>
<!-- mxml/myComponents/boxes/MyComboBox.mxml -->
<s:VGroup xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

     <s:ComboBox>
        <s:dataProvider>
            <s:ArrayCollection>
                <fx:String>Dogs</fx:String>
                <fx:String>Cats</fx:String>
                <fx:String>Mice</fx:String>
            </s:ArrayCollection>
        </s:dataProvider>
    </s:ComboBox>
</s:VGroup>
```

The following example shows an application that uses the MyComboBox component as a custom tag. The value `myComponents.boxes.*` assigns the `MyComps` namespace to the myComponents/boxes sub-directory. To run this example, store the MyComboBox.mxml file in that sub-directory.

```
<?xml version="1.0"?>
<!-- mxml/CustomMXMLComponent.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:MyComps="myComponents.boxes.*">
    <s:Panel title="My Application"
        height="150">
        <MyComps:MyComboBox/>
    </s:Panel>
</s:Application>
```

For more information about MXML components, see “Simple MXML components” on page 2399. You can also define custom Flex components in ActionScript. For more information, see “Create simple visual components in ActionScript” on page 2433.

MXML syntax

MXML is an XML language that you use to lay out user-interface components for Adobe® Flex® applications.

Basic MXML syntax

Most MXML tags correspond to ActionScript 3.0 classes or properties of classes. Flex parses MXML tags and compiles a SWF file that contains the corresponding ActionScript objects.

ActionScript 3.0 uses syntax based on the ECMAScript edition 4 draft language specification. ActionScript 3.0 includes the following features:

- Formal class definition syntax
- Formal packages structure
- Typing of variables, parameters, and return values (compile-time only)
- Implicit getters and setters that use the `get` and `set` keywords
- Inheritance
- Public and private members
- Static members
- Cast operator

For more information about ActionScript 3.0, see “Using ActionScript” on page 32.

Naming MXML files

MXML filenames must adhere to the following naming conventions:

- Filenames must be valid ActionScript identifiers, which means they must start with a letter or underscore character (_), and they can only contain letters, numbers, and underscore characters after that.
- Filenames must not be the same as ActionScript class names, component `id` values, or the word *application*. Do not use filenames that match the names of MXML tags that are in the `fx:`, `s:`, or `mx:` namespace.
- Filenames must end with a lowercase .mxml file extension.

Using tags that represent ActionScript classes

An MXML tag that corresponds to an ActionScript class uses the same naming conventions as the ActionScript class. Class names begin with a capital letter, and capital letters separate the words in class names. For example, when a tag corresponds to an ActionScript class, its properties correspond to the properties and events of that class.

Setting component properties

In MXML, a component property uses the same naming conventions as the corresponding ActionScript property. A property name begins with a lowercase letter, and capital letters separate words in the property names.

You can set most component properties as tag attributes, in the form:

```
<s:Label width="50" height="25" text="Hello World"/>
```

You can set all component properties as child tags, in the form:

```
<s:Label>
    <s:width>50</s:width>
    <s:height>25</s:height>
    <s:text>Hello World</s:text>
</s:Label>
```

You often use child tags when setting the value of a property to a complex Object because it is not possible to specify a complex Object as the value of tag attribute. In the following example, you use child tags to set the data provider of a Spark List control to an ArrayCollection object:

```
<s:List>
    <s:dataProvider>
        <s:ArrayCollection>
            <fx:String>AK</fx:String>
            <fx:String>AL</fx:String>
            <fx:String>AR</fx:String>
        </s:ArrayCollection>
    </s:dataProvider>
</s:List>
```

The one restriction on setting properties that use child tags is that the namespace prefix of a child tag, `s:` in the previous example, must match the namespace prefix of the component tag. Note that the *value* of the property in the previous example does not have to use the same namespace as the property tag.

Each of a component's properties is one of the following types:

- Scalar properties, such as a number or string
- Array of scalar values, such as an array of numbers or strings
- ActionScript object
- Array of ActionScript objects
- ActionScript properties
- XML data

Adobe recommends that you assign scalar values using tag attributes, and that you assign complex types, such as ActionScript objects, by using child tags.

Setting scalar properties

You usually specify the value of a scalar property as a property of a component tag, as the following example shows:

```
<s:Label width="50" height="25" text="Hello World"/>
```

Setting properties using constants

The valid values of many component properties are defined by static constants, where these static constants are defined in an ActionScript class. In MXML, you can either use the static constant to set the property value, or use the value of the static constant, as the following example shows:

```
<!-- Set the property using the static constant. -->
<s:Wipe direction="{spark.effects.WipeDirection.LEFT}">
    ...
</s:Wipe>

<!-- Set the property using the value of the static constant. -->
<s:Wipe direction="left">
    ...
</s:Wipe>
```

The Wipe effect defines a property named `direction` that defines the direction of the wipe effect. In this example, you explicitly set the `direction` property to cause the wipe effect to move left.

In the first example, you set the `direction` property using a static constant named `LEFT`, which is defined in the spark.effects.WipeDirection class. In MXML, you must use data binding syntax when setting a property value to a static constant. The advantage of using the static constant is that the Flex compiler recognizes incorrect property values, and issues an error message at compile time.

Alternatively, you can set the value of the `direction` property to the value of the static constant. The value of the `LEFT` static constant is `"left"`. When you use the value of the static constant to set the property value, the Flex compiler cannot determine if you used an unsupported value. If you incorrectly set the property, you will not know until you get a run-time error.

In ActionScript, you should use static constants to set property values whenevera possible, as the following example shows:

```
var myWipe:Wipe = new Wipe();
myWipe.direction=spark.effects.WipeDirection.LEFT;
```

Setting the default property

Many Flex components define a single default property. The *default property* is the MXML tag that is implicit for content inside of the MXML tag if you do not explicitly specify a property. For example, consider the following MXML tag definition:

```
<s:SomeTag>
    anything here
</s:SomeTag>
```

If this tag defines a default property named `default_property`, the preceding tag definition is equivalent to the following code:

```
<s:SomeTag>
    <s:default_property>
        anything here
    </s:default_property>
</s:SomeTag>
```

It is also equivalent to the following code:

```
<s:SomeTag default_property="anything here"/>
```

The default property provides a shorthand mechanism for setting a single property. For a Spark List, the default property is the `dataProvider` property. Therefore, the two List definitions in the following code are equivalent:

```
<?xml version="1.0"?>
<!-- mxml\DefProp.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:HorizontalLayout/>
    </s:layout>
    <!-- Omit the default property. -->
    <s:List>
        <s:ArrayCollection>
            <fx:String>AK</fx:String>
            <fx:String>AL</fx:String>
            <fx:String>AR</fx:String>
        </s:ArrayCollection>
    </s:List>

    <!-- Explicitly speficy the default property. -->
    <s:List>
        <s:dataProvider>
            <s:ArrayCollection>
                <fx:String>AK</fx:String>
                <fx:String>AL</fx:String>
                <fx:String>AR</fx:String>
            </s:ArrayCollection>
        </s:dataProvider>
    </s:List>
</s:Application>
```

Not all Flex components define a default property. To determine the default property for each component, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

You can also define a default property when you create a custom component. For more information, see “Metadata tags in custom components” on page 2376.

Escaping characters using the backslash character

When setting a property value in MXML, you can escape a reserved character by prefixing it with the backslash character (\), as the following example shows:

```
<?xml version="1.0"?>
<!-- mxml\EscapeChar.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:Label text="\{\}"/>
</s:Application>
```

In this example, you want to use literal curly brace characters ({ }) in a text string. But Flex uses curly braces to indicate a data binding operation. Therefore, you prefix each curly brace with the backslash character to cause the MXML compiler to interpret them as literal characters.

Setting String properties using the backslash character

The MXML compiler automatically escapes the backslash character in MXML when the character is part of the value specified for a property of type String. Therefore, it always converts `"\"` to `"\\"`.

This is necessary because the ActionScript compiler recognizes `"\\"` as the character sequence for a literal "\" character, and strips out the leading backslash when it initializes the property value.

***Note:** Do not use the backslash character (\) as a separator in the path to an application asset. You should always use a forward slash character (/) as the separator.*

Including a newline character in a String value

For properties of type String, you can insert a newline character in the String in several ways:

- By using data binding with the '\n' characters in your String value in MXML
- By inserting the `&#13;` code in your String value in MXML
- By inserting `"\n"` in an ActionScript String variable used to initialize the MXML property

To use data binding, wrap the newline character in curly brace characters ({ }), as the following example shows:

```
<s:TextArea width="100%" text="Display{'\n'}Content"/>
```

To use the `&#13;` code to insert a newline character, include that code in the property value in MXML, as the following example shows:

```
<s:TextArea width="100%" text="Display&#13;Content"/>
```

To use an ActionScript String variable to insert a newline character, create an ActionScript variable, and then use data binding to set the property in MXML, as the following example shows:

```
<fx:Script>
    <![CDATA[
        [Bindable]
        public var myText:String = "Display" + "\n" + "Content";
    ]]>
</fx:Script>

<s:TextArea width="100%" text="{myText}"/>
```

In this example, you set the `text` property of the TextArea control to a value that includes a newline character.

Notice that this example includes the `[Bindable]` metadata tag before the property definition. This metadata tag specifies that the `myText` property can be used as the source of a data binding expression. Data binding automatically copies the value of a `source` property of one object to the destination property of another object at run time when the `source` property changes.

If you omit this metadata tag, the compiler issues a warning message specifying that the property cannot be used as the source for data binding. For more information, see "Data binding" on page 299.

Mixing content types

Flex supports the mixing of content for attribute values. The attribute must correspond to a property of type Object or Array. Mixed content consists of non white space character data and MXML tags, as the following example shows:

```
<?xml version="1.0"?>
<!-- mxml\DefPropMixed.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:RichText  fontFamily="Verdana" fontWeight="bold">
        <s:content>
            <fx:String>Hello World!</fx:String><s:br/>
            <fx:String>Hello Universe</fx:String><s:br/>
            Hello Flex!
        </s:content>
    </s:RichText>
</s:Application>
```

In this example, the `RichText.content` property is of type Object. The property value contains values defined by `<fx:String>` tag, and by character data ("Hello Flex!"). Character data is almost always converted to a value of type String. However, an Array property may be defined to support an explicit data type for its values. In that case, the compiler converts the character data to the appropriate data type.

Setting Arrays of scalar values

When a class has a property that takes an Array as its value, you can represent the property in MXML using child tags. The component in the following example has a `children` property that contains an Array of numbers:

```
<mynamespace:MyComponent>
    <mynamespace:children>
        <fx:Array>
            <fx:Number>94062</fx:Number>
            <fx:Number>14850</fx:Number>
            <fx:Number>53402</fx:Number>
        </fx:Array>
    </mynamespace:children>
</mynamespace:MyComponent>
```

The `<fx:Array>` and `</fx:Array>` tags around the Array elements are optional. Therefore, you can also write this example as the following code shows:

```
<mynamespace:MyComponent>
    <mynamespace:children>
        <fx:Number>94062</fx:Number>
        <fx:Number>14850</fx:Number>
        <fx:Number>53402</fx:Number>
    </mynamespace:children>
</mynamespace:MyComponent>
```

In this example, since the data type of the `children` property is defined as Array, Flex automatically converts the three number definitions into a three-element array.

Component developers may have specified additional information within the component definition that defines the data type of the Array elements. For example, if the developer specified that the `dataProvider` property supports only String elements, this example would cause a compiler error because you specified numbers to it. The *ActionScript 3.0 Reference for the Adobe Flash Platform* documents the Array properties that define a required data type for the Array elements.

Setting Object properties

When a component has a property that takes an object as its value, you can represent the property in MXML using a child tag with tag attributes, as the following example shows:

```
<mynamespace:MyComponent>
    <mynamespace:nameOfProperty>
        <mynamespace:typeOfObject prop1="val1" prop2="val2"/>
    </mynamespace:nameOfProperty>
</mynamespace:MyComponent>
```

The following example shows an ActionScript class that defines an Address object. This object is used as a property of the PurchaseOrder component in the next example.

```
class Address {
    public var name:String;
    public var street:String;
    public var city:String;
    public var state:String;
    public var zip:Number;
}
```

The following example shows an ActionScript class that defines a PurchaseOrder component that has a property type of Address:

```
import example.Address;

class PurchaseOrder {
    public var shippingAddress:Address;
    public var quantity:Number;
...
}
```

In MXML, you define the PurchaseOrder component as the following example shows:

```
<mynamespace:PurchaseOrder quantity="3" xmlns:e="example">
    <mynamespace:shippingAddress>
        <mynamespace:Address name="Fred" street="123 Elm St."/>
    </mynamespace:shippingAddress>
</mynamespace:PurchaseOrder>
```

If the value of the `shippingAddress` property is a subclass of Address (such as DomesticAddress), you can declare the property value, as the following example shows:

```
<mynamespace:PurchaseOrder quantity="3" xmlns:e="example">
    <mynamespace:shippingAddress>
        <mynamespace:DomesticAddress name="Fred" street="123 Elm St."/>
    </mynamespace:shippingAddress>
</mynamespace:PurchaseOrder>
```

If the property is explicitly typed as Object like the `value` property in the following example, you can specify an anonymous object using the `<fx:Object>` tag.

```
class ObjectHolder {
    public var value:Object
}
```

The following example shows how you specify an anonymous object as the value of the `value` property:

```
<mynamespace:ObjectHolder>
    <mynamespace:value>
        <fx:Object foo='bar'/>
    </mynamespace:value>
</mynamespace:ObjectHolder>
```

Populating an Object with an Array

When a component has a property of type Object that takes an Array as its value, you can represent the property in MXML using child tags, as the following example shows:

```
<mynamespace:MyComponent>
    <mynamespace:nameOfObjectProperty>
        <fx:Array>
            <fx:Number>94062</fx:Number>
            <fx:Number>14850</fx:Number>
            <fx:Number>53402</fx:Number>
        </fx:Array>
    </mynamespace:nameOfObjectProperty>
</mynamespace:MyComponent>
```

In this example, you initialize the Object property to a three-element array of numbers.

As described in the section "Setting Arrays of scalar values" on page 26, the `<fx:Array>` tag and the `</fx:Array>` tag around the Array elements are optional and may be omitted, as the following example shows:

```
<mynamespace:MyComponent>
    <mynamespace:nameOfObjectProperty>
        <fx:Number>94062</fx:Number>
        <fx:Number>14850</fx:Number>
        <fx:Number>53402</fx:Number>
    </mynamespace:nameOfObjectProperty>
</mynamespace:MyComponent>
```

The only exception to this rule is when you specify a single Array element for the Object property. In that case, Flex does not create an Object containing a single-element array, but instead creates an object and sets it to the specified value. This is a difference between the following two lines:

```
object=[element] // Object containing a one-element array
object=element // object equals value
```

If you want to create a single-element array, include the `<fx:Array>` and `</fx:Array>` tags around the array element, as the following example shows:

```
<mynamespace:MyComponent>
    <mynamespace:nameOfObjectProperty>
        <fx:Array>
            <fx:Number>94062</fx:Number>
        </fx:Array>
    </mynamespace:nameOfObjectProperty>
</mynamespace:MyComponent>
```

Populating Arrays of objects

When a component has a property that takes an Array of objects as its value, you can represent the property in MXML using child tags, as the following example shows:

```
<mynamespace:MyComponent>
    <mynamespace:nameOfProperty>
        <fx:Array>
            <mynamespace:objectType prop1="val1" prop2="val2"/>
            <mynamespace:objectType prop1="val1" prop2="val2"/>
            <mynamespace:objectType prop1="val1" prop2="val2"/>
        </fx:Array>
    </mynamespace:nameOfProperty>
</mynamespace:MyComponent>
```

The component in the following example contains an Array of ListItem objects. Each ListItem object has properties named `label` and `data`.

```
<mynamespace:MyComponent>
    <mynamespace:dataProvider>
        <fx:Array>
            <mynamespace:ListItem label="One" data="1"/>
            <mynamespace:ListItem label="Two" data="2"/>
        </fx:Array>
    </mynamespace:dataProvider>
</mynamespace:MyComponent>
```

The following example shows how you specify an anonymous object as the value of the `dataProvider` property:

```
<mynamespace:MyComponent>
    <mynamespace:dataProvider>
        <fx:Array>
            <fx:Object label="One" data="1"/>
            <fx:Object label="Two" data="2"/>
        </fx:Array>
    </mynamespace:dataProvider>
</mynamespace:MyComponent>
```

As described in the section “Setting Arrays of scalar values” on page 26, the `<fx:Array>` tag and the `</fx:Array>` tag around the Array elements are optional and may be omitted, as the following example shows:

```
<mynamespace:MyComponent>
    <mynamespace:dataProvider>
        <fx:Object label="One" data="1"/>
        <fx:Object label="Two" data="2"/>
    </mynamespace:dataProvider>
</mynamespace:MyComponent>
```

Populating a Vector

The Vector class lets you access and manipulate a vector. A Vector is an array whose elements all have the same data type. The data type of a Vector's elements is known as the Vector's *base* type. The base type can be any class, including built in classes and custom classes. The base type is specified when declaring a Vector variable as well as when creating an instance by calling the class constructor.

In MXML, define an instance of a Vector class in a `<fx:Declarations>` block, as the following example shows:

```
<fx:Declarations>
    <fx:Vector type="String">
        <fx:String>one</fx:String>
        <fx:String>two</fx:String>
        <fx:String>three</fx:String>
    </fx:Vector>

    <fx:Vector type="Vector.&lt;String&gt;">
        <fx:Vector type="String">
            <fx:String>one</fx:String>
            <fx:String>two</fx:String>
            <fx:String>three</fx:String>
        </fx:Vector>
    </fx:Vector>
</fx:Declarations>
```

The first example defines a Vector with a base type of String. The second example defines a Vector of Vectors of type String. Notice that you use the HTML escape characters `&lt;` and `&gt;`, instead of < and >, in the nested Vector. This syntax is necessary to conform to XML syntax rules.

Setting properties that contain XML data

If a component contains a property that takes XML data, the value of the property is an XML fragment to which you can apply a namespace. In the following example, the `value` property of the MyComponent object is XML data:

```
<mynamespace:MyComponent>
    <mynamespace:value xmlns:a="http://www.example.com/myschema">
        <fx:XML>
            <a:purchaseorder>
                <a:billingaddress>
                ...
                </a:billingaddress>
                ...
            </a:purchaseorder>
        </fx:XML>
    </mynamespace:value>
</mynamespace:MyComponent>
```

Setting style properties in MXML

A style property of an MXML tag differs from other properties because it corresponds to an ActionScript style, rather than to a property of an ActionScript class. You set these properties in ActionScript using the `setStyle(`*stylename*`,` *value*`)` method rather than `object.property=value` notation.

For example, you can set the `fontFamily` style property in MXML, as the following code shows:

```
<s:TextArea id="myText" text="hello world" fontFamily="Tahoma"/>
```

This MXML code is equivalent to the following ActionScript code:

```
myText.setStyle("fontFamily", "Tahoma");
```

You define style properties in custom ActionScript classes by using the `[Style]` metadata tags, rather than defining them as ActionScript variables or setter/getter methods. For more information, see “Metadata tags in custom components” on page 2376.

Setting event properties in MXML

An event property of an MXML tag lets you specify the event listener function for an event. This property corresponds to setting the event listener in ActionScript using the `addEventListener()` method.

For example, you can set the `creationComplete` event property in MXML, as the following code shows:

```
<s:TextArea id="myText" creationComplete="creationCompleteHandler();"/>
```

This MXML code is equivalent to the following ActionScript code:

```
myText.addEventListener("creationComplete", creationCompleteHandler);
```

You define event properties in custom ActionScript classes by using the `[Event]` metadata tags, rather than defining them as ActionScript variables or setter/getter methods. For more information, see “Metadata tags in custom components” on page 2376.

Specifying a URL value

Some MXML tags, such as the `<fx:Script>` tag, have a property that takes a URL of an external file as a value. For example, you can use the `source` property in an `<fx:Script>` tag to reference an external ActionScript file instead of typing ActionScript directly in the body of the `<fx:Script>` tag.

Note: *You specify a script in the* `source` *property of an* `<fx:Script>` *tag. You do not specify ActionScript classes in the* `source` *property. For information on using ActionScript classes, see "Creating ActionScript components" on page 49.*

MXML supports the following types of URLs:

- Absolute, as in the following example:

  ```
  <fx:Style source="http://www.somesite.com/mystyles.css">
  ```

- A path used at compile time that is relative to the application, as in the following example:

  ```
  <fx:Script source="/myscript.as"/>
  ```

- Relative to the current file location, as in the following example:

  ```
  <fx:Script source="../myscript.as"/>
  ```

- A path used at run time that is relative to the context root of the Java web application in which a Flex application is running. For example:

  ```
  <mx:HTTPService url="@ContextRoot()/directory/myfile.xml"/>
  ```

  You can only use the `@ContextRoot()` token if you are using the web-tier compiler or if you set the value of the `context-root` compiler argument

Specifying a RegExp value

For a property of type RegExp, you can specify its value in MXML using the following format:

```
"/pattern/flags"
```

pattern Specifies the regular expression within the two slashes. Both slashes are required.

flags (Optional) Specifies any flags for the regular expression.

For example, the `regExpression` property of an MXML component is of type RegExp. Therefore, you can set its value as the following example shows:

```
<mynamespace:MyComponent regExpression="/\Wcat/gi"/>
```

Or set it using child tags, as the following example shows:

```
<mynamespace:MyComponent>
    <mynamespace:regExpression>/\Wcat/gi</mynamespace:regExpression>
</mynamespace:MyComponent>
```

The *flags* portion of the regular expression is optional, so you can also specify it as the following example shows:

```
<mynamespace:MyComponent regExpression="/\Wcat/"/>
```

Using compiler tags

Compiler tags are tags that do not directly correspond to ActionScript objects or properties. They include the following:

- `<fx:Binding>`
- `<fx:Component>`
- `<fx:Declarations>`

- `<fx:Definition>`
- `<fx:DesignLayer>`
- `<fx:Library>`
- `<fx:Metadata>`
- `<fx:Model>`
- `<fx:Private>`
- `<fx:Reparent>`
- `<fx:Script>`
- `<fx:Style>`

MXML tag rules

MXML has the following syntax requirements:

- The `id` property is not required on any tag.
- The `id` property is not allowed on the root tag.
- Boolean properties take only `true` and `false` values.
- The `<fx:Binding>` tag requires both `source` and `destination` properties.
- The `<fx:Binding>` tag cannot contain an `id` property.

Using ActionScript

Flex developers can use ActionScript to extend the functionality of their Adobe® Flex® applications. ActionScript provides flow control and object manipulation features that are not available in MXML. For a complete introduction to ActionScript and a reference for using the language, see *ActionScript 3.0 Developer's Guide* and *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Using ActionScript in applications

Flex developers can use ActionScript to implement custom behavior within their applications. You first use MXML tags to declare things like the containers, controls, effects, formatters, validators, and web services that your application requires, and to lay out its user interface. Each of these components provides the standard behavior you'd expect. For example, a button automatically highlights when you roll over it, without requiring you to write any ActionScript. But a declarative language like MXML is not appropriate for coding what you want to happen when the user clicks a button. For that, you need to use a procedural language like ActionScript, which offers executable methods, various types of storage variables, and flow control such as conditionals and loops. In a general sense, MXML implements the static aspects of your application, and ActionScript implements its dynamic aspects.

ActionScript is an object-oriented procedural programming language, based on the ECMAScript (ECMA-262) edition 4 draft language specification. You can use a variety of methods to mix ActionScript and MXML, including the following:

- Define event listeners inside MXML event attributes.
- Add script blocks using the `<fx:Script>` tag.
- Include external ActionScript files.

- Import ActionScript classes.
- Create ActionScript components.

ActionScript compilation

Although a simple application can be written in a single MXML or ActionScript (AS) file, most applications will be broken into multiple files. For example, it is common to move the `<fx:Script>` and `<fx:Style>` blocks into separate AS and CSS files that the application then includes.

It is also common for an application to import custom MXML and ActionScript components. These must be defined in other files, and MXML components may put their own `<fx:Script>` blocks into yet more AS files that they include. Components may also be imported from precompiled SWC files rather than source code. Finally, SWF files containing executable code can also be embedded in an application. The end result of all these input files is a single SWF file.

The Flex compiler transforms the main MXML file and other files it includes into a single ActionScript class. As a result, you cannot define classes or use statements outside of functions in the MXML files and the included ActionScript files.

You can reference imported ActionScript classes from your MXML application files, and those classes are added to the final SWF file. When the transformation to an ActionScript file is complete, Flex links all the ActionScript components and includes those classes in the final SWF file.

About generated ActionScript

When you write an MXML file and compile it, the Flex compiler creates a class and generates ActionScript that the class uses. MXML tags and ActionScript are used by the resulting class in several ways. This information is useful for understanding what is happening in the background of the application.

An MXML application (a file that starts with the `<s:Application>` tag) defines a subclass of the Spark Application class. Similarly, an MXML component (a file that starts with some other component's tag, such as `<s:Button>`) defines a subclass of that component.

The name of the subclass is the name of the file. The base class is the class of the top-level tag. An MXML application actually defines the following:

```
class MyApp extends Application
```

If MyButton.mxml starts with `<s:Button>`, you are actually defining the following:

```
class MyButton extends Button
```

The variable and function declarations in an `<fx:Script>` block define properties and methods of the subclass.

Setting an `id` property on a component instance within a class results in a public variable being autogenerated in the subclass that contains a reference to that component instance. For example, if the `<s:Button id="myButton"/>` tag is nested deeply inside several containers, you can still refer to it as `myButton`.

Event attributes become the bodies of autogenerated event listener methods in the subclass. For example:

```
<s:Button id="myButton" click="foo = 1; doSomething()">
```

becomes

```
private function __myButton_click(event:MouseEvent):void {
    foo = 1;
    doSomething()
}
```

The event attributes become method bodies, so they can access the other properties and methods of the subclass.

All the ActionScript anywhere in an MXML file, whether in its `<fx:Script>` block or inside tags, executes with the `this` keyword referring to an instance of the subclass.

The public properties and methods of the class are accessible by ActionScript code in other components, as long as that code “dots down” (for example, `myCheckoutAccordion.myAddressForm.firstNameTextInput.text`) or reaches up using the `parentDocument`, `parentApplication`, or `FlexGlobals.topLevelApplication` properties to specify which component the property or method exists on.

Using ActionScript in MXML event handlers

One way to use ActionScript code in an application is to include it within the MXML tag’s event handler, as the following example shows:

```
<?xml version="1.0"?>
<!-- usingas/HelloWorldAS.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:BasicLayout/>
    </s:layout>
    <s:Panel title="My Application" height="128" x="226" y="24">
        <s:TextArea id="textarea1" width="155" x="0" y="0"/>
        <s:Button label="Click Me"
            click="textarea1.text='Hello World';"
            width="92"
            x="31.5" y="56"/>
    </s:Panel>
</s:Application>
```

In this example, you include ActionScript code for the body of the click event handler of the Button control. The MXML compiler takes the attribute `click="..."` and generates the following event handler method:

```
public function __myButton_click(event:MouseEvent):void {
    textarea1.text='Hello World';
}
```

When the user clicks the button, this code sets the value of the TextArea control’s `text` property to the String `"Hello World."` In most cases, you do not need to look at the generated code, but it is useful to understand what happens when you write an inline event handler.

To see the generated code, set the value of the `keep-generated-actionscript` compiler option to `true`. The compiler then stores the *.as helper file in the /generated directory, which is a subdirectory of the location of the SWF file.

For more information about events, see “Events” on page 54. For more information on using the command-line compilers, see “Flex compilers” on page 2164.

Using ActionScript blocks in MXML files

You use the `<fx:Script>` tag to insert an ActionScript block in an MXML file. ActionScript blocks can contain ActionScript functions and variable declarations used in MXML applications. Code inside `<fx:Script>` tags can also declare constants (with the `const` statement) and namespaces (with `namespace`), include ActionScript files (with `include`), import declarations (with `import`), and use namespaces (with `use namespace`).

The `<fx:Script>` tag must be a child of the `<s:Application>` or other top-level component tag.

Statements and expressions are allowed only if they are wrapped in a function. In addition, you cannot define new classes or interfaces in `<fx:Script>` blocks. Instead, you must place new classes or interfaces in separate AS files and import them.

All ActionScript in the block is added to the enclosing file's class when Flex compiles the application. The following example declares a variable and sets the value of that variable inside a function:

```
<?xml version="1.0"?>
<!-- usingas/StatementSyntax.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="doSomething()">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
        public var s:Boolean;

        public function doSomething():void {
            // The following statements must be inside a function.
            s = label1.visible;
            label1.text = "label1.visible = " + String(s);
        }
        ]]>
    </fx:Script>

    <s:Label id="label1"/>

</s:Application>
```

Most ActionScript statements must be inside functions in an `<fx:Script>` block. However, the following statements can be outside functions:

- `import`
- `var`
- `include`
- `const`
- `namespace`
- `use namespace`

When using an `<fx:Script>` block, you should wrap the contents in a CDATA construct. This prevents the compiler from interpreting the contents of the script block as XML, and allows the ActionScript to be properly generated. Adobe recommends that you write all your `<fx:Script>` open and close tags as the following example shows:

```
<fx:Script>
    <![CDATA[
        ...
    ]]>
</fx:Script>
```

Flex does not parse text in a CDATA construct, which means that you can use XML-parsed characters such as angle brackets (< and >) and ampersand (&). For example, the following script that includes a greater-than (>) comparison must be in a CDATA construct:

```
<?xml version="1.0"?>
<!-- usingas/UsingCDATA.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="doSomething()">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
        public var m:Number;
        public var n:Number;

        public function doSomething():void {
            n = 40;
            m = 42;
            label1.text = "40 < 42 = " + String(n < m);
        }
        ]]>
    </fx:Script>

    <s:Label id="label1"/>

</s:Application>
```

Accessing ActionScript documentation

The ActionScript 3.0 programming language can be used from within several development environments, including Adobe® Flash® Professional and Adobe® Flash® Builder™.

The Flex documentation includes *ActionScript 3.0 Developer's Guide*, which describes the ActionScript language. The ActionScript API reference is included as part of the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Working with components

The primary use of ActionScript in your applications is probably going to be for working with the visual controls and containers in your application. Flex provides several techniques for doing this, including referencing a Flex control in ActionScript and manipulating properties during the instantiation of controls and containers.

Referring to components

To work with a component in ActionScript, you usually define an `id` property for that component in the MXML tag. For example, the following code sets the `id` property of the Button control to the String `"myButton"`:

```
<s:Button id="myButton" label="Click Me"/>
```

This property is optional if you do not want to access the component with ActionScript.

This code causes the MXML compiler to autogenerate a public variable named `myButton` that contains a reference to that Button instance. This autogenerated variable lets you access the component instance in ActionScript. You can explicitly refer to the Button control's instance with its `id` instance reference in any ActionScript class or script block. By referring to a component's instance, you can modify its properties and call its methods.

For example, the following ActionScript block changes the value of the Button control's `label` property when the user clicks the button:

```
<?xml version="1.0"?>
<!-- usingas/ButtonExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
        private function setLabel():void {
            if (myButton.label=="Click Me") {
                myButton.label = "Clicked";
            } else {
                myButton.label = "Click Me";
            }
        }
        ]]>
    </fx:Script>
    <s:Button id="myButton" label="Click Me" click="setLabel();"/>

</s:Application>
```

The IDs for all tags in an MXML component, no matter how deeply nested they are, generate public variables of the component being defined. As a result, all `id` properties must be unique within a document. This also means that if you specified an ID for a component instance, you can access that component from anywhere in the application: from functions, external class files, imported ActionScript files, or inline scripts.

You can refer to a component if it does not have an `id` property by using methods of the component's Spark container, such as the `getElementAt()` method. For MX containers, you can use the `getChildAt()` method.

You can refer to the current enclosing document or current object using the `this` keyword.

You can also get a reference to a component when you have a String that matches the name. To access an object on the application, you use the `this` keyword, followed by square brackets, with the String inside the square brackets. The result is a reference to the objects whose name matches the String.

The following example changes style properties on each Button control using a compound String to get a reference to the object:

```
<?xml version="1.0"?>
<!-- usingas/FlexComponents.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script><![CDATA[
        private var newFontStyle:String;
        private var newFontSize:int;
        public function changeLabel(s:String):void {
            s = "myButton" + s;
            if (this[s].getStyle("fontStyle")=="normal") {
                newFontStyle = "italic";
                newFontSize = 18;
            } else {
                newFontStyle = "normal";
                newFontSize = 10;
            }
            this[s].setStyle("fontStyle",newFontStyle);
            this[s].setStyle("fontSize",newFontSize);
        }
        ]]>
    </fx:Script>
    <s:Button id="myButton1"
        click="changeLabel('2')"
        label="Change Other Button's Styles"/>
    <s:Button id="myButton2"
        click="changeLabel('1')"
        label="Change Other Button's Styles"/>
</s:Application>
```

This technique is especially useful if you use a Repeater control or when you create objects in ActionScript and do not necessarily know the names of the objects you want to refer to prior to run time. However, when you instantiate an object in ActionScript, to add that object to the properties array, you must declare the variable as public and declare it in the class's scope, not inside a function.

The following example uses ActionScript to declare two Label controls in the application scope. During initialization, the labels are instantiated and their `text` properties are set. The example then gets a reference to the Label controls by appending the passed-in variable to the String when the user clicks the Button controls.

```
<?xml version="1.0"?>
<!-- usingas/ASLabels.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initLabels()">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
        import mx.controls.Label;
        public var label1:Label;
        public var label2:Label;
        // Objects must be declared in the application scope. Adds the names to
        // the application's properties array.
        public function initLabels():void {
            label1 = new Label();
            label1.text = "Change Me";
            label2 = new Label();
            label2.text = "Change Me";
            addElement(label1);
            addElement(label2);
        }
        public function changeLabel(s:String):void {
            // Create a String that matches the name of the Label control.
            s = "label" + s;
            // Get a reference to the label control using the
            // application's properties array.
            this[s].text = "Changed";
        }
        ]]>
    </fx:Script>
    <s:Button id="b1" click="changeLabel('2')" label="Change Other Label"/>
    <s:Button id="b2" click="changeLabel('1')" label="Change Other Label"/>
</s:Application>
```

Calling component methods

You can invoke the public methods of a component instance in your application by using the following dot-notation syntax:

```
componentInstance.method([parameters]);
```

The following example invokes the `adjustThumb()` method when the user clicks the button, which invokes the public `setThumbValueAt()` method of the HSlider control:

```
<?xml version="1.0"?>
<!-- usingas/ComponentMethods.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
        public function adjustThumb(s:HSlider):void {
            var randomNumber:int = (Math.floor(Math.random() * 10));
            s.setThumbValueAt(0, randomNumber);
        }
        ]]>
    </fx:Script>
    <mx:HSlider id="slider1" tickInterval="1"
        labels="[1,2,3,4,5,6,7,8,9,10]" width="282"/>
    <s:Button id="myButton"
        label="Change Thumb Position"
        click="adjustThumb(slider1);"/>
</s:Application>
```

To invoke a method from a child document (such as a custom MXML component), you can use the `parentApplication`, `parentDocument`, or `FlexGlobals.topLevelApplication` properties. For more information, see "Application containers" on page 393.

***Note:** Because Flex invokes the `initialize` event before drawing the component, you cannot access size and position information of that component from within the `initialize` event handler unless you use the `creationComplete` event handler. For more information on the order of initialization events, see "About startup order" on page 2334.*

Creating visual components in ActionScript

You can use ActionScript to programmatically create visual components using the `new` operator, in the same way that you create instances of any ActionScript class. The created component has default values for its properties, but it does not yet have a parent or any children (including any kind of internal DisplayObjects), and it is not yet on the display list in Flash Player or Adobe® AIR™, so you can't see it. After creating the component, you should use standard assignment statements to set any properties whose default values aren't appropriate.

Finally, you must add the new component to a container, by using the Spark container's `addElement()` or `addElementAt()` methods, so that it becomes part of the visual hierarchy of an application. (For MX containers, you can use the `addChild()` or `addChildAt()` methods.) The first time that it is added to a container, a component's children are created. Children are created late in the component's life cycle so that you can set properties that can affect children as they are created.

When creating visual controls, you must import the appropriate package. In most cases, this is the mx.controls package, although you should check the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

The following example creates a Button control inside the HGroup container:

```
<?xml version="1.0"?>
<!-- usingas/ASVisualComponent.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
        import spark.components.Button;
        public var button2:Button;
        public function createObject():void {
            button2 = new Button();
            button2.label = "Click Me";
            hb1.addElement(button2);
        }
        ]]>
    </fx:Script>
    <s:HGroup id="hb1">
        <s:Button label="Create Object" click="createObject()"/>
    </s:HGroup>
</s:Application>
```

Flex creates the new child as the last child in the container. If you do not want the new child to be the last in the Spark container, use the `addElementAt()` method to change the order. You can use the `setItemIndex()` method after the call to the `addElement()` method, but this is less efficient. For MX containers, you use the `addChildAt()`, `setChildIndex()`, and `addChild()` methods.

You should declare an instance variable for each dynamically created component and store a reference to the newly created component in it, just as the MXML compiler does when you set an `id` property for a component instance tag. You can then access your dynamically created components in the same way as those declaratively created in MXML.

To programmatically remove a control in Spark containers, you can use the `removeElement()`, `removeElementAt()`, and `removeAllElements()` methods. For MX containers, you use the `removeChild()` or `removeChildAt()` methods. You can also use the `removeAllChildren()` method to remove all child controls from a container.

Calling the "remove" methods does not actually delete the objects from memory. If you do not have any other references to the child, Flash Player includes the object in garbage collection at some future point. But if you have a reference to that child, the child is not garbage collected.

In some cases, you declaratively define a component with an MXML tag. You can set the `creationPolicy` property of the component's container to `none` to defer the creation of the controls inside that container. You can then create the component programmatically rather than declaratively. For information on using the `creationPolicy` property, see "Improving startup performance" on page 2333.

The only component you can pass to the `addElement()` method is a class that implements the IVisualElement interface. In other words, if you create a new object that is not a subclass of mx.core.IVisualElement, you must wrap it in a class that implments IVisualElement before you can attach it to a container. The following example creates a new Sprite object, which is not a subclass of IVisualElement, and adds it as a child of the UIComponent (which implements IVisualElement) before adding it to the Panel container:

```
<?xml version="1.0"?>
<!-- usingas/AddingChildrenAsUIComponents.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
        import flash.display.Sprite;
        import mx.core.UIComponent;
        private var xLoc:int = 20;
        private var yLoc:int = 20;
        private var circleColor:Number = 0xFFCC00;
        private function addChildToPanel():void {
            var circle:Sprite = new Sprite();
            circle.graphics.beginFill(circleColor);
            circle.graphics.drawCircle(xLoc, yLoc, 15);
            var c:UIComponent = new UIComponent();
            c.addChild(circle);
            panel1.addElement(c);

            xLoc = xLoc + 5;
            yLoc = yLoc + 1;
            circleColor = circleColor + 20;
        }
        ]]>
    </fx:Script>
    <s:Panel id="panel1" height="250" width="300"/>
    <s:Button id="myButton" label="Click Me" click="addChildToPanel();"/>

</s:Application>
```

About scope

Scoping in ActionScript is largely a description of what the `this` keyword refers to at a particular point. In your application’s core MXML file, you can access the Application object by using the `this` keyword. In a file defining an MXML component, `this` is a reference to the current instance of that component.

In an ActionScript class file, the `this` keyword refers to the instance of that class. In the following example, the `this` keyword refers to an instance of myClass. Because `this` is implicit, you do not have to include it, but it is shown here to illustrate its meaning.

```
class myClass {
    var _x:Number = 3;
    function get x():Number {
        return this._x;
    }
    function set x(y:Number):void {
        if (y > 0) {
            this._x = y;
        } else {
            this._x = 0;
        }
    }
}
```

However, in custom ActionScript and MXML components or external ActionScript class files, Flex executes in the context of those objects and classes, and the `this` keyword refers to the current scope and not the Application object scope.

Flex includes a `FlexGlobals.topLevelApplication` property that you can use to access the root application. In some cases, you can also use the `parentDocument` property to access the next level up in the document chain of an application, or the `parentApplication` property to access the next level up in the application chain when one Application object loads another Application object.

You cannot use these properties to access the root application if the loaded application was loaded into a separate ApplicationDomain or SecurityDomain, as is the case with sandboxed and multi-versioned applications. For more information, see “Accessing the main application from sub-applications” on page 197.

If you write ActionScript in a component’s event listener, the scope is not the component but rather the application. For example, the following code changes the label of the Button control to `"Clicked"` once the Button control is pressed:

```
<?xml version="1.0"?>
<!-- usingas/ButtonScope.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:BasicLayout/>
    </s:layout>
    <s:Panel width="250" height="100" x="65" y="24">
        <s:Button id="myButton"
            label="Click Me"
            click="myButton.label='Clicked'"
            x="79.5" y="20"/>
    </s:Panel>
    <s:Button label="Reset"
        x="158" y="149"
        click="myButton.label='Click Me'"/>
</s:Application>
```

Contrast the previous example with the following code:

```
<?xml version="1.0"?>
<!-- usingas/AppScope.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <!-- The following throws a compiler error because the app level scope does
         not have a label to set. -->
    <!-- <s:Button id="myButton" label="Click Me" click="{this.label='Clicked'}"/> -->
    <!-- <s:Button label="Reset" click="myButton.label='Click Me'"/> -->
</s:Application>
```

This code does not work because when an event listener executes, the `this` keyword does not refer to the Button instance; the `this` keyword refers to the Application or other top-level component instance. The second example attempts to set the `label` property of the Application object, not the `label` property of the Button.

Variables declared within a function are locally scoped to that function. These variables can share the same name as variables in outer scopes, and they do not affect the outer-scoped variable. If a variable is just used temporarily by a single method, make it a local variable of that method rather than an instance variable. Use instance variables only for storing the state of an instance, because each instance variable will take up memory for the entire lifetime of the instance. You can refer to the outer-scoped variable with the `this.` prefix.

Including versus importing ActionScript code

To make your MXML code more readable, you can reference ActionScript files in your `<fx:Script>` tags, rather than insert large blocks of script. You can either include or import ActionScript files.

There is a distinct difference between including and importing code in ActionScript. *Including* copies lines of code from one file into another, as if they had been pasted at the position of the `include` statement. *Importing* adds a reference to a class file or package so that you can access objects and properties defined by external classes. Files that you import must be found in the source path. Files that you include must be located relative to the file that uses the `include` statement, or you must use an absolute path.

You use the `include` statement or the `<fx:Script source="`*`filename`*`">` tag to add ActionScript code to your applications.

You use `import` statements in an `<fx:Script>` block to define the locations of ActionScript classes and packages that your applications might use.

Including ActionScript files

To include ActionScript code, you reference an external ActionScript file in your `<fx:Script>` tags. At compile time, the compiler copies the entire contents of the file into your MXML application, as if you had actually typed it. As with ActionScript in an `<fx:Script>` block, ActionScript statements can only be inside functions. Included files can also declare constants and namespaces, include other ActionScript files, import declarations, and use namespaces. You cannot define classes in included files.

Variables and functions defined in an included ActionScript file are available to any component in the MXML file. An included ActionScript file is not the same as an imported ActionScript class. Flex provides access to the included file's variables and functions, but does not add a new class, because the MXML file itself is a class.

Included ActionScript files do not need to be in the same directory as the MXML file. However, you should organize your ActionScript files in a logical directory structure.

There are two ways to include an external ActionScript file in your application:

- The `source` attribute of the `<fx:Script>` tag. This is the preferred method for including external ActionScript class files.
- The `include` statement inside `<fx:Script>` blocks.

Using the source attribute to include ActionScript files

You use the `source` attribute of the `<fx:Script>` tag to include external ActionScript files in your applications. This provides a way to make your MXML files less cluttered and promotes code reuse across different applications.

Do not give the script file the same name as the application file. This causes a compiler error.

The following example shows the contents of the IncludedFile.as file:

```
// usingas/includes/IncludedFile.as
public function computeSum(a:Number, b:Number):Number {
    return a + b;
}
```

The following example uses the `<fx:Script>` tag to include the contents of the IncludedFile.as file. This file is located in the /includes subdirectory.

```
<?xml version="1.0"?>
<!-- usingas/SourceInclude.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script source="includes/IncludedFile.as"/>
    <s:TextInput id="ta1st" text="3" width="40" x="170" y="24" textAlign="right"/>
    <s:TextInput id="ta2nd" text="3" width="40" x="170" y="52" textAlign="right"/>
    <s:TextArea id="taMain" height="25" width="78" x="132" y="82" textAlign="right"/>
    <s:Button id="b1" label="Compute Sum"
        click="taMain.text=String(computeSum(Number(ta1st.text), Number(ta2nd.text)));"
        x="105" y="115"/>
    <s:Label x="148" y="52" text="+" fontWeight="bold" fontSize="17" width="23"/>
</s:Application>
```

The `source` attribute of the `<fx:Script>` tag supports both relative and absolute paths. For more information, see "Referring to external files that have been included" on page 46.

You cannot use the `source` attribute of an `<fx:Script>` tag and wrap ActionScript code inside that same `<fx:Script>` tag. To include a file and write ActionScript in the MXML file, use two `<fx:Script>` tags.

Using the include directive

The `include` directive is an ActionScript statement that copies the contents of the specified file into your MXML file. The `include` directive uses the following syntax:

```
include "file_name";
```

The following example includes the myfunctions.as file:

```
<?xml version="1.0"?>
<!-- usingas/IncludeASFile.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
        /*  The myfunctions.as file defines two methods that
            return Strings. */
        include "includes/myfunctions.as";
        ]]>
    </fx:Script>
    <s:Button id="myButton"
        label="Call Methods in Included File"
        click="ta1.text=doSomething();ta1.text+=doSomethingElse()"/>
    <s:TextArea width="268" id="ta1"/>
    <s:Button label="Clear" click="ta1.text=''"/>
</s:Application>
```

You can specify only a single file for each `include` directive, but you can use any number of `include` directives. You can nest `include` directives; files with `include` directives can include files that have `include` directives.

The `include` directive supports only relative paths. For more information, see "Referring to external files that have been included" on page 46.

You can use the `include` only where multiple statements are allowed. For example, the following is not allowed:

```
if (expr)
    include "foo.as"; // First statement is guarded by IF, but rest are not.
...
```

The following is allowed:

```
if (expr) {
    include "foo.as"; // All statements inside { } are guarded by IF.
}
```

The use of curly braces ({ }) allows multiple statements because you can add multiple statements inside the braces.

Adobe recommends that you not use the `include` directive if you use a large number of included ActionScript files. You should try to break the code into separate class files where appropriate and store them in logical package structures.

Referring to external files that have been included

The `source` attribute of the `<fx:Script>` tag and the `include` directive refer to files in different ways.

The following are the valid paths to external files that are referenced in an `<fx:Script>` tag's `source` attribute:

- Absolute URLs, such as http://www.macromedia.com or file:///C|/site_flashteam/foo.gif.
- Relative URLs, such as ../myscript.as. A relative URL that does not start with a slash is resolved relative to the file that uses it. If the tag `<fx:Script source="../IncludedFile.as">` is included in "mysite/myfiles/myapp.mxml," the system searches for "mysite/IncludedFile.as".

For an ActionScript `include` directive, you can reference only relative URLs.

Flex searches the source path for imported classes and packages. Flex does not search the source path for files that are included using the `include` directive or the `source` attribute of the `<fx:Script>` tag.

Importing classes and packages

If you create many utility classes or include multiple ActionScript files to access commonly used functions, you might want to store them in a set of classes in their own package. You can import ActionScript classes and packages using the `import` statement. By doing this, you do not have to explicitly enter the fully qualified class names when accessing classes within ActionScript.

The following example imports the MyClass class in the MyPackage.Util package:

```
<?xml version="1.0"?>
<!-- usingas/AccessingPackagedClasses.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import MyPackage.Util.MyClass;
            private var mc:MyClass = new MyClass;
        ]]>
    </fx:Script>
    <s:Button id="myButton" label="Click Me" click="myButton.label=mc.returnAString()"/>
</s:Application>
```

In your ActionScript code, instead of referring to the class with its fully qualified package name (MyPackage.Util.MyClass), you refer to it as MyClass.

You can also use the wildcard character (*) to import the entire package. For example, the following statement imports the entire MyPackage.Util package:

```
import MyPackage.Util.*;
```

Flex searches the source path for imported files and packages, and includes only those that are used in the final SWF file.

It is not sufficient to simply specify the fully qualified class name. You should use fully qualified class names only when necessary to distinguish two classes with the same class name that reside in different packages.

If you import a class but do not use it in your application, the class is not included in the resulting SWF file's bytecode. As a result, importing an entire package with a wildcard does not create an unnecessarily large SWF file.

Techniques for separating ActionScript from MXML

The following sample application, which calls a single function, shows several methods of separating ActionScript from the MXML.

The Temperature application takes input from a single input field and uses a function to convert the input from Fahrenheit to Celsius. It then displays the resulting temperature in a Label control.

One MXML document (event handling logic in event attribute)

The following code shows the ActionScript event handling logic inside the MXML tag's `click` event:

```
<?xml version="1.0"?>
<!-- usingas/ASOneFile.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    width="700">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:Panel title="Temperature Application" width="90%">
        <s:HGroup>
            <s:Label text="Temperature in Fahrenheit:"/>
            <s:TextInput id="fahrenheit" width="120"/>
            <s:Button label="Convert"
                click="celsius.text=String(Math.round((Number(fahrenheit.text)-32)/1.8 *
10)/10);"/>
            <s:Label text="Temperature in Celsius:"/>
            <s:Label id="celsius" width="120" fontSize="24"/>
        </s:HGroup>
    </s:Panel>
</s:Application>
```

One MXML document (event handling logic in <fx:Script> block)

In this example, the logic for the function is inside an `<fx:Script>` block in the MXML document, and is called from the MXML tag's `click` event, as the following code shows:

```
<?xml version="1.0"?>
<!-- usingas/ASScriptBlock.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    width="700">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
        public function calculate():void {
            var n:Number = Number(fahrenheit.text);
            var t:Number = Math.round((n-32)/1.8*10)/10;
            celsius.text=String(t);
        }
        ]]>
    </fx:Script>
    <s:Panel title="Temperature Application" width="90%">
        <s:HGroup>
            <s:Label text="Temperature in Fahrenheit:"/>
            <s:TextInput id="fahrenheit" width="120"/>
            <s:Button label="Convert" click="calculate();" />
            <s:Label text="Temperature in Celsius:"/>
            <s:Label id="celsius" width="120" fontSize="24"/>
        </s:HGroup>
    </s:Panel>
</s:Application>
```

One MXML document and one ActionScript file (event handling logic in separate script file)

Here, the function call is in an MXML event attribute, and the function is defined in a separate ActionScript file, as the following code shows:

```
<?xml version="1.0"?>
<!-- usingas/ASSourceFile.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    width="700">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <!-- Specify the ActionScript file that contains the function. -->
    <fx:Script source="includes/Sample3Script.as"/>
    <s:Panel title="Temperature Application" width="90%">
        <s:HGroup>
            <s:Label text="Temperature in Fahrenheit:"/>
            <s:TextInput id="fahrenheit" width="120"/>
            <s:Button label="Convert" click="celsius.text=calculate(fahrenheit.text);"/>
            <s:Label text="Temperature in Celsius:"/>
            <s:Label id="celsius" width="120" fontSize="24"/>
        </s:HGroup>
    </s:Panel>
</s:Application>
```

The Sample3Script.as ActionScript file contains the following code:

```
// usingas/includes/Sample3Script.as
public function calculate(s:String):String {
    var n:Number = Number(s);
    var t:Number = Math.round((n-32)/1.8*10)/10;
    return String(t);
}
```

Creating ActionScript components

You can create reusable components that use ActionScript and reference these components in your applications as MXML tags. Components created in ActionScript can contain graphical elements, define custom business logic, or extend existing components. They can inherit from any components available in Flex.

Defining your own components in ActionScript has several benefits. Components let you divide your applications into individual modules that you can develop and maintain separately. By implementing commonly used logic within custom components, you can build a suite of reusable components that you can share among multiple applications.

Also, you can base your custom components on the set of components by extending from the Flex class hierarchy. You can create custom versions of Flex visual controls, as well as custom versions on nonvisual components, such as data validators, formatters, and effects.

For example, you can define a custom button, derived from the Button control, in the myControls package, as the following example shows:

```
package myControls {
    import mx.controls.Button;
    public class MyButton extends Button {
        public function MyButton() {
            ...
        }
        ...
    }
}
```

In this example, you write your MyButton control to the MyButton.as file, and you store the file in the myControls subdirectory of the root directory of your application. The fully qualified class name of your component reflects its location. In this example, the component's fully qualified class name is myControls.MyButton.

You can reference your custom Button control from an application file, such as MyApp.mxml, as the following example shows:

```
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:cmp="myControls.*">
    <cmp:MyButton label="Jack"/>
</s:Application>
```

In this example, you define the `cmp` namespace that defines the location of your custom component in the application's directory structure. You then reference the component as an MXML tag using the namespace prefix.

Typically, you put custom ActionScript components in directories that are in the source path. These include any directory that you specify in the source path.

You can also create custom components using MXML. For more information, see "Custom components" on page 2356.

Types of custom components

You can create the following types of components in ActionScript:

User-interface components *User-interface components* contain both processing logic and visual elements. These components usually extend the component hierarchy. You can extend from the UIComponent classes, or any of the components, such as Button, ComboBox, or DataGrid. Your custom ActionScript component inherits all of the public methods, along with public and protected properties of its base class.

Nonvisual components *Nonvisual components* define no visual elements. A nonvisual component is an ActionScript class that does not extend the UIComponent class. They can provide greater efficiency at run time.

Performing object introspection

Object introspection is a technique for determining the elements of a class at run time, such as its properties and methods. There are two ways to do introspection in ActionScript:

- Using `for..in` loops
- Using the introspection API

You might find object introspection a useful technique when debugging your application. For example, you might write a method that takes a generic object of type Object as an argument. You can use introspection to output all of the properties and methods of the Object to determine exactly what your application passed to it.

Using for..in loops

You can use a `for..in` loop to iterate over objects and output their properties and their values. A `for..in` loop enumerates only dynamically added properties. Declared variables and methods of classes are not enumerated in `for..in` loops. This means that most classes in the ActionScript API will not display any properties in a `for..in` loop. However, the generic type Object is still a dynamic object and will display properties in a `for..in` loop.

The following example creates a generic Object, adds properties to that object, and then iterates over that object when you click the button to inspect its properties:

```
<?xml version="1.0"?>
<!-- usingas/IntrospectionForIn.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp()">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
        private var obj:Object = new Object();
        private function initApp():void {
            // Create the object.
            obj.a = "Schotten Totten";
            obj.b = "Taj Majal";
            obj.c = "Durche die Wuste";
        }
        public function dumpObj():void {
            for (var p:String in obj) {
                ta1.text += p + ":" + obj[p] + "\n";
            }
        }
        ]]>
    </fx:Script>
    <s:TextArea id="ta1" width="400" height="200"/>
    <s:Button label="Dump Object" click="dumpObj()"/>
</s:Application>
```

You can also use the `mx.utils.ObjectUtil.toString()` method to print all the dynamically added properties of an object, for example:

```
<?xml version="1.0"?>
<!-- usingas/ObjectUtilToString.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp()">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
        import mx.utils.ObjectUtil;
        private var obj:Object = new Object();
        private function initApp():void {
            // Create the object.
            obj.a = "Schotten Totten";
            obj.b = "Taj Majal";
            obj.c = "Durche die Wuste";
        }
        public function dumpObj():void {
            ta1.text = ObjectUtil.toString(obj);
        }
        ]]>
    </fx:Script>
    <s:TextArea id="ta1" width="400" height="200"/>
    <s:Button label="Dump Object" click="dumpObj()"/>
</s:Application>
```

The mx.utils.ObjectUtil class has other useful methods such as `compare()`, `copy()`, and `isSimple()`. For more information, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Using the introspection API

If you want to list all the public properties and methods of a nondynamic (or sealed) class or class instance, use the `describeType()` method and parse the results using the E4X API. The `describeType()` method is in the flash.utils package. The method's only parameter is the target object that you want to introspect. You can pass it any ActionScript value, including all available ActionScript types such as object instances, primitive types such as `uint`, and class objects. The return value of the `describeType()` method is an E4X XML object that contains an XML description of the object's type.

The `describeType()` method returns only public members. The method does not return private members of the caller's superclass or any other class where the caller is not an instance. If you call `describeType(this)`, the method returns information only about nonstatic members of the class. If you call `describeType(getDefinitionByName("MyClass"))`, the method returns information only about the target's static members.

The following example introspects the Button control and prints the details to TextArea controls:

```
<?xml version="1.0"?>
<!-- usingas/IntrospectionAPI.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="getDetails()">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
        import flash.utils.*;
        public function getDetails():void {
            // Get the Button control's E4X XML object description.
            var classInfo:XML = describeType(button1);
            // Dump the entire E4X XML object into ta2.
            ta2.text = classInfo.toString();
            // List the class name.
            ta1.text = "Class " + classInfo.@name.toString() + "\n";
            // List the object's variables, their values, and their types.
            for each (var v:XML in classInfo..variable) {
                ta1.text += "Variable " + v.@name + "=" + button1[v.@name] +
                    " (" + v.@type + ")\n";
            }
            // List accessors as properties.
            for each (var a:XML in classInfo..accessor) {
                // Do not get the property value if it is write only.
                if (a.@access == 'writeonly') {
                    ta1.text += "Property " + a.@name + " (" + a.@type +")\n";
                }
                else {
                    ta1.text += "Property " + a.@name + "=" +
                        button1[a.@name] +  " (" + a.@type +")\n";
                }
            }
            // List the object's methods.
            for each (var m:XML in classInfo..method) {
                ta1.text += "Method " + m.@name + "():" + m.@returnType + "\n";
            }
        }
        ]]>
    </fx:Script>
    <s:Button label="This Button Does Nothing" id="button1"/>
    <s:TextArea id="ta1" width="400" height="200"/>
    <s:TextArea id="ta2" width="400" height="200"/>
</s:Application>
```

The output displays accessors, variables, and methods of the Button control, and appears similar to the following:

```
Class mx.controls::Button
...
Variable id=button1 (String)
Variable __width=66 (Number)
Variable layoutWidth=66 (Number)
Variable __height=22 (Number)
Variable layoutHeight=22 (Number)
...
Property label=Submit (String)
Property enabled=true (Boolean)
Property numChildren=2 (uint)
Property enabled=true (Boolean)
Property visible=true (Boolean)
Property toolTip=null (String)
...
Method dispatchEvent():Boolean
Method hasEventListener():Boolean
Method layoutContents():void
Method getInheritingStyle():Object
Method getNonInheritingStyle():Object
```

Another useful method is the ObjectUtil's `getClassInfo()` method. This method returns an Object with the name and properties of the target object. The following example uses the `getClassInfo()` and `toString()` methods to show the properties of the Button control:

```
<?xml version="1.0"?>
<!-- usingas/IntrospectionObjectUtil.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    height="650">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script><![CDATA[
        import mx.controls.Alert;
        import mx.utils.ObjectUtil;
        private function showProps(b:Button):void {
            var o:Object = ObjectUtil.getClassInfo(b);
            ta1.text = ObjectUtil.toString(o);
        }
        ]]>
    </fx:Script>
    <s:Button id="b1" label="Show Properties" click="showProps(b1)"/>
    <s:TextArea id="ta1" width="300" height="500"/>
</s:Application>
```

For more information about using E4X, see Working with XML.

Events

One of the most important parts of your Adobe® Flex™ application is handling events by using controls and ActionScript.

About Flex events

Events let a developer know when something happens within an application. They can be generated by user devices, such as the mouse and keyboard, or other external input, such as the return of a web service call. Events are also triggered when changes happen in the appearance or life cycle of a component, such as the creation or destruction of a component or when the component is resized.

Any user interaction with your application can generate events. Events can also occur without any direct user interaction, such as when data finishes loading from a server or when an attached camera becomes active. You can “handle” these events in your code by adding an event handler. *Event handlers* are the functions or methods that you write to respond to specific events. They are also sometimes referred to as *event listeners*.

The Flex event model is based on the Document Object Model (DOM) Level 3 events model. Although Flex does not adhere specifically to the DOM standard, the implementations are very similar. The event model in Flex comprises the Event object and its subclasses, and the event dispatching model. For a quick start in using events in Flex, see the sample code in “Using events” on page 57.

Components generate and dispatch events and *consume* (listen to) other events. An object that requires information about another object’s events registers a listener with that object. When an event occurs, the object dispatches the event to all registered listeners by calling a function that was requested during registration. To receive multiple events from the same object, you must register your listener for each event.

Components have built-in events that you can handle in ActionScript blocks in your MXML applications. You can also take advantage of the Flex event system’s dispatcher-listener model to define your own event listeners outside of your applications, and define which methods of your custom listeners will listen to certain events. You can register listeners with the target object so that when the target object dispatches an event, the listeners get called.

All visual objects, including Flex controls and containers, are subclasses of the DisplayObject class. They are in a tree of visible objects that make up your application. The root of the tree is the Stage. Below that is the SystemManager object, and then the Application object. Child containers and components are leaf nodes of the tree. That tree is known as the *display list*. An object on the display list is analogous to a node in the DOM hierarchical structure. The terms *display list object* and *node* are used interchangeably.

For information about each component’s events, see the component’s description in “UI Controls” on page 643 or the control’s entry in *ActionScript 3.0 Reference for the Adobe Flash Platform*.

For a detailed description of a component’s startup life cycle, including major events in that life cycle, see “Create advanced MX visual components in ActionScript” on page 2475.

About the event flow

You can instruct any container or control to listen for events dispatched by another container or control. When Adobe® Flash® Player dispatches an Event object, that Event object makes a roundtrip journey from the root of the display list to the target node, checking each node for registered listeners. The *target node* is the node in the display list where the event occurred. For example, if a user clicks a Button control named Child1, Flash Player dispatches an Event object with Child1 defined as the target node.

The event flow is conceptually divided into three parts: the capturing phase, the targeting phase, and the bubbling phase, as briefly described next. For more information about the event flow, see “Event propagation” on page 81.

About the capturing phase

The first part of the event flow is called the *capturing phase*. This phase comprises all of the nodes from the root node to the parent of the target node. During this phase, Flash Player examines each node, starting with the root, to see if it has a listener registered to handle the event. If it does, Flash Player sets the appropriate values of the Event object and then calls that listener. Flash Player stops after it reaches the target node's parent and calls any listeners registered on the parent. For more information, see "Capturing phase" on page 82.

About the targeting phase

The second part of the event flow, the *targeting phase*, consists solely of the target node. Flash Player sets the appropriate values on the Event object, checks the target node for registered event listeners, and then calls those listeners. For more information, see "Targeting phase" on page 83.

About the bubbling phase

The third part of the event flow, the *bubbling phase*, comprises all of the nodes from the target node's parent to the root node. Starting with the target node's parent, Flash Player sets the appropriate values on the Event object and then calls event listeners on each of these nodes. Flash Player stops after calling any listeners on the root node. For more information about the bubbling phase, see "Bubbling phase" on page 83.

About the Event class

The Event class is an ActionScript class with properties that contain information about the event that occurred. An Event object is an implicitly created object, similar to the request and response objects in a JavaServer Page (JSP) that are implicitly created by the application server.

Flex creates an Event object each time an event is dispatched. You can use the Event object inside an event listener to access details about the event that was dispatched, or about the component that dispatched the event. Passing an Event object to, and using it in, an event listener is optional. However, if you want to access the Event object's properties inside your event listeners, you must pass the Event object to the listener.

Flex creates only one Event object when an event is dispatched. During the bubbling and capturing phases, Flex changes the values on the Event object as it moves up or down the display list, rather than creating a new Event object for each node.

About event subclasses

There are many classes that extend the flash.events.Event class. These classes are defined mostly in the following packages:

- spark.events.*
- mx.events.*
- flash.events.*

The mx.events package defines event classes that are specific to most Flex controls, including the DataGridEvent, DragEvent, and ColorPickerEvent. The spark.events package defines event classes that are specific to a few Spark controls, including the TextOperationEvent and VideoEvent. The flash.events package describes events that are not unique to Flex but are instead defined by Flash Player. These event classes include MouseEvent, DataEvent, and TextEvent. All of these events are commonly used in applications.

In addition to these packages, some packages also define their own event objects: for example, mx.messaging.events.ChannelEvent and mx.logging.LogEvent.

Child classes of the Event class have additional properties and methods that may be unique to them. In some cases, you will want to use a more specific event type rather than the generic Event object so that you can access these unique properties or methods. For example, the LogEvent class has a `getLevelString()` method that the Event class does not.

For information on using Event subclasses, see “Using event subclasses” on page 89.

About the EventDispatcher class

Every object in the display list can trace its class inheritance back to the DisplayObject class. The DisplayObject class, in turn, inherits from the EventDispatcher class. The EventDispatcher class is a base class that provides important event model functionality for every object on the display list. Because the DisplayObject class inherits from the EventDispatcher class, any object on the display list has access to the methods of the EventDispatcher class.

This is significant because every item on the display list can participate fully in the event model. Every object on the display list can use its `addEventListener()` method—inherited from the EventDispatcher class—to listen for a particular event, but only if the listening object is part of the event flow for that event.

Although the name EventDispatcher seems to imply that this class’s main purpose is to send (or dispatch) Event objects, the methods of this class are used much more frequently to register event listeners, check for event listeners, and remove event listeners.

The EventDispatcher class implements the IEventDispatcher interface. This allows developers who create custom classes that cannot inherit from EventDispatcher or one of its subclasses to implement the IEventDispatcher interface to gain access to its methods.

The `addEventListener()` method is the most commonly used method of this class. You use it to register your event listeners. For information on using the `addEventListener()` method, see “Using the addEventListener() method” on page 64.

Advanced programmers use the `dispatchEvent()` method to manually dispatch an event or to send a custom Event object into the event flow. For more information, see “Manually dispatching events” on page 78.

Several other methods of the EventDispatcher class provide useful information about the existence of event listeners. The `hasEventListener()` method returns `true` if an event listener is found for that specific event type on a particular display list object. The `willTrigger()` method checks for event listeners on a particular display list object, but it also checks for listeners on all of that display list object’s ancestors for all phases of the event flow. The method returns `true` if it finds one.

Using events

Using events in Flex is a two-step process. First, you write a function or class method, known as an *event listener* or *event handler,* that responds to events. The function often accesses the properties of the Event object or some other settings of the application state. The signature of this function usually includes an argument that specifies the event type being passed in.

The following example shows a simple event listener function that reports when a control triggers the event that it is listening for:

```
<?xml version="1.0"?>
<!-- events/SimpleEventHandler.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp();">
    <fx:Script>
        <![CDATA[
        import mx.controls.Alert;
        private function initApp():void {
            b1.addEventListener(MouseEvent.CLICK, myEventHandler);
        }
        private function myEventHandler(event:Event):void {
            Alert.show("An event occurred.");
        }
        ]]>
    </fx:Script>
    <s:Button id="b1" label="Click Me"/>
</s:Application>
```

As you can see in this example, you also register that function or class method with a display list object by using the addEventListener() method.

Most Flex controls simplify listener registration by letting you specify the listener inside the MXML tag. For example, instead of using the `addEventListener()` method to specify a listener function for the Button control's `click` event, you specify it in the `click` attribute of the `<mx:Button>` tag:

```
<?xml version="1.0"?>
<!-- events/SimplerEventHandler.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <fx:Script>
        <![CDATA[
        import mx.controls.Alert;
        private function myEventHandler(event:Event):void {
            Alert.show("An event occurred.");
        }
        ]]>
    </fx:Script>
    <s:Button id="b1" label="Click Me" click="myEventHandler(event)"/>
</s:Application>
```

This is equivalent to the `addEventListener()` method in the previous code example. However, it is best practice to use the `addEventListener()` method. This method gives you greater control over the event by letting you configure the priority and capturing settings, and use event constants. In addition, if you use `addEventListener()` to add an event handler, you can use `removeEventListener()` to remove the handler when you no longer need it. If you add an event handler inline, you cannot call `removeEventListener()` on that handler.

Each time a control generates an event, Flex creates an Event object that contains information about that event, including the type of event and a reference to the dispatching control. To use the Event object, you specify it as a parameter in the event handler function, as the following example shows:

```
<?xml version="1.0"?>
<!-- events/EventTypeHandler.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
        import mx.controls.Alert;
        private function myEventHandler(e:Event):void {
            Alert.show("An event of type '" + e.type + "' occurred.");
        }
        ]]>
    </fx:Script>
    <s:Button id="b1" label="Click Me" click="myEventHandler(event)"/>
</s:Application>
```

If you want to access the Event object in an event handler that was triggered by an inline event, you must add the `event` keyword inside the MXML tag so that Flex explicitly passes it to the handler, as in the following:

```
<mx:Button id="b1" label="Click Me" click="myEventHandler(event)"/>
```

You are not required to use the Event object in a handler function. The following example creates two event handler functions and registers them with the events of a ComboBox control. The first event handler, `openEvt()`, takes no arguments. The second event handler, `changeEvt()`, takes the Event object as an argument and uses this object to access the `value` and `selectedIndex` of the ComboBox control that triggered the event.

```
<?xml version="1.0"?>
<!-- events/MultipleEventHandlers.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script><![CDATA[
        private function openEvt():void {
            forChange.text="";
        }
        private function changeEvt(e:Event):void {
            forChange.text =
            "Value: " + e.currentTarget.selectedItem + "\n" +
            "Index: " + e.currentTarget.selectedIndex;
        }
    ]]></fx:Script>
    <s:ComboBox open="openEvt()" change="changeEvt(event)">
        <s:dataProvider>
            <s:ArrayList>
                <fx:String>AK</fx:String>
                <fx:String>AL</fx:String>
                <fx:String>AR</fx:String>
            </s:ArrayList>
        </s:dataProvider>
    </s:ComboBox>
    <s:TextArea id="forChange" width="150" height="100"/>
</s:Application>
```

This example shows accessing the `target` property of the Event object. For more information, see “Accessing the currentTarget property” on page 60.

Specifying the Event object

You specify the object in a listener function’s signature as type Event, as the following example shows:

```
function myEventListener(e:Event):void { ... }
```

However, if you want to access properties that are specific to the type of event that was dispatched, you must instead specify a more specific event type, such as ToolTipEvent or KeyboardEvent, as the following example shows:

```
import mx.events.ToolTip
function myEventListener(e:ToolTipEvent):void { ... }
```

In some cases, you must import the event’s class in your ActionScript block.

Most objects have specific events that are associated with them, and most of them can dispatch more than one type of event.

If you declare an event of type Event, you can cast it to a more specific type to access its event-specific properties. For more information, see “Using event subclasses” on page 89.

Accessing the currentTarget property

Event objects include a reference to the instance of the dispatching component (or *target*), which means that you can access all the properties and methods of that instance in an event listener. The following example accesses the `id` of the Button control that triggered the event:

```
<?xml version="1.0"?>
<!-- events/AccessingCurrentTarget.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
            import mx.controls.Alert;
            private function myEventHandler(e:Event):void {
                Alert.show("The button '" + e.currentTarget.id + "' was clicked.");
            }
        ]]>
    </fx:Script>
    <s:Button id="b1" label="Click Me" click="myEventHandler(event)"/>
</s:Application>
```

You can access members of the `currentTarget`. If you do not cast the current target to a specific type, the compiler assumes that it is of type Object. Objects can have any property or method because the Object type is dynamic in ActionScript. Therefore, when accessing methods and properties of the `currentTarget`, it is best practice to cast `currentTarget` to whatever class you anticipate will dispatch that event. This gives you strong type checking at compile time, and helps avoid the risk of throwing a run-time error.

The following example casts the current target to a TextInput class before calling the `selectRange()` method, but does not cast it before trying to set the `tmesis` property. The `tmesis` property does not exist on the TextInput class. This illustrates that you will get a run-time error but not a compile-time error when you try to access members that don’t exist, unless you cast `currentTarget` to a specific type so that type checking can occur:

```
<?xml version="1.0"?>
<!-- events/InvokingOnCurrentTarget.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    width="500">
    <fx:Script>
        <![CDATA[
        import mx.core.UIComponent;
        private function tiHandler(e:Event):void {
            /*
            The following enforces type checking:
            */
            TextInput(e.currentTarget).selectRange(0,3);
            /*
            The following throws a run-time error but not a compile-time error:
            e.currentTarget.tmesis = 4;
            */
            /*
            ... unless you cast it to the expected type like the following. Then
            the compiler throws an error.
            TextInput(e.currentTarget).tmesis = 4;
            */
        }
        ]]>
    </fx:Script>
    <s:TextInput id="ti1" click="tiHandler(event)"
        text="When you click on this control, the first three characters are selected."
        width="400"/>
</s:Application>
```

You could also cast `currentTarget` to UIComponent or some other more general class that still has methods of display objects. That way, if you don't know exactly which control will dispatch an event, at least you can ensure there is some type checking.

You can also access methods and properties of the `target` property, which contains a reference to the current node in the display list. For more information, see "About the target and currentTarget properties" on page 81.

Registering event handlers

There are several strategies that you can employ when you register event handlers with your Flex controls:

1 Define an event handler inline. This binds a call to the handler function to the control that triggers the event.

```
<?xml version="1.0"?>
<!-- events/SimplerEventHandler.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <fx:Script>
        <![CDATA[
        import mx.controls.Alert;
        private function myEventHandler(event:Event):void {
            Alert.show("An event occurred.");
        }
        ]]>
    </fx:Script>
    <s:Button id="b1" label="Click Me" click="myEventHandler(event)"/>
</s:Application>
```

In this example, whenever the user clicks the Button control, Flex calls the `myClickHandler()` function.

For more information on defining event handlers inline, see “Defining event listeners inline” on page 63.

2 Use the `addEventListener()` method, as follows:

```
<?xml version="1.0"?>
<!-- events/SimpleEventHandler.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp();">
    <fx:Script>
        <![CDATA[
        import mx.controls.Alert;
        private function initApp():void {
            b1.addEventListener(MouseEvent.CLICK, myEventHandler);
        }
        private function myEventHandler(event:Event):void {
            Alert.show("An event occurred.");
        }
        ]]>
    </fx:Script>
    <s:Button id="b1" label="Click Me"/>
</s:Application>
```

As with the previous example, whenever the user clicks the Button control, Flex calls the `myClickHandler()` handler function. However, registering your event handlers using this method provides more flexibility. You can register multiple components with this event handler, add multiple handlers to a single component, or remove the handler. For more information, see “Using the addEventListener() method” on page 64.

3 Create an event handler class and register components to use the class for event handling. This approach to event handling promotes code reuse and lets you centralize event handling outside your MXML files. For more information on creating custom event handler classes, see “Creating event handler classes” on page 69.

Defining event listeners inline

The simplest method of defining event handlers in applications is to point to a handler function in the component's MXML tag. To do this, you add any of the component's events as a tag attribute followed by an ActionScript statement or function call.

You add an event handler inline using the following syntax:

```
<s:tag_nameevent_name="handler_function"/>
```

For example, to listen for a Button control's `click` event, you add a statement in the `<mx:Button>` tag's `click` attribute. If you add a function, you define that function in an ActionScript block. The following example defines the `submitForm()` function as the handler for the Button control's `click` event:

```
<fx:Script><![CDATA[
    function submitForm():void {
        // Do something.
    }
]]></fx:Script>
<s:Button label="Submit" click="submitForm();"/>
```

Event handlers can include any valid ActionScript code, including code that calls global functions or sets a component property to the return value. The following example calls the `trace()` global function:

```
<s:Button label="Get Ver" click="trace('The button was clicked');"/>
```

There is one special parameter that you can pass in an inline event handler definition: the `event` parameter. If you add the `event` keyword as a parameter, Flex passes the Event object and inside the handler function, you can then access all the properties of the Event object.

The following example passes the Event object to the `submitForm()` handler function and specifies it as type MouseEvent:

```
<?xml version="1.0"?>
<!-- events/MouseEventHandler.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
        import mx.controls.Alert;

        private function myEventHandler(event:MouseEvent):void {
            // Do something with the MouseEvent object.
            Alert.show("An event of type '" + event.type + "' occurred.");
        }
        ]]>
    </fx:Script>
    <s:Button id="b1" label="Click Me" click="myEventHandler(event)"/>
</s:Application>
```

It is best practice to include the `event` keyword when you define all inline event listeners and to specify the most stringent Event object type in the resulting listener function (for example, specify MouseEvent instead of Event).

You can use the Event object to access a reference to the target object (the object that dispatched the event), the type of event (for example, `click`), or other relevant properties, such as the row number and value in a list-based control. You can also use the Event object to access methods and properties of the target component, or the component that dispatched the event.

Although you will most often pass the entire Event object to an event listener, you can just pass individual properties, as the following example shows:

```
<?xml version="1.0"?>
<!-- events/PropertyHandler.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
        import mx.controls.Alert;

        private function myEventHandler(s:String):void {
            Alert.show("Current Target: " + s);
        }
        ]]>
    </fx:Script>
    <s:Button id="b1" label="Click Me" click="myEventHandler(event.currentTarget.id)"/>
</s:Application>
```

Registering an event listener inline provides less flexibility than using the `addEventListener()` method to register event listeners. The drawbacks are that you cannot set the `useCapture` or `priority` properties on the Event object and that you cannot remove the listener once you add it.

Using the addEventListener() method

The addEventListener() method lets you register event listener functions with the specified control or object. The following example adds the `myClickListener()` function to the b1 instance of a Button control. When the user clicks b1, Flex calls the `myClickListener()` method:

```
b1.addEventListener(MouseEvent.CLICK, myClickListener);
```

The `addEventListener()` method has the following signature:

```
componentInstance.addEventListener(
    event_type:String,
    event_listener:Function,
    use_capture:Boolean,
    priority:int,
    weakRef:Boolean
)
```

The *`event_type`* argument is the kind of event that this component dispatches. This can be either the event type String (for example, “click” or “mouseOut”) or the event type static constant (such as `MouseEvent.CLICK` or `MouseEvent.MOUSE_OUT`). This argument is required.

The constants provide an easy way to refer to specific event types. You should use these constants instead of the strings that they represent. If you misspell a constant name in your code, the compiler catches the mistake. If you instead use strings and make a typographical error, it can be harder to debug and could lead to unexpected behavior.

You should use the constants wherever possible. For example, when you are testing to see whether an Event object is of a certain type, use the following code:

```
if (myEventObject.type == MouseEvent.CLICK) {/* your code here */}
```

Do not use the following code:

```
if (myEventObject.type == "click") {/* your code here */}
```

The *event_listener* argument is the function that handles the event. This argument is required.

The *use_capture* parameter of the addEventListener() method lets you control the phase in the event flow in which your listener will be active. It sets the value of the useCapture property of the Event object. If useCapture is set to true, your listener is active during the capturing phase of the event flow. If useCapture is set to false, your listener is active during the targeting and bubbling phases of the event flow, but not during the capturing phase. The default value is determined by the type of event, but is false in most cases.

To listen for an event during all phases of the event flow, you must call addEventListener() twice, once with the useCapture parameter set to true, and again with *use_capture* set to false. This argument is optional. For more information, see "Capturing phase" on page 82.

The *priority* parameter sets the priority for that event listener. The higher the number, the sooner that event handler executes relative to other event listeners for the same event. Event listeners with the same priority are executed in the order that they were added. This parameter sets the priority property of the Event object. The default value is 0, but you can set it to negative or positive integer values. If several event listeners are added without priorities, the earlier a listener is added, the sooner it is executed. For more information on setting priorities, see "Event priorities" on page 88.

The *weakRef* parameter provides you with some control over memory resources for listeners. A strong reference (when weakRef is false) prevents the listener from being garbage collected. A weak reference (when weakRef is true) does not. The default value is false.

When you add a listener function and that function is invoked, Flex implicitly creates an Event object for you and passes it to the listener function. You must declare the Event object in the signature of your listener function.

If you add an event listener by using the addEventListener() method, you are required to declare an event object as a parameter of the *listener_function*, as the following example shows:

```
b1.addEventListener(MouseEvent.CLICK, performAction);
```

In the listener function, you declare the Event object as a parameter, as follows:

```
public function performAction(e:MouseEvent):void {
    ...
}
```

The following example defines a new handler function myClickListener(). It then registers the click event of the Button control with that handler. When the user clicks the button, Flex calls the myClickHandler() function.

```
<?xml version="1.0"?>
<!-- events/AddEventListenerExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    initialize="createListener()">
    <fx:Script>
        <![CDATA[
            import mx.controls.Alert;
            private function createListener():void {
                b1.addEventListener(MouseEvent.CLICK, myClickHandler, false, 0);
            }
            private function myClickHandler(e:MouseEvent):void {
                Alert.show("The button was clicked.");
            }
        ]]>
    </fx:Script>
    <s:Button label="Click Me" id="b1"/>
</s:Application>
```

Using addEventListener() inside an MXML tag

You can add event listeners with the `addEventListener()` method inline with the component definition. The following Button control definition adds the call to the `addEventListener()` method inline with the Button control's `initialize` property:

```
<?xml version="1.0"?>
<!-- events/CallingAddEventListenerInline.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
            import mx.controls.Alert;
            private function myClickHandler(event:Event):void {
               Alert.show("The button was clicked.");
            }
        ]]>
    </fx:Script>
    <s:Button id='b1'
        label="Click Me"
        initialize='b1.addEventListener(MouseEvent.CLICK, myClickHandler, false, 1);'
    />
</s:Application>
```

This is the equivalent of defining the event handler inline. However, defining a handler by using the `addEventListener()` method rather than setting `click="`*`handler_function`*`"` lets you set the value of the `useCapture` and `priority` properties of the Event object. Furthermore, you cannot remove a handler added inline, but when you use the `addEventListener()` method to add a handler, you can call the `removeEventListener()` method to remove that handler.

Using nested inner functions as event listeners

Rather than passing the name of an event listener function to the `addEventListener()` method, you can define an inner function (also known as a closure).

In the following example, the nested inner function is called when the button is clicked:

```
<?xml version="1.0"?>
<!-- events/AddingInnerFunctionListener.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp()">
    <fx:Script>
        <![CDATA[
        import mx.controls.Alert;
        private function initApp():void {
            b1.addEventListener("click",
                function(e:Event):void {
                    Alert.show("The button was clicked.");
                }
            );
        }
        ]]>
    </fx:Script>
    <s:Button id='b1' label="Click Me"/>
</s:Application>
```

Function closures are created any time a function is executed apart from an object or a class. They retain the scope in which they were defined. This creates interesting results when a function is passed as an argument or a return value into a different scope.

For example, the following code creates two functions: `foo()`, which returns a nested function named `rectArea()` that calculates the area of a rectangle, and `bar()`, which calls `foo()` and stores the returned function closure in a variable named `myProduct`. Even though the `bar()` function defines its own local variable `x` (with a value of 2), when the function closure `myProduct()` is called, it retains the variable `x` (with a value of 40) defined in function `foo()`. The `bar()` function therefore returns the product of the numbers in the TextInput controls, rather than 8.

```
<?xml version="1.0"?>
<!-- events/FunctionReturnsFunction.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="foo()">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
        [Bindable]
        private var answer:String;
        private function foo():Function {
            var x:int = int(ti1.text);
            function rectArea(y:int):int { // function closure defined
                return x * y;
            }
            return rectArea;
        }
        private function bar():void {
            var x:int = 2; // ignored
            var y:int = 4; // ignored
            var myProduct:Function = foo();
            answer = myProduct(int(ti2.text)); // function closure called
        }

        ]]>
    </fx:Script>
    <s:Form width="107">
        <s:FormItem label="X">
            <s:TextInput id="ti1" text="10" width="37" textAlign="right"/>
        </s:FormItem>
        <s:FormItem label="Y" width="71">
            <s:TextInput id="ti2" text="20" width="38" textAlign="right"/>
        </s:FormItem>
        <s:Label id="label1" text="{answer}" width="71" textAlign="right"/>
    </s:Form>
    <s:Button id='b1' label="Compute Product" click="bar()"/>

</s:Application>
```

If the listener that you pass to `addEventListener()` method is a nested inner function, you should not pass `true` for the `useWeakReference` argument. For example:

```
addEventListener("anyEvent",
    function(e:Event) { /* My listener function. */ },
    false, 0, true);
```

In this example, passing `true` as the last argument can lead to unexpected results. To Flex, an inner function is actually an object, and can be freed by the garbage collector. If you set the value of the `useWeakReference` argument to `true`, as shown in the previous example, there are no persistent references at all to the inner function. The next time the garbage collector runs, it might free the function, and the function will not be called when the event is triggered.

If there are other references to the inner function (for example, if you saved it in another variable), the garbage collector will not free it.

Regular class-level member functions are not subject to garbage collection; as a result, you can set the value of the `useWeakReference` argument to `true` and they will not be garbage collected.

Removing event handlers

It is a good idea to remove any handlers that will no longer be used. This removes references to objects so that they can be targeted for garbage collection. You can use the `removeEventListener()` method to remove an event handler that you no longer need. All components that can call `addEventListener()` can also call the `removeEventListener()` method. The syntax for the `removeEventListener()` method is as follows:

```
componentInstance.removeEventListener(event_type:String, listener_function:Function,
use_capture:Boolean)
```

For example, consider the following code:

```
myButton.removeEventListener(MouseEvent.CLICK, myClickHandler);
```

The *event_type* and *listener_function* parameters are required. These are the same as the required parameters for the `addEventListener()` method.

The *use_capture* parameter is also identical to the parameter used in the addEventListener() method. Recall that you can listen for events during all event phases by calling addEventListener() twice: once with *use_capture* set to true, and again with it set to false. To remove both event listeners, you must call removeEventListener() twice: once with *use_capture* set to true, and again with it set to false.

You can remove only event listeners that you added with the addEventListener() method in an ActionScript block. You cannot remove an event listener that was defined in the MXML tag, even if it was registered using a call to the addEventListener() method that was made inside a tag attribute.

The following sample application shows what type of handler can be removed and what type cannot:

```
<?xml version="1.0"?>
<!-- events/RemoveEventListenerExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    initialize="createHandler(event)">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
        import mx.controls.Alert;
        private function createHandler(e:Event):void {
            b1.addEventListener(MouseEvent.CLICK, myClickHandler);
        }
        private function removeMyHandlers(e:Event):void {
            /* Remove listener for b1's click event because it was added
            with the addEventListener() method. */
            b1.removeEventListener(MouseEvent.CLICK, myClickHandler);
            /* Does NOT remove the listener for b2's click event because it
            was added inline in an MXML tag. */
            b2.removeEventListener(MouseEvent.CLICK, myClickHandler);
        }
        private function myClickHandler(e:Event):void {
            Alert.show("The button was clicked.");
        }
        ]]>
    </fx:Script>
    <s:Button id="b1" label="Click Me"/>
    <s:Button label="Click Me Too" id="b2" click="myClickHandler(event)"/>
    <s:Button label="Remove Event Listeners" id="b3" click="removeMyHandlers(event)"/>
</s:Application>
```

Creating event handler classes

You can create an external class file and use the methods of this class as event handlers. Objects themselves cannot be event handlers, but methods of an object can be. By defining one class that handles all your event handlers, you can use the same event handling logic across applications, which can make your MXML applications more readable and maintainable.

To create a class that handles events, you usually import the flash.events.Event class. You also usually write an empty constructor. The following ActionScript class file calls the Alert control's show() method whenever it handles an event with the handleAllEvents() method:

```
// events/MyEventHandler.as
package { // Empty package.
    import flash.events.Event;
    import mx.controls.Alert;
    public class MyEventHandler {
        public function MyEventHandler() {
            // Empty constructor.
        }
        public function handleAllEvents(event:Event):void {
            Alert.show("Some event happened.");
        }
    }
}
```

In your MXML file, you declare a new instance of MyEventHandler and use the `addEventListener()` method to register its `handleAllEvents()` method as a handler to the Button control's `click` event, as the following example shows:

```
<?xml version="1.0"?>
<!-- events/CustomHandler.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    initialize="createHandler()">
    <fx:Script>
        <![CDATA[
            private var myListener:MyEventHandler = new MyEventHandler();
            private function createHandler():void {
                b1.addEventListener(MouseEvent.CLICK, myListener.handleAllEvents);
            }
        ]]>
    </fx:Script>
    <s:Button label="Submit" id="b1"/>
</s:Application>
```

The best approach is to define the event handler's method as static. When you make the event handler method static, you are not required to instantiate the class inside your MXML application. The following `createHandler()` function registers the `handleAllEvents()` method as an event handler without instantiating the MyStaticEventHandler class:

```
<?xml version="1.0"?>
<!-- events/CustomHandlerStatic.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    initialize="createHandler()">
    <fx:Script>
        <![CDATA[
            private function createHandler():void {
                b1.addEventListener(MouseEvent.CLICK, MyStaticEventHandler.handleAllEvents);
            }
        ]]>
    </fx:Script>
    <s:Button label="Submit" id="b1"/>
</s:Application>
```

In the class file, you just add the `static` keyword to the method signature:

```
// events/MyStaticEventHandler.as
package { // Empty package.
    import flash.events.Event;
    import mx.controls.Alert;
    public class MyStaticEventHandler {
        public function MyStaticEventHandler() {
            // Empty constructor.
        }
        public static function handleAllEvents(event:Event):void {
            Alert.show("Some event happened.");
        }
    }
}
```

Store your event listener class in a directory in your source path. You can also store your ActionScript class in the same directory as your MXML file, although Adobe does not recommend this.

Defining multiple listeners for a single event

You can define multiple event handler functions for a single event in two ways. When defining events inside MXML tags, you separate each new handler function with a semicolon. The following example adds the `submitForm()` and `debugMessage()` functions as handlers of the `click` event:

```
<?xml version="1.0"?>
<!-- events/MultipleEventHandlersInline.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script><![CDATA[
        [Bindable]
        private var s:String = "";

        private function submitForm(e:Event):void {
            // Handle event here.
            s += "The submitForm() method was called. ";
        }
        private function debugMessage(e:Event):void {
            // Handle event here.
            s += "The debugMessage() method was called. ";
        }
    ]]></fx:Script>

    <s:Button id="b1"
        label="Do Both Actions"
        click='submitForm(event); debugMessage(event);'
    />
    <s:Label id="l1" text="{s}"/>

    <s:Button id="b2" label="Reset" click="s='';"/>

</s:Application>
```

For events added with the addEventListener() method, you can add any number of handlers with additional calls to the addEventListener() method. Each call adds a handler function that you want to register to the specified object. The following example registers the submitForm() and debugMessage() handler functions with b1's click event:

```
<?xml version="1.0"?>
<!-- events/MultipleEventHandlersAS.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="createHandlers(event)">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script><![CDATA[
        [Bindable]
        private var s:String = "";
        public function createHandlers(e:Event):void {
            b1.addEventListener(MouseEvent.CLICK, submitForm);
            b1.addEventListener(MouseEvent.CLICK, debugMessage);
        }
        private function submitForm(e:Event):void {
            // Handle event here.
            s += "The submitForm() method was called. ";

        }
        private function debugMessage(e:Event):void {
            // Handle event here.
            s += "The debugMessage() method was called. ";
        }
    ]]></fx:Script>
    <s:Button id="b1" label="Do Both Actions"/>
    <s:Label id="l1" text="{s}"/>

    <s:Button id="b2" label="Reset" click="s='';"/>
</s:Application>
```

You can mix the methods of adding event handlers to any component; alternatively, you can add handlers inline and with the addEventListener() method. The following example adds a click event handler inline for the Button control, which calls the performAction() method. It then conditionally adds a second click handler to call the logAction() method, depending on the state of the CheckBox control.

```
<?xml version="1.0"?>
<!-- events/ConditionalHandlers.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    initialize="initApp(event)">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import mx.controls.Alert;
            private function initApp(e:Event):void {
               cb1.addEventListener(MouseEvent.CLICK, handleCheckBoxChange);
               b1.addEventListener(MouseEvent.CLICK, logAction);
            }
            private function handleCheckBoxChange(e:Event):void {
               if (cb1.selected) {
                    b1.addEventListener(MouseEvent.CLICK, logAction);
                    ta1.text += "Added log listener." + "\n";
                } else {
                    b1.removeEventListener(MouseEvent.CLICK, logAction);
                    ta1.text += "Removed log listener." + "\n";
                }
            }
            private function performAction(e:Event):void {
                Alert.show("You performed the action.");
            }
            private function logAction(e:Event):void {
                ta1.text += "Action performed: " + e.type + ".\n";
            }
        ]]>
    </fx:Script>
    <s:Button label="Perform Action" id="b1" click="performAction(event)"/>
    <s:CheckBox id="cb1" label="Log?" selected="true"/>
    <s:TextArea id="ta1" height="200" width="300"/>
</s:Application>
```

You can set the order in which event listeners are called by using the `priority` parameter of the `addEventListener()` method. You cannot set a priority for a listener function if you added the event listener using MXML inline. For more information on setting priorities, see “Event priorities” on page 88.

Registering a single listener with multiple components

You can register the same listener function with any number of events of the same component, or events of different components. The following example registers a single listener function, `submitForm()`, with two different buttons:

```
<?xml version="1.0"?>
<!-- events/OneHandlerTwoComponentsInline.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
        import mx.controls.Alert;
        private function submitForm(e:Event):void {
            // Handle event here.
            Alert.show("Current Target: " + e.currentTarget.id);
        }
        ]]>
    </fx:Script>
    <s:Button id="b1"
        label="Click Me"
        click="submitForm(event)"/>
    <s:Button id="b2"
        label="Click Me, Too"
        click="submitForm(event)"/>

</s:Application>
```

When you use the `addEventListener()` method to register a single listener to handle the events of multiple components, you must use a separate call to the `addEventListener()` method for each instance, as the following example shows:

```
<?xml version="1.0"?>
<!-- events/OneHandlerTwoComponentsAS.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="createHandlers(event)">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
        import mx.controls.Alert;
        public function createHandlers(e:Event):void {
            b1.addEventListener(MouseEvent.CLICK, submitForm);
            b2.addEventListener(MouseEvent.CLICK, submitForm);
        }
        private function submitForm(e:Event):void {
            // Handle event here.
            Alert.show("Current Target: " + e.currentTarget.id);
        }
        ]]>
    </fx:Script>
    <s:Button id="b1" label="Click Me"/>
    <s:Button id="b2" label="Click Me, Too"/>
</s:Application>
```

When doing this, you should add logic to the event listener that processes the type of event. The event target (or object that dispatched the event) is added to the Event object for you. No matter what triggered the event, you can conditionalize the event processing based on the `target` or `type` properties of the Event object. Flex adds these two properties to all Event objects.

The following example registers a single listener function (`myEventHandler()`) to the `click` event of a Button control and the `click` event of a CheckBox control. To detect what type of object called the event listener, the listener checks the `className` property of the target in the Event object in a `case` statement.

```
<?xml version="1.0"?>
<!-- events/ConditionalTargetHandler.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp()">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
        import mx.controls.Alert;

        public function initApp():void {
            button1.addEventListener(MouseEvent.CLICK, myEventHandler);
            cb1.addEventListener(MouseEvent.CLICK, myEventHandler);
        }
        public function myEventHandler(event:Event):void {
            switch (event.currentTarget.className) {
                case "Button":
                    // Process Button click.
                    Alert.show("You clicked the Button control.");
                    break;
                case "CheckBox":
                    // Process CheckBox click.
                    Alert.show("You clicked the CheckBox control.");
                    break;
            }
        }
        ]]>
    </fx:Script>
    <s:Button label="Click Me" id="button1"/>
    <s:CheckBox label="Select Me" id="cb1"/>
</s:Application>
```

Passing additional parameters to listener functions

You can pass additional parameters to listener functions depending on how you add the listeners. If you add a listener with the `addEventListener()` method, you cannot pass any additional parameters to the listener function by arbitrarily adding new parameters to the function signature. The default listener function can declare only a single argument, the Event object (or one of its subclasses).

For example, the following code throws an error because the `clickListener()` method expects two arguments:

```
<fx:Script>
    public function addListeners():void {
        b1.addEventListener(MouseEvent.CLICK,clickListener);
    }
    public function clickListener(e:MouseEvent, a:String):void { ... }
</fx:Script>
<mx:Button id="b1"/>
```

Because the second parameter of the `addEventListener()` method is a function, you can define that function and pass the event object plus any additional parameters through to a different handler. The following example creates a new function in the `addEventListener()` method, add two parameters to the new handler's call, and then handles all of the parameters in the `myClickListener()` method.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- events/CustomListenerFunction.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp(event)">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            private var specialParam1:String;
            private var specialParam2:String = "42";
            private function initApp(e:Event):void {
                assignSpecialParam(e);

                /* Change the value of specialParam whenever the user changes it
                   in the TextInput and clicks the button. */
                ti1.addEventListener("focusOut", assignSpecialParam);

                /* Define the pass-through method in the addEventListener() method call.
                   You can add any number of parameters, as long as teh target method's
                   signature agrees. */
                myButton.addEventListener(MouseEvent.CLICK, function (e:MouseEvent):void {
                        myClickListener(e, specialParam1, specialParam2);
                    }
                );
            }

            private function assignSpecialParam(e:Event):void {
                specialParam1 = ti1.text;
            }

            /* This method acts as the event listener, and it has any
             number of parameters that we defined in the addEventListener() call. */
            private function myClickListener(e:MouseEvent, s1:String, s2:String) : void {
                myButton.label = s1 + " " + s2;
            }
        ]]>
    </fx:Script>
    <s:Button id="myButton" label="Click Me"/>
    <s:TextInput id="ti1" text="Enter a custom String here." width="250"/>
</s:Application>
```

Another approach to passing additional parameters to the listener function is to define them in the listener function and then call the final method with those parameters. If you define an event listener inline (inside the MXML tag), you can add any number of parameters as long as the listener function's signature agrees with that number of parameters.

The following example passes a string and the Event object to the `runMove()` method:

```
<?xml version="1.0"?>
<!-- events/MultipleHandlerParametersInline.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
        public function runMove(dir:String, e:Event):void {
            if (dir == "up") {
                moveableButton.y = moveableButton.y - 5;
            } else if (dir == "down") {
                moveableButton.y = moveableButton.y + 5;
            } else if (dir == "left") {
                moveableButton.x = moveableButton.x - 5;
            } else if (dir == "right") {
                moveableButton.x = moveableButton.x + 5;
            }
        }
        ]]>
    </fx:Script>
  <mx:Canvas height="100%" width="100%">
     <s:Button id="moveableButton"
        label="{moveableButton.x.toString()},{moveableButton.y.toString()}"
        x="75"
        y="100"
        width="80"
     />
  </mx:Canvas>
  <s:VGroup horizontalAlign="center">
```

```
     <s:Button id="b1"
        label="Up"
        click='runMove("up",event);'
        width="75"/>
        <s:HGroup horizontalAlign="center">
           <mx:Button id="b2"
            label="Left"
            click='runMove("left",event);'
            width="75"/>
           <s:Button id="b3"
            label="Right"
            click='runMove("right",event);'
            width="75"/>
        </s:HGroup>
     <s:Button id="b4"
        label="Down"
        click='runMove("down",event);'
        width="75"/>
  </s:VGroup>
</s:Application>
```

Manually dispatching events

You can manually dispatch events using a component instance's dispatchEvent() method. All components that extend UIComponent have this method. The method is inherited from the EventDispatcher class, which UIComponent extends.

The syntax for the `dispatchEvent()` method is as follows:

```
objectInstance.dispatchEvent(event:Event):Boolean
```

When dispatching an event, you must create a new Event object. The syntax for the Event object constructor is as follows:

```
Event(event_type:String, bubbles:Boolean, cancelable:Boolean)
```

The *event_type* parameter is the `type` property of the Event object. The *bubbles* and *cancelable* parameters are optional and both default to `false`. For information on bubbling and capturing, see "Event propagation" on page 81.

You can use the `dispatchEvent()` method to dispatch any event you want, not just a custom event. You can dispatch a Button control's `click` event, even though the user did not click a Button control, as in the following example:

```
<?xml version="1.0"?>
<!-- events/DispatchEventExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    initialize="createListener(event);">

    <fx:Script><![CDATA[
        import mx.controls.Alert;
        private function createListener(e:Event):void {
            b1.addEventListener(MouseEvent.MOUSE_OVER, myEventHandler);
            b1.addEventListener(MouseEvent.CLICK, myClickHandler);
        }
        private function myEventHandler(e:Event):void {
      var result:Boolean = b1.dispatchEvent(new MouseEvent(MouseEvent.CLICK, true, false));
        }
        private function myClickHandler(e:Event):void {
           Alert.show("The event dispatched by the MOUSE_OVER was of type '" + e.type + "'.");
        }
    ]]></fx:Script>
    <s:Button id="b1" label="Click Me"/>
</s:Application>
```

You can also manually dispatch an event in an MXML tag. In the following example, moving the mouse pointer over the button triggers the button’s `click` event:

```
<?xml version="1.0"?>
<!-- events/DispatchEventExampleInline.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    initialize="createListener(event);">
    <fx:Script>
        <![CDATA[
        import mx.controls.Alert;
        private function createListener(e:Event):void {
            b1.addEventListener(MouseEvent.CLICK, myClickHandler);
        }
        private function myClickHandler(e:Event):void {
           Alert.show("The event dispatched by the MOUSE_OVER was of type '" + e.type + "'.");
        }
        ]]>
    </fx:Script>
    <s:Button id="b1"
        label="Click Me"
        mouseOver="b1.dispatchEvent(new MouseEvent(MouseEvent.CLICK, true, false));"
    />
</s:Application>
```

Your application is not required to handle the newly dispatched event. If you trigger an event that has no listeners, Flex ignores the event.

You can set properties of the Event object in ActionScript, but you cannot add new properties because the object is not dynamic. The following example intercepts a `click` event. It then creates a new MouseEvent object and dispatches it as a `doubleClick` event. In addition, it sets the value of the `shiftKey` property of the MouseEvent object to `true`, to simulate a Shift-click on the keyboard.

```
<?xml version="1.0"?>
<!-- events/DispatchCustomizedEvent.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="addListeners()">

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script><![CDATA[
        private function customLogEvent(e:MouseEvent):void {
            l1.text = String(e.currentTarget.id);
            l2.text = String(e.type);
            l3.text = String(e.shiftKey);
            // Remove current listener to avoid recursion.
            e.currentTarget.removeEventListener("doubleClick", customLogEvent);
        }
        private function handleEvent(e:MouseEvent):void {
            // Add new handler for custom event about to be dispatched.
            e.currentTarget.addEventListener("doubleClick", customLogEvent);
            // Create new event object.
            var mev:MouseEvent = new MouseEvent("doubleClick");
            // Customize event object.
            mev.shiftKey = true;
            // Dispatch custom event.
            e.currentTarget.dispatchEvent(mev);
        }
        private function addListeners():void {
            b1.addEventListener("click",handleEvent);
            b2.addEventListener("click",handleEvent);
        }
    ]]></fx:Script>
        <s:Button id="b1" label="Click Me (b1)"/>
        <s:Button id="b2" label="Click Me (b2)"/>

        <s:Form>
            <s:FormItem label="Current Target:">
                <s:Label id="l1"/>
            </s:FormItem>
            <s:FormItem label="Event Type:">
                <s:Label id="l2"/>
            </s:FormItem>
            <s:FormItem label="Shift Key Pressed:">
                <s:Label id="l3"/>
            </s:FormItem>
        </s:Form>
</s:Application>
```

If you want to add custom properties to an Event object, you must extend the Event object and define the new properties in your own custom class. You can then manually dispatch your custom events with the `dispatchEvent()` method, as you would any event.

If you create a custom ActionScript class that dispatches its own events but does not extend UIComponent, you can extend the flash.events.EventDispatcher class to get access to the `addEventListener()`, `removeEventListener()`, and `dispatchEvent()` methods.

To make your code more efficient, you can check to see if the intended target of a dispatched event is listening for the event. If it is not, then there is no reason to dispatch the event. This is especially true if the event bubbles because that means many calls will be made by the system while it searches for a target. You can check by using the `hasEventListner()` and `willTrigger()` methods. Peter deHaan has a blog post on using these methods.

Event propagation

When events are triggered, there are three phases in which Flex checks whether there are event listeners. These phases occur in the following order:

- Capturing
- Targeting
- Bubbling

During each of these phases, the nodes have a chance to react to the event. For example, assume the user clicks a Button control that is inside a VBox container. During the capturing phase, Flex checks the Application object and the VBox for listeners to handle the event. Flex then triggers the Button's listeners in the target phase. In the bubbling phase, the VBox and then the Application are again given a chance to handle the event but now in the reverse order from the order in which they were checked in the capturing phase.

In ActionScript 3.0, you can register event listeners on a target node and on any node along the event flow. Not all events, however, participate in all three phases of the event flow. Some types of events are dispatched directly to the target node and participate in neither the capturing nor the bubbling phases. All events can be captured unless they are dispatched from the top node.

Other events may target objects that are not on the display list, such as events dispatched to an instance of the Socket class. These event objects flow directly to the target node, without participating in the capturing or bubbling phases. You can also cancel an event as it flows through the event model so that even though it was supposed to continue to the other phases, you stopped it from doing so. You can do this only if the `cancelable` property is set to `true`.

Capturing and bubbling happen as the Event object moves from node to node in the display list: parent-to-child for capturing and child-to-parent for bubbling. This process has nothing to do with the inheritance hierarchy. Only DisplayObject objects (visual objects such as containers and controls) can have a capturing phase and a bubbling phase in addition to the targeting phase.

Mouse events and keyboard events are among those that bubble. Any event can be captured, but no DisplayObject objects listen during the capturing phase unless you explicitly instruct them to do so. In other words, capturing is disabled by default.

When a faceless event dispatcher, such as a Validator, dispatches an event, there is only a targeting phase, because there is no visual display list for the Event object to capture or bubble through.

About the target and currentTarget properties

Every Event object has a `target` and a `currentTarget` property that help you to keep track of where it is in the process of propagation. The `target` property refers to the dispatcher of the event. The `currentTarget` property refers to the current node that is being examined for event listeners.

When you handle a mouse event such as `MouseEvent.CLICK` by writing a listener on some component, the `event.target` property does not necessarily refer to that component; it is often a subcomponent, such as the Button control's UITextField, that defines the label.

When Flash Player or Adobe® AIR™ dispatches an event, it dispatches the event from the frontmost object under the mouse. Because children are in front of parents, that means the player or AIR might dispatch the event from an internal subcomponent, such as the UITextField of a Button.

The `event.target` property is set to the object that dispatched the event (in this case, UITextField), not the object that is being listened to (in most cases, you have a Button control listen for a `click` event).

MouseEvent events bubble up the parent chain, and can be handled on any ancestor. As the event bubbles, the value of the `event.target` property stays the same (UITextField), but the value of the `event.currentTarget` property is set at each level to be the ancestor that is handling the event. Eventually, the `currentTarget` will be Button, at which time the Button control's event listener will handle the event. For this reason, you should use the `event.currentTarget` property rather than the `event.target` property; for example:

```
<mx:Button label="OK" click="trace(event.currentTarget.label)"/>
```

In this case, in the Button event's click event listener, the `event.currentTarget` property always refers to the Button, while `event.target` might be either the Button or its UITextField, depending on where on the Button control the user clicked.

Capturing phase

In the capturing phase, Flex examines an event target's ancestors in the display list to see which ones are registered as a listener for the event. Flex starts with the root ancestor and continues down the display list to the direct ancestor of the target. In most cases, the root ancestors are the Stage, then the SystemManager, and then the Application object.

For example, if you have an application with a Panel container that contains a TitleWindow container, which in turn contains a Button control, the structure appears as follows:

```
Application
    Panel
        TitleWindow
            Button
```

If your listener is on the `click` event of the Button control, the following steps occur during the capturing phase if capturing is enabled:

1 Check the Application container for click event listeners.

2 Check the Panel container for click event listeners.

3 Check the TitleWindow container for click event listeners.

During the capturing phase, Flex changes the value of the `currentTarget` property on the Event object to match the current node whose listener is being called. The `target` property continues to refer to the dispatcher of the event.

By default, no container listens during the capturing phase. The default value of the *use_capture* argument is `false`. The only way to add a listener during this phase is to pass `true` for the *use_capture* argument when calling the `addEventListener()` method, as the following example shows:

```
myPanel.addEventListener(MouseEvent.MOUSE_DOWN, clickHandler, true);
```

If you add an event listener inline with MXML, Flex sets this argument to `false`; you cannot override it.

If you set the *use_capture* argument to true—in other words, if an event is propagated through the capturing phase—the event can still bubble, but capture phase listeners will not react to it. If you want your event to traverse both the capturing and bubbling phases, you must call addEventListener() twice: once with *use_capture* set to true, and then again with *use_capture* set to false.

The capturing phase is very rarely used, and it can also be computationally intensive. By contrast, bubbling is much more common.

Targeting phase

In the targeting phase, Flex invokes the event dispatcher's listeners. No other nodes on the display list are examined for event listeners. The values of the currentTarget and the target properties on the Event object during the targeting phase are the same.

Bubbling phase

In the bubbling phase, Flex examines an event's ancestors for event listeners. Flex starts with the dispatcher's immediate ancestor and continues up the display list to the root ancestor. This is the reverse of the capturing phase.

For example, if you have an application with a Panel container that contains a TitleWindow container that contains a Button control, the structure appears as follows:

```
Application
    Panel
        TitleWindow
            Button
```

If your listener is on the click event of the Button control, the following steps occur during the bubble phase if bubbling is enabled:

1 Check the TitleWindow container for click event listeners.

2 Check the Panel container for click event listeners.

3 Check the Application container for click event listeners.

An event only bubbles if its bubbles property is set to true. Mouse events and keyboard events are among those that bubble; it is less common for higher-level events that are dispatched by Flex to bubble. Events that can be bubbled include change, click, doubleClick, keyDown, keyUp, mouseDown, and mouseUp. To determine whether an event bubbles, see the event's entry in the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

During the bubbling phase, Flex changes the value of the currentTarget property on the Event object to match the current node whose listener is being called. The target property continues to refer to the dispatcher of the event.

When Flex invokes an event listener, the Event object might have actually been dispatched by an object deeper in the display list. The object that originally dispatched the event is the target. The object that the event is currently bubbling through is the currentTarget. So, you should generally use the currentTarget property instead of the target property when referring to the current object in your event listeners.

If you set the useCapture property to true—in other words, if an event is propagated through the capturing phase—then it does not bubble, regardless of its default bubbling behavior. If you want your event to traverse both the capturing and bubbling phases, you must call addEventListener() twice: once with useCapture set to true, and then again with useCapture set to false.

An event only bubbles up the parent's chain of ancestors in the display list. Siblings, such as two Button controls inside the same container, do not intercept each other's events.

Detecting the event phase

You can determine what phase you are in by using the Event object's `eventPhase` property. This property contains an integer that represents one of the following constants:

- 1 — Capturing phase (`CAPTURING_PHASE`)
- 2 — Targeting phase (`AT_TARGET`)
- 3 — Bubbling phase (`BUBBLING_PHASE`)

The following example displays the current phase and information about the current target:

```
<?xml version="1.0"?>
<!-- events/DisplayCurrentTargetInfo.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script><![CDATA[
        import mx.controls.Alert;
        private function showInfo(e:MouseEvent):void {
            Alert.show("Phase: " + e.eventPhase + "\n" +
                "ID: " + e.currentTarget.id + "\n" +
                "Label: " + e.currentTarget.label + "\n" +
                "Font Size: " + e.currentTarget.getStyle("fontSize"), "Current Target Info");
        }
    ]]></fx:Script>
    <s:Button id="b1" label="Click Me" click="showInfo(event)"/>
</s:Application>
```

Stopping propagation

During any phase, you can stop the traversal of the display list by calling one of the following methods on the Event object:

- stopPropagation()
- stopImmediatePropagation()

You can call either the event's `stopPropagation()` method or the `stopImmediatePropagation()` method to prevent an Event object from continuing on its way through the event flow. The two methods are nearly identical and differ only in whether the current node's remaining event listeners are allowed to execute. The `stopPropagation()` method prevents the Event object from moving on to the next node, but only after any other event listeners on the current node are allowed to execute.

The `stopImmediatePropagation()` method also prevents the Event objects from moving on to the next node, but it does not allow any other event listeners on the current node to execute.

The following example creates a TitleWindow container inside a Panel container. Both containers are registered to listen for a `mouseDown` event. As a result, if you click on the TitleWindow container, the `showAlert()` method is called twice unless you add a call to the `stopImmediatePropagation()` method, as the following example shows:

```
<?xml version="1.0"?>
<!-- events/StoppingPropagation.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    initialize="init(event);">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
        import mx.controls.Alert;
        import flash.events.MouseEvent;
        import flash.events.Event;
        public function init(e:Event):void {
            p1.addEventListener(MouseEvent.MOUSE_DOWN, showAlert);
            tw1.addEventListener(MouseEvent.MOUSE_DOWN, showAlert);
            tw1.addEventListener(Event.CLOSE, closeWindow);
            p2.addEventListener(MouseEvent.MOUSE_DOWN, showAlertWithoutStoppingPropagation);
            tw2.addEventListener(MouseEvent.MOUSE_DOWN, showAlertWithoutStoppingPropagation);
            tw2.addEventListener(Event.CLOSE, closeWindow);
        }
        public function showAlert(e:Event):void {
            Alert.show("Alert!\n" + "Current Target: " + e.currentTarget + "\n" +
                "Phase: " + e.eventPhase);
            e.stopImmediatePropagation();
        }
        public function showAlertWithoutStoppingPropagation(e:Event):void {
            Alert.show("Alert!\n" + "Current Target: " + e.currentTarget + "\n" +
                "Phase: " + e.eventPhase);
        }
        public function closeWindow(e:Event):void {
            p1.removeChild(tw1);
        }
        ]]>
    </fx:Script>
    <s:Panel id="p1" title="Stops Propagation">
```

```
        <mx:TitleWindow id="tw1"
            width="300"
            height="100"
            showCloseButton="true"
            title="Title Window 1">
            <s:Button label="Click Me"/>
            <s:TextArea id="ta1"/>
        </mx:TitleWindow>
    </s:Panel>
    <s:Panel id="p2" title="Does Not Stop Propagation">
        <mx:TitleWindow id="tw2"
            width="300"
            height="100"
            showCloseButton="true"
            title="Title Window 2">
            <s:Button label="Click Me"/>
            <s:TextArea id="ta2"/>
        </mx:TitleWindow>
    </s:Panel>
</s:Application>
```

***Note:** A call to either the `Event.stopPropogation()` or the `Event.stopImmediatePropogation()` methods does not prevent default behavior from occurring.*

Event examples

In the following example, the parent container’s click handler disables the target control after the target handles the event. It shows that you can reuse the logic of a single listener (click the HGroup container) for multiple events (all the clicks).

```
<?xml version="1.0"?>
<!-- events/NestedHandlers.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script><![CDATA[
        public function disableControl(event:MouseEvent):void {
            // Use this same logic for all events.
            event.currentTarget.enabled = false;
        }
        public function doSomething(event:MouseEvent):void {
            b1.label = "clicked";
            ta1.text += "Something happened.";
        }
        public function doSomethingElse(event:MouseEvent):void {
            b2.label = "clicked";
            ta1.text += "Something happened again.";
        }
    ]]></fx:Script>
    <s:HGroup id="hb1" height="200" click="disableControl(event)">
        <s:Button id='b1' label="Click Me" click="doSomething(event)"/>
        <s:Button id='b2' label="Click Me" click="doSomethingElse(event)"/>
        <s:TextArea id="ta1"/>
    </s:HGroup>
    <s:Button id="resetButton"
        label="Reset"
        click="hb1.enabled=true;b1.enabled=true;b2.enabled=true;b1.label='Click 
Me';b2.label='Click Me';"/>
</s:Application>
```

By having a single listener on a parent control instead of many listeners (one on each child control), you can reduce your code size and make your applications more efficient. Reducing the number of calls to the `addEventListener()` method potentially reduces application startup time and memory usage.

The following example registers an event handler for the Panel container, rather than registering a listener for each link. All children of the Panel container inherit this event handler. Since Flex invokes the handler on a bubbled event, you use the `target` property rather than the `currentTarget` property. In this handler, the `currentTarget` property would refer to the Panel control, whereas the `target` property refers to the LinkButton control, which has the label that you want.

```
<?xml version="1.0"?>
<!-- events/SingleRegisterHandler.mxml -->
<s:Application     xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="createLinkHandler();">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
        private function linkHandler(event:MouseEvent):void {
            try {
                var url:URLRequest = new URLRequest("http://finance.google.com/finance?q=" +
                event.target.label);
                navigateToURL(url);
            } catch (e:Error) {
                /**
                *  Do nothing; just want to catch the error that occurs when a user clicks on
                 *  the Panel and not one of the LinkButtons.
                 **/
            }
        }
        private function createLinkHandler():void {
            p1.addEventListener(MouseEvent.CLICK,linkHandler);
        }
        ]]>
    </fx:Script>

    <s:Panel id="p1" title="Click on a stock ticker symbol">
        <s:layout>
            <s:HorizontalLayout/>
        </s:layout>
        <mx:LinkButton label="ADBE"/>
        <mx:LinkButton label="GE"/>
        <mx:LinkButton label="IBM"/>
        <mx:LinkButton label="INTC"/>
    </s:Panel>
</s:Application>
```

Event priorities

You can register any number of event listeners with a single event. Flex registers event listeners in the order in which the addEventListener() methods are called. Flex then typically calls the listener functions when the event occurs in the order in which they were registered. However, if you register some event listeners inline and some with the `addEventListener()` method, the order in which the listeners are called for a single event can be unpredictable.

You can change the order in which Flex calls event listeners by using the *priority* parameter of the `addEventListener()` method. It is the fourth argument of the `addEventListener()` method.

Flex calls event listeners in priority order, from highest to lowest. The highest priority event is called first. In the following example, Flex calls the `verifyInputData()` method before the `saveInputData()` function. The `verifyInputData()` method has the highest priority. The last method to be called is `returnResult()` because the value of its `priority` parameter is lowest.

```
<?xml version="1.0"?>
<!-- events/ShowEventPriorities.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp()">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
        private function returnResult(e:Event):void {
            ta1.text += "returnResult() method called last (priority 1)\n";
        }
        private function verifyInputData(e:Event):void {
            ta1.text += "verifyInputData() method called first (priority 3)\n";
        }
        private function saveInputData(e:Event):void {
            ta1.text += "saveInputData() method called second (priority 2)\n";
        }
        private function initApp():void {
            b1.addEventListener(MouseEvent.CLICK, returnResult, false, 1);
            b1.addEventListener(MouseEvent.CLICK, saveInputData, false, 2);
            b1.addEventListener(MouseEvent.CLICK, verifyInputData, false, 3);
        }
        ]]>
    </fx:Script>
    <s:Button id="b1" label="Click Me"/>

    <s:TextArea id="ta1" height="200" width="300"/>

</s:Application>
```

You can set the event priority to any valid integer, positive or negative. The default value is 0. If multiple listeners have the same priority, Flex typically calls them in the order in which they were registered, although the order is not guaranteed.

If you want to change the priority of an event listener once the event listener has already been defined, you must remove the listener by calling the `removeEventListener()` method. You add the event again with the new priority.

The *priority* parameter of the `addEventListener()` method is not an official part of the DOM Level 3 events model. ActionScript 3.0 provides it so that programmers can be more flexible when organizing their event listeners.

If your listeners rely on a specific order of execution, you can call one listener function from within another, or dispatch a new event from within the first event listener. For more information on manually dispatching events, see "Manually dispatching events" on page 78.

Using event subclasses

Depending on the event type, the Event object can have a wide range of properties. These properties are based on those defined in the W3C specification http://www.w3.org/TR/DOM-Level-3-Events/), but Flex does not implement all of these.

When you declare an Event object in a listener function, you can declare it of type Event, or you can specify a subclass of the Event object. In the following example, you specify the event object as type MouseEvent:

```
public function performAction(e:MouseEvent):void {
    ...
}
```

Most controls generate an object that is of a specific event type; for example, a mouse click generates an object of type MouseEvent. By specifying a more specific event type, you can access specific properties without having to cast the Event object to something else. In addition, some subclasses of the Event object have methods that are unique to them. For example, the LogEvent has a `getLevelString()` method, which returns the log level as a String. The generic Event object does not have this method.

An event object that you define at run time can be a subclass of the compile-time type. You can access the event-specific properties inside an event listener even if you did not declare the specific event type, as long as you cast the Event object to a specific type. In the following example, the function defines the object type as Event. However, inside the function, in order to access the `localX` and `localY` properties, which are specific to the MouseEvent class, you must cast the Event object to be of type MouseEvent.

```
<?xml version="1.0"?>
<!-- events/AccessEventSpecificProperties.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    initialize="addListeners()">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import mx.controls.Alert;
            private function customLogEvent(e:Event):void {
                var a:MouseEvent = MouseEvent(e);
                Alert.show("Y: " + a.localY + "\n" + "X: " + a.localX);
            }
            private function addListeners():void {
                b1.addEventListener(MouseEvent.CLICK, customLogEvent);
            }
        ]]>
    </fx:Script>
    <s:Button id="b1" label="Click Me"/>
</s:Application>
```

If you declare the Event object as a specific type, you are not required to cast that object in the handler, as the following example shows:

```
private function customLogEvent(e:MouseEvent):void { ... }
```

In the previous example, you can also cast the Event object for only the property access, using the syntax shown in the following example:

```
<?xml version="1.0"?>
<!-- events/SinglePropertyAccess.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    initialize="addListeners()">
    <fx:Script>
        <![CDATA[
        import mx.controls.Alert;
        private function customLogEvent(e:Event):void {
            Alert.show("Y: " + MouseEvent(e).localY + "\n" + "X: " + MouseEvent(e).localX);
        }
        private function addListeners():void {
            b1.addEventListener(MouseEvent.CLICK, customLogEvent);
        }
        ]]>
    </fx:Script>

    <s:Button id="b1" label="Click Me"/>
</s:Application>
```

This approach can use less memory and system resources, but it is best to declare the event’s type as specifically as possible.

Each of the Event object’s subclasses provides additional properties and event types that are unique to that category of events. The MouseEvent class defines several event types related to that input device, including the `CLICK`, `DOUBLE_CLICK`, `MOUSE_DOWN`, and `MOUSE_UP` event types.

For a list of types for each Event subclass, see the subclass’s entry in *ActionScript 3.0 Reference for the Adobe Flash Platform*.

About keyboard events

It is common for applications to respond to a key or series of keys and perform some action—for example, Control+q to quit the application. While Flash Player supports all the basic functionality of key combinations from the underlying operating system, it also lets you override or trap any key or combination of keys to perform a custom action.

Handling keyboard events

In some cases, you want to trap keys globally, meaning no matter where the user is in the application, their keystrokes are recognized by the application and the action is performed. Flex recognizes global keyboard events whether the user is hovering over a button or the focus is inside a TextInput control.

A common way to handle global key presses is to create a listener for the `KeyboardEvent.KEY_DOWN` or `KeyboardEvent.KEY_UP` event on the application. Listeners on the application container are triggered every time a key is pressed, regardless of where the focus is (as long as the focus is in the application on not in the browser controls or outside of the browser). Inside the handler, you can examine the key code or the character code using the `charCode` and `keyCode` properties of the KeyboardEvent class, as the following example shows:

```
<?xml version="1.0"?>
<!-- events/TrapAllKeys.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp();">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
        import mx.core.FlexGlobals;

        private function initApp():void {
          FlexGlobals.topLevelApplication.addEventListener(KeyboardEvent.KEY_UP, keyHandler);
        }
        private function keyHandler(event:KeyboardEvent):void {
            t1.text = event.keyCode + "/" + event.charCode;
        }
        ]]>
    </fx:Script>
    <s:TextInput id="myTextInput"/>

    <s:Label id="t1"/>
</s:Application>
```

To run this example, you must first set the focus to something inside the application, such as the TextInput control, by clicking on it.

Because any class that extends UIComponent dispatches the `keyUp` and `keyDown` events, you can also trap keys pressed when the focus is on an individual component.

Understanding the keyCode and charCode properties

You can access the `keyCode` and `charCode` properties to determine what key was pressed and trigger other actions as a result. The `keyCode` property is a numeric value that corresponds to the value of a key on the keyboard. The `charCode` property is the numeric value of that key in the current character set (the default character set is UTF-8, which supports ASCII). The primary difference between the key code and character values is that a key code value represents a particular key on the keyboard (the 1 on a keypad is different than the 1 in the top row, but the 1 on the keyboard and the key that generates the ! are the same key), and the character value represents a particular character (the *R* and *r* characters are different).

The mappings between keys and key codes are device and operating system dependent. ASCII values, on the other hand, are available in the ActionScript documentation.

The following example shows the character and key code values for the keys you press. When you run this example, you must be sure to put the focus in the application before beginning.

```
<?xml version="1.0"?>
<!-- charts/ShowCharAndKeyCodes.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="init()"
    width="650">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <fx:Script><![CDATA[
     import flash.events.KeyboardEvent;
     private function init():void {
        ti1.setFocus();
        this.addEventListener(KeyboardEvent.KEY_DOWN, trapKeys);
     }

     private function trapKeys(e:KeyboardEvent):void {
        ta1.text = String(e.toString());

        l1.text = numToChar(e.charCode) + " (" + String(e.charCode) + ")";
        l2.text = numToChar(e.keyCode) + " (" + String(e.keyCode) + ")";
     }

    private function numToChar(num:int):String {
        if (num > 47 && num < 58) {
            var strNums:String = "0123456789";
            return strNums.charAt(num - 48);
        } else if (num > 64 && num < 91) {
            var strCaps:String = "ABCDEFGHIJKLMNOPQRSTUVWXYZ";
            return strCaps.charAt(num - 65);
        } else if (num > 96 && num < 123) {
            var strLow:String = "abcdefghijklmnopqrstuvwxyz";
            return strLow.charAt(num - 97);
        } else {
            return num.toString();
        }
    }
  ]]></fx:Script>
  <s:TextInput width="50%" id="ti1"/>

  <s:Panel id="mainPanel" width="100%" height="100%">
     <s:Form>
        <s:FormItem label="Char (Code)">
           <s:Label id="l1"/>
        </s:FormItem>
        <s:FormItem label="Key (Code)">
           <s:Label id="l2"/>
        </s:FormItem>
        <s:FormItem label="Key Event">
           <s:TextArea id="ta1" width="500" height="200" editable="false"/>
        </s:FormItem>
     </s:Form>
  </s:Panel>

</s:Application>
```

You can listen for specific keys or combinations of keys by using a conditional operator in the KeyboardEvent handler. The following example listens for the combination of the Shift key plus the q key and prompts the user to close the browser window if they press those keys at the same time:

```
<?xml version="1.0"?>
<!-- events/TrapQKey.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp();">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
        import mx.core.FlexGlobals;

        private function initApp():void {
          FlexGlobals.topLevelApplication.addEventListener(KeyboardEvent.KEY_UP,keyHandler);

            // Set the focus somewhere inside the application.
            ta1.setFocus();
        }
        //This function quits the application if the user presses Shift+Q.
        private function keyHandler(event:KeyboardEvent):void {
            var bShiftPressed:Boolean = event.shiftKey;
            if (bShiftPressed) {
                var curKeyCode:int = event.keyCode;
                if (curKeyCode == 81) { // 81 is the keycode value for the Q key
                    /* Quit the application by closing the browser using JavaScript.
                       This may not work in all browsers. */
                    var url:URLRequest = new
                    URLRequest("javascript:window.close()");
                    navigateToURL(url,"_self");
                }
            }
        }
        ]]>
    </fx:Script>
    <s:TextArea id="ta1" text="Focus here so that Shift+Q will quit the browser."/>
</s:Application>
```

Notice that this application must have focus when you run it in a browser so that the application can capture keyboard events.

Understanding KeyboardEvent precedence

If you define `keyUp` or `keyDown` event listeners for both a control and its parent, you will notice that the keyboard event is dispatched for each component because the event bubbles. The only difference is that the `currentTarget` property of the KeyboardEvent object is changed.

In the following example, the application, the `my_vgroup` container, and the `my_textinput` control all dispatch `keyUp` events to the `keyHandler()` event listener function:

```
<?xml version="1.0"?>
<!-- events/KeyboardEventPrecedence.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp();"
    width="650">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script><![CDATA[
        import mx.core.FlexGlobals;

        private function initApp():void {
          FlexGlobals.topLevelApplication.addEventListener(KeyboardEvent.KEY_UP, keyHandler);
            my_vgroup.addEventListener(KeyboardEvent.KEY_UP, keyHandler);
            my_textinput.addEventListener(KeyboardEvent.KEY_UP, keyHandler);
            // Set the focus somewhere inside the application.
            my_textinput.setFocus();
        }
        private function keyHandler(event:KeyboardEvent):void {
            ta1.text += event.target + "(" + event.currentTarget + "): " +
                event.keyCode + "/" + event.charCode + "\n";
        }
    ]]></fx:Script>

    <s:VGroup id="my_vgroup">
        <s:TextInput id="my_textinput"/>
    </s:VGroup>
    <s:TextArea id="ta1" height="300" width="550"/>
</s:Application>
```

When you examine the output, you will notice that the `target` property of the KeyboardEvent object stays the same because it refers to the original dispatcher of the event (in this case, my_textinput). But the `currentTarget` property changes depending on what the current node is during the bubbling (in this case, it changes from my_textinput to my_vgroup to the application itself).

The order of calls to the event listener is determined by the object hierarchy and not the order in which the `addEventListener()` methods were called. Child controls dispatch events before their parents. In this example, for each key pressed, the TextInput control dispatches the event first, the VGroup container next, and finally the application.

When handling a key or key combination that the underlying operating system or browser recognizes, the operating system or browser generally processes the event first. For example, in Microsoft Internet Explorer, pressing Control+w closes the browser window. If you trap that combination in your application, Internet Explorer users never know it, because the browser closes before the ActiveX Flash Player has a chance to react to the event.

Handling keyboard-related mouse events

The MouseEvent class and all MouseEvent subclasses (such as ChartItemEvent, DragEvent, and LegendMouseEvent) have the following properties that you can use to determine if a specific key was held down when the event occurred:

Property	Description
`altKey`	Is set to `true` if the Alt key was held down when the user pressed the mouse button; otherwise, `false`.
`ctrlKey`	Is set to `true` if the Control key was held down when the user pressed mouse button; otherwise, `false`.
`shiftKey`	Is set to `true` if the Shift key was held down when the user pressed mouse button; otherwise, `false`.

The following example deletes Button controls, based on whether the user holds down the Shift key while pressing the mouse button:

```
<?xml version="1.0"?>
<!-- events/DetectingShiftClicks.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp();">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script><![CDATA[
        import spark.components.Button;
        private function initApp():void {
            var b1:Button = new Button();
            b1.label = "Button 1";
            var b2:Button = new Button();
            b2.label = "Button 2";
            b1.addEventListener(MouseEvent.CLICK, removeButtons);
            b2.addEventListener(MouseEvent.CLICK, removeButtons);
            vg1.addElement(b1);
            vg1.addElement(b2);
        }
        private function removeButtons(event:MouseEvent):void {
            if (event.shiftKey) {
                vg1.removeElement(Button(event.currentTarget));
            } else {
                event.currentTarget.toolTip = "Shift+click to remove this button.";
            }
        }
    ]]></fx:Script>
    <s:VGroup id="vg1"/>

    <s:Button id="resetButton" label="Reset" click="initApp();"/>
</s:Application>
```

SDK configuration

Use the configuration files included with Adobe® Flex® SDK to configure the compilers and other aspects of Flex.

About configuration files

Root variables

For Flex SDK, the *flex_install_dir* variable is the top-level directory where you installed the SDK. Under this directory are the bin, frameworks, lib, and samples directories. The *flex_app_root* directory is the top level location for many files.

Configuration files layout

The layout of the configuration files for Flex SDK is simple. It includes a jvm.config file, fdb command-line debugger shell script, and the mxmlc and compc command-line compiler shell scripts for configuring the JVM that the compiler uses. It also includes the flex-config.xml file that sets the compiler options, as well as executable files for fdb, mxmlc, and compc.

The layout of the configuration files for Flex SDK is as follows:

```
sdk_install_dir/
        bin/jvm.config
        bin/mxmlc
        bin/mxmlc.exe
        bin/compc
        bin/compc.exe
        bin/fdb
        bin/fdb.exe
        frameworks/flex-config.xml
```

Flex SDK configuration

Flex SDK includes the mxmlc and compc command-line compilers. You use mxmlc to compile applications from MXML, ActionScript, and other source files. You use the compc compiler to compile component libraries, Runtime Shared Libraries (RSLs), and theme files.

The compilers are located in the *sdk_install_dir*/bin directory. You can configure the compiler options with the flex-config.xml file or command line options.

The compilers use the Java JRE. As a result, you can also configure settings such as memory allocation and source path with the JVM arguments.

***Note:** You must use a 32-bit version of the JDK, version 1.5 or later. The command line compilers do not work with a 64-bit JDK.*

Command-line compiler configuration

The flex-config.xml file defines the default compiler options for the compc and mxmlc command-line compilers. You can use this file to set options such as debugging, SWF file metadata, and themes to apply to your application. For a complete list of compiler options, see “Using mxmlc, the application compiler” on page 2174 and “Using compc, the component compiler” on page 2194.

The flex-config.xml file is located in the *sdk_install_dir*/frameworks directory. If you change the location of this file relative to the location of the command-line compilers, you can use the `load-config` compiler option to point to its new location.

You can also use a local configuration file that overrides the compiler options of the flex-config.xml file. You give this local configuration file the same name as the MXML file, plus "-config.xml" and store it in the same directory. For example, MyApp-config.xml. When you compile your MXML file, the compiler looks for a local configuration file first, then the flex-config.xml file.

For more information on compiler configuration files, see "About configuration files" on page 2171.

JVM configuration

The Flex compilers use the Java JRE. Configuring the JVM can result in faster and more efficient compilations. Without a JVM, you cannot use the mxmlc and compc command-line compilers. You can configure JVM settings such as the Java source path, Java library path, and memory settings.

You must use JDK 1.5 or later with the command-line compilers. These compilers are 32-bit executables and cannot launch 64-bit processes. As a result, they require a 32-bit version of Java to run. If you have both a 32-bit and 64-bit JDK installed, you can use several techniques to target the 32-bit version for compilation, including:

- Using the `JAVA_HOME` environment variable to point to the 32-bit version of the JDK when you compile with mxmlc or compc
- Modifying the Flex SDK's jvm.config file to point to the 32-bit version of the JDK
- Using batch files that point to the 32-bit version of the JDK to launch the compilers

On Windows, you use the compc.exe and mxmlc.exe executable files in the bin directory to compile Flex applications and component libraries. You use the fdb.exe executable file in the bin directory to debug applications. The executable files use the jvm.config file to set JVM arguments. The jvm.config file is in the same directory as the executable files. If you move it or the executable files to another directory, they use their default settings and not the settings defined in the jvm.config file.

The fdb, compc, and mxmlc shell scripts (for UNIX, Linux, or Windows systems running a UNIX-shell emulator such as Cygwin) do not take a configuration file. You set the JVM arguments inside the shell script file.

The jvm.config file is used by the Java process opened by the mxmlc and compc command-line executable files. The file is located in *sdk_install_dir*/bin.

Changing the JVM heap size

The most common JVM configuration is to set the size of the Java heap. The Java heap is the amount of memory reserved for the JVM. The actual size of the heap during run time varies as classes are loaded and unloaded. If the heap requires more memory than the maximum amount allocated, performance will suffer as the JVM performs garbage collection to maintain enough free memory for the applications to run.

You can set the initial heap size (or minimum) and the maximum heap size on most JVMs. By providing a larger heap size, you give the JVM more memory with which to defer garbage collection. However, you must not assign all of the system's memory to the Java heap so that other processes can run optimally.

To set the initial heap size on the Sun HotSpot JVM, change the value of the `Xms` property. To change the maximum heap size, change the value of the `Xmx` property. The following example sets the initial heap size to 256M and the maximum heap size to 512M:

```
java.args=-Xms256m -Xmx512m -Dsun.io.useCanonCaches=false
```

In addition to increasing your JVM's heap size, you can tune the JVM in other ways. Some JVMs provide more granular control over garbage collecting, threading, and logging. For more information, consult your JVM documentation or view the options on the command line. If you are using the Sun HotSpot JVM, for example, you can enter `java -X` or `java -D` on the command line to see a list of configuration options.

In many cases, you can also use a different JVM. Benchmark your Flex application and the application server on several different JVMs. Choose the JVM that provides you with the best performance.

Setting the `useCanonCaches` argument to `false` is required to support Windows file names.

Flash Player configuration

You can use the standard version or the debugger version of Adobe® Flash® Player as clients for your Flex applications. The debugger version of Flash Player can log output from the `trace()` global method as well as data services messages and custom log events.

You enable and disable logging and configure the location of the output file in the mm.cfg file. For more information on locating and editing the mm.cfg file, see "Editing the mm.cfg file" on page 2224.

You can configure the standard version and the debugger version of Flash Player to use auto-update and other settings by using the mms.cfg file. This file is in the same directory as the mm.cfg file. For more information on auto-update, see the Flash Player documentation.

Chapter 3: Application architecture

Application development phases

Design phase

In the design phase, you make basic decisions about how to write code for reusability, how your application interacts with its environment, how your application accesses application resources, and many other decisions. In the design phase, also define your development and deployment environments, including the directory structure of your application.

Although these design decisions specify how your application interacts with its environment, you also have architectural issues to decide. For example, you might choose to develop your application based on a particular design pattern, such as Model-View-Controller (MVC).

About design patterns

One common starting point of the design phase is to identify one or more design patterns relevant for your application. A design pattern describes a solution to a common programming problem or scenario. Although the design pattern might give you insight into how to approach an application design, it does not necessarily define how to write code for that solution.

Many types of design patterns have been catalogued and documented. For example, the Functional design pattern specifies that each module of your application performs a single action, with little or no side effects for the other modules in your application. The design pattern does not specify what a module is, commonly though it corresponds to a class or method.

About MVC

The goal of the Model-View-Controller (MVC) architecture is that by creating components with a well-defined and limited scope in your application, you increase the reusability of the components and improve the maintainability of the overall system. Using the MVC architecture, you can partition your system into three categories of components:

Model components Encapsulates data and behaviors related to the data processed by the application. The model might represent an address, the contents of a shopping cart, or the description of a product.

View components Defines your application's user interface, and the user's view of application data. The view might contain a form for entering an address, a DataGrid control for showing the contents of a shopping cart, or an image of a product.

Controller components Handles data interconnectivity in your application. The Controller provides application management and the business logic of the application. The Controller does not necessarily have any knowledge of the View or the Model.

For example, with the MVC design, you could implement a data-entry form that has three distinct pieces:

- The model consists of XML data files or the remote data service calls to hold the form data.
- The view is the presentation of any data and display of all user interface elements.
- The controller contains logic that manipulates the model and sends the model to the view.

The promise of the MVC architecture is that by creating components with a well-defined and limited scope, you increase the reusability of these components and improve the maintainability of the overall system. In addition, you can modify components without affecting the entire system.

Although you can consider a Flex application as part of the View in a distributed MVC architecture, you can use Flex to implement the entire MVC architecture on the client. A Flex application has its own view components that define the user interface, model components that represent data, and controller components that communicate with back-end systems.

About Struts

Struts is an open-source framework that facilitates the development of web applications based on Java servlets and other related technologies. Because it provides a solution to many of the common problems that developers face when building these applications, Struts has been widely adopted in a large variety of development efforts, from small projects to large-scale enterprise applications.

Struts is based on a Model-View-Controller (MVC) architecture, with a focus on the controller part of the MVC architecture. In addition, it provides JSP tag libraries to help you create the view in a traditional JSP/HTML environment.

Configure phase

Before you write your first line of application code, or before you deploy an application, you must ensure that you configure your environment correctly. Configuration is a broad term and encompasses several different tasks.

For example, you must configure your development and deployment environments to ensure that your application can access the required resources and data services. If your application requires access to a web service, ensure that your application has the correct access rights to the web service. If your application runs outside a firewall, ensure that it can access resources inside the firewall.

The following sections contain an overview of configuration tasks.

About run-time configuration

Most run-time configuration has to do with configuring access to remote data services, such as web services. For example, during application development, you run your application behind a firewall, where the application has access to all necessary resources and data services. However, when you deploy the application, you must ensure that an executing application can still access the necessary resources when the application runs outside of the firewall.

One configuration issue for Flex SDK applications is the placement of a crossdomain.xml file. For security, by default Flash Player does not allow an application to access a remote data service from a domain other than the domain from which the application was served. Therefore, a server that hosts a data service must be in the same domain as the server hosting your application, or the remote server must define a crossdomain.xml file. A crossdomain.xml file is an XML file that provides a way for a server to indicate that its data and documents are available to SWF files served from specific domains, or from all domains. By default, place the crossdomain.xml at the root directory of the server that is serving the data.

Flex SDK does not include a server-side proxy for handling data service requests. Therefore, you must ensure that you configure data services for direct access by your application, or make data service requests through your own proxy server.

Build phase

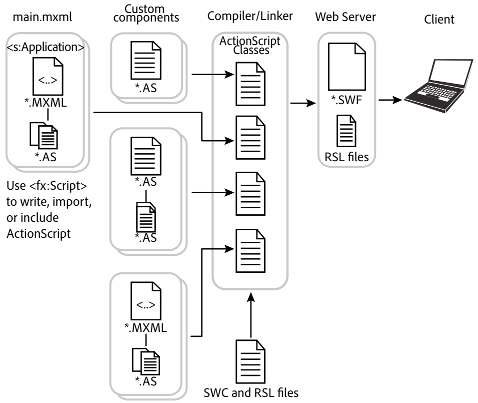
Building your application is an iterative process that includes three main tasks:

1. Compile
2. Debug
3. Test

About compiling

Compiling your application converts your application files and assets into a single SWF file. During compilation, you set compiler options to enable accessibility, enable debug information in the output, set library paths, and set other options. You can configure the compiler as part of configuring your project in Flash Builder, by using command-line arguments to the compiler, or by setting options in a configuration file.

When you compile your application, the Flex compiler creates a single SWF file from all of the application files (Adobe® MXML™, AS, RSL, SWC, and asset files), as the following example shows:



Flex provides two compilers: mxmlc and compc. You can use the compc and mxmlc compilers from within Flash Builder or from a command line.

You use mxmlc to compile MXML, ActionScript, SWC, and RSL files into a single SWF file. After your application is compiled and deployed on your web or application server, a user can make an HTTP request to download and play the SWF file on their computer.

You use compc to create resources that you use to create the application. For example, you can compile components, classes, and other files into SWC files or into RSLs, and then statically or dynamically link these libraries to your application.

For more information, see “Flex compilers” on page 2164.

About debugging an application

Flex provides several tools that you use to debug your application, including the following:

AIR Debug Launcher (ADL) A command line version of the Adobe® AIR™ debugger that you can use outside of Adobe® Flex™ Builder™.

Flash Player You can run Flex applications in two different versions of Adobe® Flash® Player: the standard version, which the general public uses, and the debugger version, which application developers use to debug their applications during the development process.

Flash Builder visual debugger The Flash Builder debugger allows you to run and debug applications. You can use the debugger to set and manage breakpoints; control application execution by suspending, resuming, and terminating the application; step into and over the code; watch variables; evaluate expressions; and so on.

Flex Command-line debugger A command line version of the debugger that you can use outside of Flash Builder.

For more information, see “Command-line debugger” on page 2209.

About testing an application

Due to the size, complexity, and large amounts of data handled by applications, maintaining the quality of a large software application can be difficult. To help with this task, you can use automated testing tools that test and validate application behavior without human intervention.

The Flex Automation Package provides developers with the ability to create Flex applications that use the Automation API. You can use this API to create automation agents or to ensure that your applications are ready for testing. In addition, the Flex Automation Package includes support for HP QuickTest Professional (QTP) automation tool. For more information, see “Creating applications for testing” on page 2270.

Deploy phase

When you deploy your application, you make it available to customers. Typically, you deploy the application as a SWF file on a web server so that users can access it by using an HTTP request to the SWF file.

When you deploy the application’s SWF file, you must also deploy all of the assets required by the application. For example, if the application requires access to video or image files, or to XML data files, you must make sure to deploy those assets as well. If the application uses an RSL, you must also deploy the RSL.

Deploying assets may not necessarily be as simple as copying the assets to a location on your web server. Flash Player has built-in security features that controls the access of application assets at run time.

This section contains an overview of the deployment phase. For more information, see “Deploying applications” on page 2544.

What happens during a request to a SWF file

When a customer requests the SWF file, the web server or application server returns the SWF file to the client computer. The SWF file then runs locally on the client.

In some cases, a request to a Flex SWF file can cause multiple requests to multiple SWF files. For example, if your application uses Runtime Shared Libraries (RSLs), the web server or application server returns an RSL as a SWC file to the client along with the application SWF file.

Server-side caching

Your web server or application server typically caches the SWF file on the first request, and then serves the cached file on subsequent requests. You configure server-side caching by using the options available in your web server or application server.

Client-side caching

The SWF file returned to the client is typically cached by the customer’s browser on first request. Depending on the browser configuration, the SWF file typically remains in the cache until the browser closes. When the browser reopens, the next request to the SWF file must reload it from the server.

Integrating Flex applications with your web application

To incorporate a Flex application into a website, you typically embed the SWF file in an HTML, JSP, Adobe® ColdFusion®, or other type of web page. The page that embeds the SWF file is known as the *wrapper*.

A wrapper consists of an `<object>` tag and an `<embed>` tag that format the SWF file on the page, define data object locations, and pass run-time variables to the SWF file. In addition, the wrapper can include support for deep linking and Flash Player version detection and deployment.

When you compile an application with Flash Builder, it automatically creates a wrapper file for you in the bin directory associated with the Flash Builder project. You can copy the contents of the wrapper file into your HTML pages to reference the SWF file. Flash Builder uses the SWFObject 2 library to embed the SWF file in the HTML page.

You can edit the wrapper to manipulate how Flex appears in the browser. You can also add JavaScript or other logic in the page to communicate with Flex or generate customized pages.

When using the mxmlc command-line compiler, you generally write the wrapper yourself. You can also use the wrapper included with Flex as a template for creating your own. If you use ant to compile your applications, you can use the `html-wrapper` ant task.

"Creating a wrapper" on page 2552

"Using the html-wrapper task" on page 2350

Secure phase

Security is not necessarily a phase of the application development process, but is an issue that you should take into consideration during the entire development process. That is, you do not configure, build, test, and deploy an application, and then define the security issues. Rather, you take security into consideration during all phases.

Building security into your application often takes the following main efforts:

- Using the security features built into Flash Player
- Building security into your application

Flash Player has several security features built into it, including sandbox security, that you can take advantage of because you are building applications for Flash Player.

But, Flash Player security is not enough for many application requirements. For example, your application may require the user to log in, or perform authentication in some other way, before accessing data services. When you must handle security issues beyond those built into Flash Player, design them into your application from the initial design phase, test them during the compile phase, and verify them during the deploy phase.

For more information on security, see "Security" on page 117.

About the security model

The Flex security model protects both the client and the server. Consider the following general aspects of security when you deploy Flex applications:

- Flash Player operating in a sandbox on the client
- Authorizing and authenticating users who access a server's resources

  Flash Player runs inside a security sandbox that prevents the client from being hijacked by malicious application code. This sandbox prevents a user from running a Flex application that can access system files and perform other tasks.

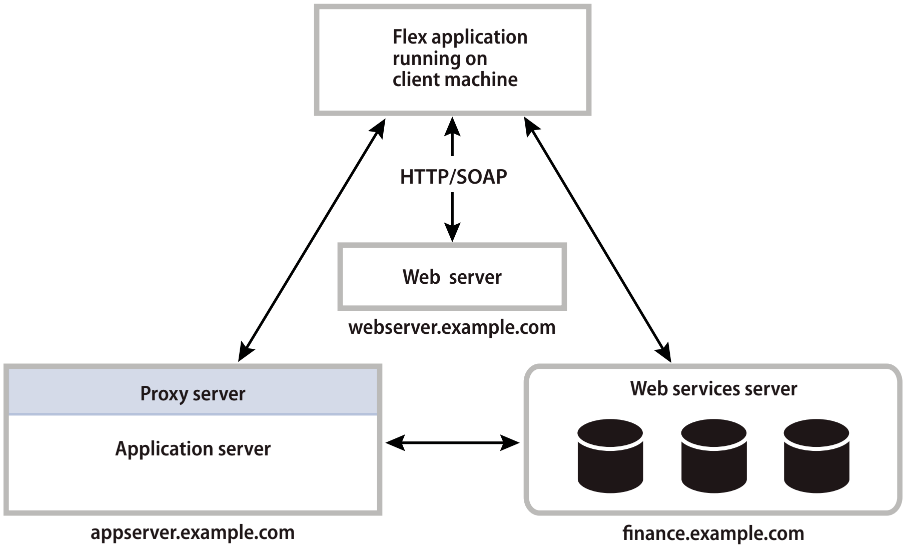
Flash Player security

Flash Player has an extensive list of features that ensure Flash content is secure, including the following:

- Uses the encryption capabilities of SSL in the browser to encrypt all communications between a Flash application and the server
- Includes an extensive sandbox security system that limits transfer of information that might pose a risk to security or privacy
- Does not allow applications to read data from the local drive, except for SharedObjects that were created by that domain
- Does not allow writing any data to the disk except for data that is encapsulated in SharedObjects
- Does not allow web content to read any data from a server that is not from the same domain, unless that server explicitly allows access
- Enables the user to disable the storage of information for any domain
- Does not allow data to be sent from a camera or microphone unless the user gives permission

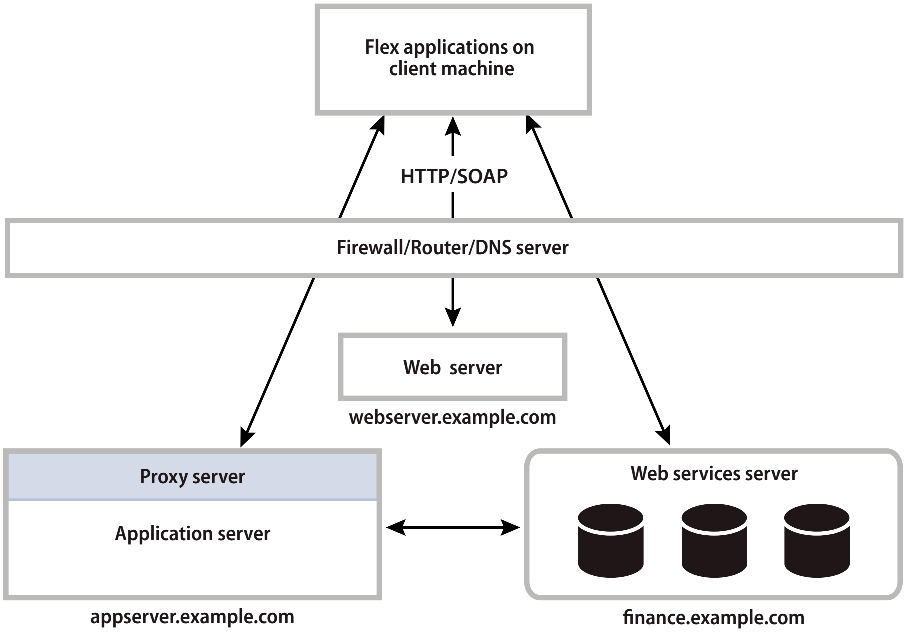
Application Development in Flex SDK

The following example shows a typical development environment for a Flex SDK application:



In this example, application development happens in an environment that is behind a firewall, and you deploy your application SWF file on webserver.example.com. To run the application, you make a request to it from a computer that is also within the firewall. The executing SWF file can access resources on any other server as necessary. In the development environment, the SWF file can directly access web services, or it can access them through a proxy server.

The following example shows a typical deployment environment for a Flex SDK application:



In this example, the customer requests the application SWF file from webserver.example.com, the server returns the SWF file to the customer, and the SWF file plays. The executing SWF file must be able to access the necessary resources from outside the firewall.

Design phase

With Flex SDK, one of your first design decisions might be to choose a design pattern that fits your application requirements. That design pattern might have implications on how you structure your development environment, determine the external data services that your application must access, and define how you integrate your Flex application into a larger web application.

Configure phase

For run-time configuration, you ensure that your executing SWF file can access the necessary resources including asset files (such as image files) and external data services. If you access a resource on a domain other than the domain from which the SWF file is served, you must define a crossdomain.xml file on the target server, or make the request through a proxy server.

Build phase

To build an application for Flex SDK, you define a directory structure on your development system for application files, and define the location of application assets. You then compile, debug, and test your application.

The compile-time configuration for a Flex SDK application is primarily a process of setting compiler options to define the location of SWC and RSLs, to create a SWF file with debug information, or to set additional compiler options. When compiling applications, you compile your application into a single SWF file, and then deploy the SWF file to a web server or application server for testing.

Deploy phase

With Flex SDK, you deploy your application SWF file on your web server or application server. Users then access the deployed SWF file by making an HTTP request in the form:

```
http://hostname/path/filename.swf
```

If you embed your SWF file in an HTML or other type of web page using a wrapper, users request the wrapper page. The request to the wrapper page causes the web server or application server to return the SWF file along with the wrapper page.

Secure phase

Security issues for Flex SDK applications often have to do with how the application accesses external resources. For example, you might require a user to log in to access resources, or you might want the application to be able to access external data services that implement some other form of access control.

Application structure

Installation directory structure

Before you can begin to set up your application development environment, be familiar with the Flex installation directory structure for the following products:

- Flex SDK
- Adobe ® Flash® Builder™

Flex SDK installation directory structure

When you install Flex SDK, the installer creates the following directory structure under the installation directory:

Directory	Description
/ant	Contains the Flex Ant tasks, which provide a convenient way to build your Flex projects.
/asdoc	Contains ASDoc, a command-line tool that you can use to create API language reference documentation as HTML pages from the classes in your Flex application.
/bin	Contains the executable files, such as the mxmlc and compc compilers.
/frameworks	Contains configuration files, such as flex-config.xml and default.css.
/frameworks/libs	Contains the library SWC files. You use the files to compile your application.
/frameworks/locale	Contains the localization resource files.
/frameworks/projects	Contains the Flex framework source code.
/frameworks/rsls	Contains the RSL for the Flex framework.
/frameworks/themes	Contains the theme files that define the basic look and feel of all Flex components.
/lib	Contains JAR files.
/runtimes	Contains the standard and debugger versions of Adobe ® Flash® Player and the Adobe® AIR™ components.
/samples	Contains sample applications.
/templates	Contains template HTML wrapper files. This includes history management files for deep linking as well as the playerProductInstall.swf file for Player updating.

Flash Builder installation directory structure

When you install Flash Builder, you install Flex SDK plus Flash Builder. The installer creates the following directory structure:

Directory	Description
Flash Builder 4.6	The top-level directory for Flash Builder.
/configuration	A standard Eclipse folder that contains the config.ini file and error logs.
/features	A standard Eclipse folder that contains the plug-ins corresponding to features of Flash Builder.
/jre	Contains the Java Runtime Environment installed with Flash Builder used by default when you run the stand-alone version of Flash Builder.
/player	Contains the different versions of Flash Player—the standard version and the debugger version.
/plugins	Contains the Eclipse plugins used by Flash Builder.
/sdks	Contains the different Flex SDKs. For a directory description, see "Flex SDK installation directory structure" on page 107.

Development directory structure

As part of the process of setting up the directory structure of your development environment, you define the directory location for application-specific assets, assets shared across applications, and the location of other application files and assets.

Flex file types

A Flex application consists of many different file types. Consider the following options when you decide where to place each type of file.

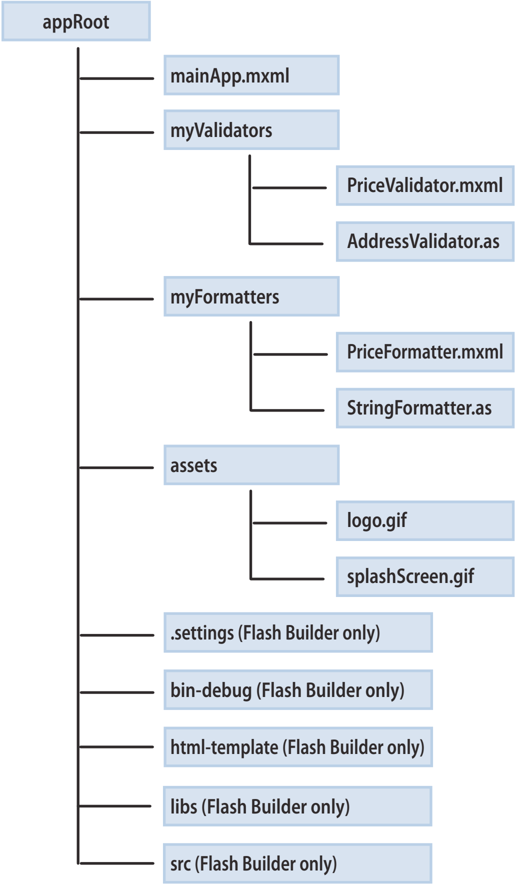
The following table describes the different Flex file types:

File format	Extension	Description
MXML	.mxml	Your application typically has one main application MXML file that contains the `<s:Application>` tag, and one or more MXML files that implement your custom MXML components.
ActionScript	.as	A utility class, Flex custom component class, or other logic implemented as an ActionScript file.
SWC	.swc	A custom library file, or a custom component implemented as an MXML or ActionScript file, then packaged as a SWC file. A SWC file contains components that you package and reuse among multiple applications. The SWC file is then statically linked into your application at compile time when you create the application's SWF file.
RSL	.swc	A custom library implemented as an MXML or ActionScript file, and then deployed as a Runtime Shared Library (RSL). An RSL is a stand-alone SWC file that is downloaded separately from your application's SWF file, cached on the client computer for use with multiple application SWF files, and dynamically linked to your application.
CSS file	.css	A text file template for creating a Cascading Style Sheets file.
Assets	.flv, .mp3, .jpg, .gif, .swf, .png, .svg, .xml, other	The assets required by your application, including image, skin, sound, and video files.

Flex SDK directory structure

A typical Flex application consists of a main MXML file (the file that contains the `<s:Application>` tag), one or more MXML files that implement custom MXML components, one or more ActionScript files that contains custom components and custom logic, and asset files.

The following example shows an example of the directory structure of a simple Flex application:



This application consists of a root application directory and directories for different types of files. Everything required to compile and run the application is contained in the directory structure of the application.

Flash Builder adds additional directories to the application that are not present for Flex SDK applications:

.settings Contains the preference settings for your Flash Builder project

bin-debug Contains the debug SWF and debug wrapper files

bin-release Contains the generated SWF file and wrapper file, created by Flash Builder when you select File > Export > Release Version

html-template Contains additional files used by specific Flex features, such as deep linking or Player detection. Flash Builder uses these files to generate an HTML wrapper for your SWF file.

libs Contains additional SWC files and other files used by the application.

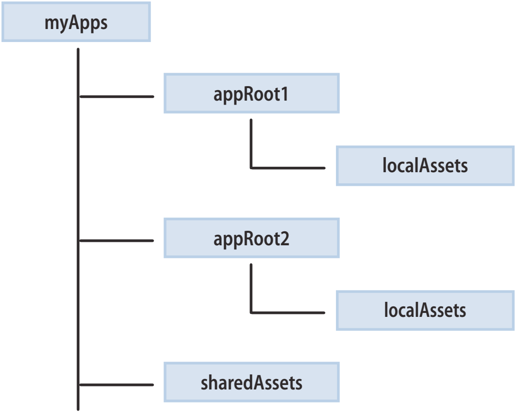
src Contains the application source code.

There are no inherent restrictions in Flex for the location of the root directory of your application, so you can put it almost anywhere in the file system of your computer. If you are using Flash Builder, the default location of the application root directory in Microsoft Windows is My Documents\Flash Builder 4.6*project_name* (for example, C:\Documents and Settings*userName*\My Documents\Flash Builder 4.6\myFlexApp).

Sharing assets among applications

Typically, you do not develop a single application in isolation from all other applications. Your application shares files and assets with other applications.

The following example shows two Flex applications, appRoot1 and appRoot2. Each application has a directory for local assets, and can access shared assets from a directory outside of the application's directory structure:



The location of the shared assets does not have to be at the same level as the root directories of the Flex applications. It only needs to be somewhere accessible by the applications at compile time.

In the following example, you use the Image control in an MXML file in the appRoot1 directory to access an asset from the shared assets directory:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- apparch/EmbedExample.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <s:Image id="loader1"
        source="@Embed(source='../assets/butterfly.gif')"/>
</s:Application>
```

Consideration for accessing application assets

One of the decisions that you must make when you create a Flex application is whether to load your assets at run time, or to embed the assets within the application's SWF file.

When you embed an asset, you compile it into your application's SWF file. The advantage to embedding an asset is that it is included in the SWF file, and can be accessed faster than having to load it from a remote location at run time. The disadvantage of embedding is that your SWF file is larger than if you load the asset at run time.

If you decide to access an asset at run time, you can load it from the local file system of the computer on which the SWF file runs, or you can access a remote asset, typically though an HTTP request over a network.

A SWF file can access one type of external asset: local or over a network; the SWF file cannot access both types. You determine the type of access allowed by the SWF file by using the `use-network` flag when you compile your application. When you set the `use-network` flag to `false`, you can access assets in the local file system, but not over the network. The default value is `true`, which lets you access assets over the network, but not in the local file system.

For more information on the `use-network` flag, see "Flex compilers" on page 2164. For more information on embedding application assets, see "Embedding assets" on page 1699.

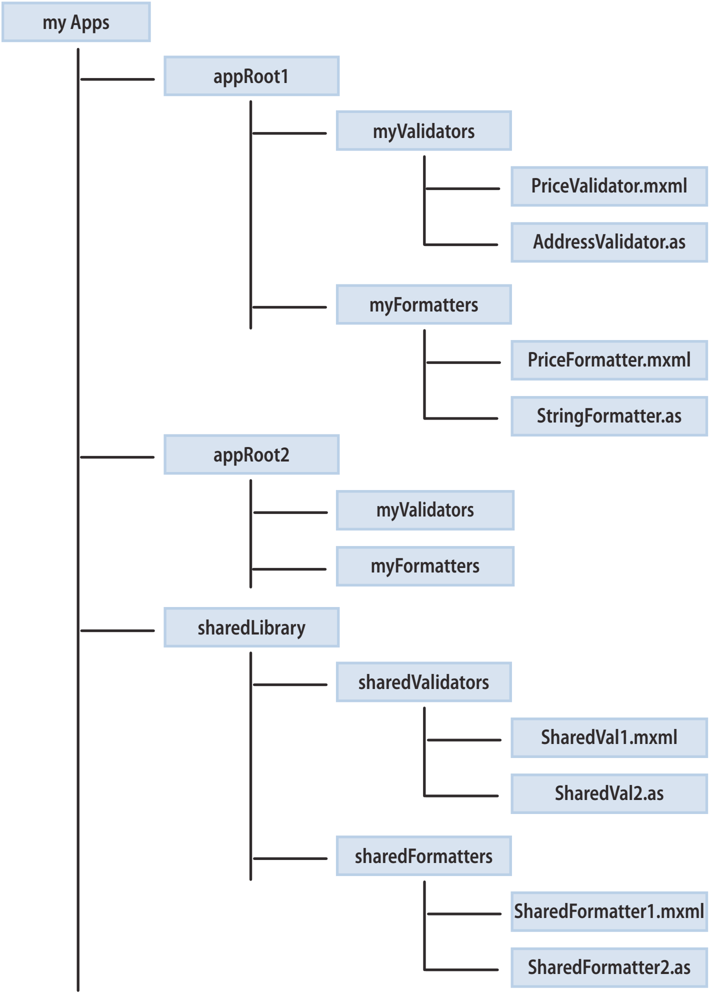
Sharing MXML and ActionScript files among applications

You can build an entire Flex application in a single MXML file that contains both your MXML code and any supporting ActionScript code. As your application gets larger, your single file also grows in size and complexity. This type of application would soon become difficult to understand and debug, and very difficult for multiple developers to work on simultaneously.

Flex supports a component-based development model. You use the predefined components included with Flex to build your applications, and create components for your specific application requirements. You can create custom components using MXML or ActionScript.

Defining your own components has several benefits. One advantage is that components let you divide your applications into modules that you can develop and maintain separately. By implementing commonly used logic within custom components, you can also build a suite of reusable components that you can share among multiple Flex applications.

The following example shows two Flex applications, appRoot1 and appRoot2. Each application has a subdirectory for local MXML and ActionScript components, and can also reference a library of shared components:



The Flex compiler uses the source path to determine the directories where it searches for MXML and ActionScript files. By default, the root directory of the application is included in the source path; therefore, a Flex application can access any MXML and ActionScript files in its main directory, or in a subdirectory.

For shared MXML and ActionScript files that are outside of the application's directory structure, you modify the source path to include the directories that the compiler searches for MXML and ActionScript files. The component search order in the source path is based on the order of the directories listed in the source path.

You can set the source path as part of configuring your project in Flash Builder, in the flex-config.xml file, or set it when you open the command-line compiler. In this example, you set the source path to:

```
C:\myApps\sharedLibrary
```

To access a component in an MXML file, you specify a namespace definition that defines the directory location of the component relative to the source path. In the following example, an MXML file in the appRoot1 directory accesses an MXML component in the local directory structure, and in the directory containing the shared library of components:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- apparch/ComponentNamespaces.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyLocalComps="myFormatters.*"
    xmlns:MySharedComps="sharedFormatters.*">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <MyLocalComps:PriceFormatter/>
    <MySharedComps:SharedFormatter2/>
</s:Application>
```

The MXML tag name for a custom component is composed of two parts: the namespace prefix, in this example MyLocalComps and MySharedComps, and the tag name. The namespace prefix tells Flex the directory in the source path that contains the file that implements the custom component. The tag name corresponds to the filename of the component, in this example PriceFormatter.mxml and SharedFormatter2.mxml.

Using a SWC file in a Flex SDK application

A SWC file is a Flex library file that contains one or more components implemented in MXML or ActionScript. All Flex library files are shipped as SWC files in the frameworks/libs directory. The list of library files includes:

- framework.swc
- rpc.swc
- core.swc
- charts.swc
- advanceddatagrid.swc

You can also create SWC files that you package and reuse among multiple applications. You typically use static linking with SWC files, which means the compiler includes all components, classes, and their dependencies in the application SWF file when you compile the application. For more information on static linking, see “About linking” on page 254.

By default, the Flex compiler includes all linked SWC files in the frameworks/libs directory when it compiles your application. SWC files that contain only classes that are not used in your application are not included. For your custom SWC files, you use the `library-path` option of the mxmlc compiler, or set the library path in Flash Builder, to specify the location of the SWC file.

Using an RSL in a Flex SDK application

One way to reduce the size of your application’s SWF file is by externalizing shared assets into stand-alone files that can be separately downloaded and cached on the client. These shared assets are loaded by any number of applications at run time, but must be transferred to the client only once. These shared files are known as Runtime Shared Libraries or RSLs.

An RSL is a stand-alone file that the client downloads separately from your application’s SWF file, and caches on the client computer for use with multiple application SWF files. Using an RSL reduces the resulting file size for your applications. The benefits increase as the number of applications that use the RSL increases. If you only have one application, putting components into RSLs does not reduce the aggregate download size, and might increase it.

You create an RSL as a SWC file that you package and reuse among multiple applications. To reference an RSL, you use the `runtime-shared-libraries` option for the command-line compiler, or Flash Builder. You typically use dynamic linking with RSLs, which means that the classes in the RSL are left in an external file that is loaded at run time.

Every Flex application uses some aspects of the Flex framework, which is a relatively large set of ActionScript classes that define the infrastructure of a Flex application. If a client loads two different Flex applications, the application will likely load overlapping class definitions. To further reduce the SWF file size, you can use *framework* RSLs. Framework RSLs let you externalize the framework libraries and can be used with any Flex application.

For more information on RSLs, framework RSLs, and dynamic linking, see "Runtime Shared Libraries" on page 253.

Using modules in a Flex SDK application

Modules are SWF files that can be loaded and unloaded by an application. They cannot be run independently of an application, but any number of applications can share the modules.

Modules let you split your application into several separate SWF files. The main application, or shell, can dynamically load other SWF files that it requires, when it needs them. It does not have to load all modules when it starts, nor does it have to load any modules if the user does not interact with them. When the application no longer needs a module, it can unload the module to free up memory and resources.

For more information, see "Modular applications" on page 138.

Compiling an application

Compiling your application converts your application files and assets into a single SWF file. During compilation, you set compiler options to enable accessibility, enable debug information in the output, set library paths, and set other options. You can configure the compiler as part of configuring your project in Flash Builder, by using command-line arguments to the compiler, or by setting options in a configuration file.

For more information on compiling applications, see "Flex compilers" on page 2164.

About case sensitivity during a compile

The Flex compilers use a case-sensitive file lookup on all file systems. On case-insensitive file systems, such as the Macintosh and Windows file systems, the Flex compiler generates a case-mismatch error when you use a component with the incorrect case. On case-sensitive file systems, such as the UNIX file system, the Flex compiler generates a component-not-found error when you use a component with the incorrect case.

Compiling a Flex SDK application

Flex SDK includes two compilers, mxmlc and compc. You use mxmlc to compile MXML files, ActionScript files, SWC files, and RSLs into a single SWF file. After your application is compiled and deployed on your web or application server, a user can make an HTTP request to download and play the SWF file on their computer. You use the compc compiler to compile components, classes, and other files into SWC files or RSLs.

To compile an application with Flex SDK, you use the mxmlc compiler in the bin directory of your Flex SDK directory. The most basic mxmlc example is one in which the MXML file for your application has no external dependencies (such as components in a SWC file or ActionScript classes). In this case, you open mxmlc from the command line and point it to your MXML file, as the following example shows:

```
$ mxmlc c:/myFiles/app.mxml
```

The mxmlc compiler has many options that you can specify on the command line, or that you can set in the flex-config.xml file. For example, to disable warning messages, you set the `warnings` options to `false`, as the following example shows:

```
$ mxmlc -warnings=false c:/myFiles/app.mxml
```

You only specify the main application file, the file that contains the `<s:Application>` tag, to the compiler. The compiler searches the default source path for any MXML and ActionScript files that your application references. If your application references MXML and ActionScript files in directories that are not included in the default source path, you can use the `sourcepath-` option to add a directory to the source path, as the following example shows:

```
$ mxmlc -source-path path1 path2 path3 c:/myFiles/app.mxml
```

In this example, you specify a list of directories, separated by spaces, and terminate that list with `--`.

For more information on mxmlc options, see "Using mxmlc, the application compiler" on page 2174.

Compiling an application that uses SWC files

Often, you use SWC files when compiling MXML files. You specify the SWC files in the compiler by using the `library-path` option.

The following example adds two SWC files to the `library-path` when it compiles your application:

```
$ mxmlc -library-path+=/myLibraries/MyRotateEffect.swc;/myLibraries/MyButtonSwc.swc
c:/myFiles/app.mxml
```

Compiling an application that uses RSLs

To use an RSL in your application, use the `runtime-shared-library-path` compiler option. The following example compiles an application with an RSL at the command line:

```
$ mxmlc -runtime-shared-library-path=../lib/mylib.swc,../bin/library.swf Main.mxml
```

Compiling an application that uses modules

The way you compile modules is similar to the way you compile applications. On the command line, you use the mxmlc command-line compiler. The result is a SWF file that you load into your application as a module.

You cannot run the module-based SWF file as a stand-alone application or load it into a browser window. It must be programmatically loaded by an application as a module.

For more information on compiling modules on the command line, see "Modular applications" on page 138.

Compiling a Flash Builder application

When you compile a project with Flash Builder, you run the Flex compilers from within Flash Builder itself, not from the command line. You can build your projects manually or let Flash Builder automatically compile them for you. In either case, the Flash Builder compiler creates the application files, generates a wrapper, places the output files in the proper location, and alerts you to any errors encountered during compilation. You then run and debug your applications as needed.

For mobile applications, Flash Builder creates and deploys the APK file for you.

If you must modify the default build settings, you have several options for controlling how your projects are built into applications. For example, you can set build preferences on individual projects or on all the projects in your workspace, modify the build output path, change the build order, and so on. You can also create custom build instructions using third-party tools, such as Apache Ant.

When your projects are built, automatically or manually, Flash Builder places the SWF file in the project output folder along with the wrapper. By default, this is the debug version of your application. It contains debugging information and, therefore, is used when you debug your application. A wrapper file embeds the application SWF file and is used to run or debug your application in a web browser. The standard version of your application SWF files, which you generate through Export Release Version, does not include the additional debugging information and is smaller.

For more information about compiling Flash Builder applications, see Build projects.

Compiling an application that uses modules

In Flash Builder, you create modules as applications and compile them by either building the project or running the application. The result is a SWF file that you load into your application as a module.

You cannot run the module-based SWF file as a stand-alone Flex application or load it into a browser window. It must be loaded by an application as a module. When you run it in Flash Builder to compile it, you should close the Player or browser Window and ignore any errors. Modules should not be requested by the Player or through a browser directly.

For information on compiling modules in Flash Builder, see "Modular applications" on page 138.

Deployment directory structure

When you deploy an application, ensure that the directory structure of the deployed application is correct.

When you deploy your application, must be aware of how your application accesses its assets. If you embedded all of your application assets into the SWF file, you can deploy the application as a stand-alone SWF file.

However, if your application accesses assets at run time, the application requests assets during execution. You must ensure that you deploy all of the necessary assets, in the correct location, so that you can run the application correctly.

Assets that you deploy at run time include:

Asset type	More information
HTML wrapper	"Creating a wrapper" on page 2552
Deep linking files	"Deep linking" on page 2022
Express Install files	"Using Express Install in the wrapper" on page 2558
RSLs	"Runtime Shared Libraries" on page 253
Modules	"Modular applications" on page 138
Sub-applications	"Developing and loading sub-applications" on page 176
Compiled CSS SWF files	"Loading style sheets at run time" on page 1547
Resource modules	"Resource Bundles" on page 2091
Images, sound files, and other binary assets that are not embedded	
Data files	

In some cases, the deployed locations of these files must match the locations of the files during development. For example, if you load modules from the same directory as your main application, then you must deploy these modules to that directory, unless you programmatically handle alternative locations to load the modules from.

In other cases, the deployed locations of these files is specified. For example, the deep linking files history.css, historyFrame.html, and history.js must all reside in a /history subdirectory that is located relative to the application's SWF file.

And in other cases, you specify the eventual deployed location of these assets when you compile your application. For example, if you compiled your application using an RSL, you must ensure that the RSL is also deployed to your web server, along with your application's SWF file. The directory location of the RSL must match the directory location that you specified at compile time using the `runtime-shared-libraries` or `runtime-shared-library-path` options for the compiler.

For more information about what assets to deploy with your application, see "Deployment checklist" on page 2548.

Security

Introduction to security

Adobe® Flash® Player runs applications built as SWF files. Content is delivered as a series of instructions in binary format to Flash Player over web protocols in the precisely described SWF (.swf) file format. The SWF files themselves are typically hosted on a server and then downloaded to, and displayed on, the client computer when requested. Most of the content consists of binary ActionScript instructions. ActionScript is the ECMA standards-based scripting language that Flash uses that features APIs designed to allow the creation and manipulation of client-side user interface elements and for working with data.

The Flex security model protects both client and the server. Consider the following two general aspects to security:

- Authorization and authentication of users accessing a server's resources
- Flash Player operating in a sandbox on the client

Flex supports working with the web application security of any J2EE application server. In addition, precompiled applications can integrate with the authentication and authorization scheme of any underlying server technology to prevent users from accessing your applications. The Flex framework also includes several built-in security mechanisms that let you control access to web services, HTTP services, and server-based resources such as EJBs.

Flash Player runs inside a security sandbox that prevents the client from being hijacked by malicious application code.

***Note:** SWF content running in the Adobe® AIR™ follows different security rules than content running in the browser. For details, see Adobe AIR Security.*

Declarative compared to programmatic security

The two common approaches to security are declarative and programmatic. Often, declarative security is server based. Using the server's configuration, you provide protection to a resource or set of resources. You use the container's authentication and authorization schemes to protect that resource from unauthorized access.

The declarative approach to security casts a wide net. Declarative security is implemented as a separate layer from the web components that it works with. You set up a security system, such as a set of file permissions or users, groups, and roles, and then you plug your application's authentication mechanism into that layer.

With declarative security, either a user gains access to the resource or they do not. Usually the content cannot be customized based on roles. In an HTML-based application, the result is that users are denied access to certain pages. However, in a Flex environment, the typical result of declarative security is that the user is denied access to the entire application, since the application is seen as a single resource to the container.

Declarative security lets programmers who write web applications ignore the environment in which they write. Declarative security is typically set up and maintained by the deployer and not the developer of the application. Also, updates to the web application do not generally require a refactoring of the security model.

Programmatic security gives the developer of the application more control over access to the application and its resources. Programmatic security can be much more detailed than declarative security. For example, a developer using programmatic security can allow or deny a user access to a particular component inside the application.

Although programmatic security is typically configured by the developer of the application, it usually interacts with the same systems as declarative security, so the relationship between developer and deployer of the application must be cooperative when implementing programmatic security.

Declarative security is recommended over programmatic security for most applications because the design promotes code reuse, making it more maintainable. Furthermore, declarative security puts the responsibility of security into the hands of the people who specialize in its implementation; application programmers can concentrate on writing applications and people who deploy the applications in a specific environment can concentrate on enforcing security policies and take advantage of that context.

Client security overview

When considering security issues, you cannot think of applications as traditional web applications. Applications built with Flex often consist of a single monolithic SWF file that is loaded by the client once, or a series of SWF files loaded as modules or RSLs. Web applications, on the other hand, usually consist of many individual pages that are loaded one at a time.

Most web applications access resources such as web services that are outside of the client. When an application accesses an external resource, two factors apply:

- Is the user authorized to access this resource?
- Can the client load the resource, or is it prevented from loading the resource, because of its sandbox limitations?

The following basic security rules always apply by default:

- Resources in the same security sandbox can always access each other.
- SWF files in a remote sandbox can never access local files and data.

You should consider the following security issues related to the client architecture that affect applications.

Flash Player security features

Much of Flash Player security is based on the domain of origin for loaded SWF files, media, and other assets. A SWF file from a specific Internet domain, such as www.example.com, can always access all data from that domain. These assets are put in the same security grouping, known as a security sandbox. For example, a SWF file can load SWF files, bitmaps, audio, text files, and any other asset from its own domain. Also, cross-scripting between two SWF files from the same domain is permitted, as long as both files are written using ActionScript 3.0. Cross-scripting is the ability of one SWF file to use ActionScript to access the properties, methods, and objects in another SWF file. Cross-scripting is not supported between SWF files written using ActionScript 3.0 and files using previous versions of ActionScript; however, these files can communicate by using the LocalConnection class.

Memory usage and disk storage protections

Flash Player includes security protections for disk data and memory usage on the client computer.

The only type of persistent storage is through the SharedObject class, which is embodied as a file in a directory whose name is related to that of the owning SWF file. An application cannot typically write, modify, or delete any files on the client computer other than SharedObject data files, and it can only access SharedObject data files under the established settings per domain.

Flash Player helps limit potential denial-of-service attacks involving disk space (and system memory) through its monitoring of the usage of SharedObject classes. Disk space is conserved through limits automatically set by Flash Player (the default is 100K of disk space for each domain). The author can set the application to prompt the user for more disk space, or Flash Player automatically prompts the user if an attempt is made to store data that exceeds the limit. In either case, the disk space limit is enforced by Flash Player until the user gives explicit permission for an increased allotment for that domain.

Flash Player contains memory and processor safeguards that help prevent applications from taking control of excess system resources for an indefinite period of time. For example, Flash Player can detect an application that is in an infinite loop and select it for termination by prompting the user. The resources that the application uses are immediately released when the application closes.

Flash Player uses a garbage collector engine. The processing of new allocation requests always first ensures that memory is cleared so that the new usage always obtains only clean memory and cannot view any previous data.

Privacy

Privacy is an important aspect of overall security. Adobe products, including Flash Player, provide very little information that would reveal anything about a user (or their computer). Flash Player does not provide personal information about users (such as names, e-mail addresses, and phone numbers), or provide access to other sensitive information (such as credit card numbers or account information).

What Flash Player does provide is basically standardized hardware and software configuration information that authors might use to enhance the user experiences in the environment encountered. The same information is often available already from the operating system or web browser.

Information about the client environment that is available to the application includes:

- User agent string, which typically identifies the embedding browser type and operating system of the client
- System capabilities such as the language or the presence of an MP3 decoder (see the Capabilities class)
- Presence of a camera and microphone
- Keyboard and mouse input

ActionScript also includes the ability to replace the contents of the client's Clipboard by using the `setClipboard()` method of the System class. This method does not have a corresponding `getClipboard()` method, so protected data that might be stored in the Clipboard already is not accessible to Flash Player.

About sandboxes

The sandbox type indicates the type of security zone in which the SWF file is operating. In Flash Player, all SWF files (and HTML files, for the purposes of SWF-to-HTML scripting) are placed into one of four types of sandbox:

remote All files from non-local URLs are placed in a remote sandbox. There are many such sandboxes, one for each Internet (or intranet) domain from which files are loaded.

local-with-filesystem The default sandbox for local files. SWF files in this sandbox may not contact the Internet (or any servers) in any way—they may not access network endpoints with addresses such as HTTP URLs.

local-with-networking SWF file in this sandbox may communicate over the network but may not read from local file systems.

local-trusted This sandbox is not restricted. Any local file can be placed in this sandbox if given authorization by the end user. This authorization can come in two forms: interactively through the Settings Manager or noninteractively through an executable installer that creates Flash Player configuration files on the user's computer.

You can determine the current sandbox type by using the `sandboxType` property of the Security class, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- security/DetectCurrentSandbox.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp()">

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script><![CDATA[
        [Bindable]
        private var mySandboxType:String;
        private function initApp():void {
            mySandboxType = String(Security.sandboxType);
        }
    ]]></fx:Script>
    <s:HGroup>
        <s:Label text="Sandbox Type: "/>
        <s:Label id="tb1" text="{mySandboxType}"/>
    </s:HGroup>
</s:Application>
```

When you compile an application, you have some control over which sandbox the application is in. This determination is a combination of the value of the `use-network` compiler option (the default is `true`) and whether the SWF file was loaded by the client over a network connection or as a local file.

The following table shows how the sandbox type is determined:

use-network	Loaded	Sandbox type
false	locally	local-with-filesystem
true	locally	local-with-network
true	network	remote
false	network	n/a (causes an error)

Browser security

Flash Player clients can be one of the following four types:

- Embedded Flash Player
- Debugger version of embedded Flash Player
- Stand-alone Flash Player
- Debugger version of stand-alone Flash Player

The stand-alone Flash Player runs on the desktop. It is typically used by people who are running applications that are installed and maintained by an IT department that has access to the desktop on which the application runs.

The embedded Flash Player is run within a browser. Anyone with Internet access can run applications from anywhere with this player. For Internet Explorer, the embedded player is loaded as an ActiveX control inside the browser. For Netscape-based browsers (including Firefox), it is loaded as a plug-in inside the browser. Using an embedded player lets the developer use browser-based technologies such as FORM and BASIC authentication as well as SSL.

Browser APIs

Applications hosting the Flash Player ActiveX control or Flash Player plug-in can use the EnforceLocalSecurity and DisableLocalSecurity API calls to control security settings. If DisableLocalSecurity is opened, the application does not benefit from the local-with-networking and local-with-file-system sandboxes. All files loaded from the local file system are placed into the local-trusted sandbox. The default behavior for an ActiveX control hosted in a client application is DisableLocalSecurity.

If EnforceLocalSecurity is opened, the application can use all three local sandboxes. The default behavior for the browser plug-in is EnforceLocalSecurity.

Cross-scripting

Cross-scripting is when a SWF file communicates directly with another SWF file. This communication includes calling methods and setting properties of the other SWF file.

SWF file loading and cross-scripting are always permitted between SWF files that reside in the same sandbox. For example, any local-with-filesystem SWF file can load and cross-script any other local-with-filesystem SWF file; any local-with-networking SWF file can load and cross-script any other local-with-networking SWF file; and so on. The restrictions appear when two SWF files from different sandboxes or two remote SWF files with different domains attempt to cooperate.

For SWF files in the remote sandbox, if two SWF files were loaded from the same domain, they can cross-script without any restrictions. If both SWF files were loaded from a network, but from different domains, you must provide permissions to allow them to cross-script.

To enable cross-scripting between SWF files, use the Security class's `allowDomain()` and `allowInsecureDomain()` methods.

You call these methods from the called SWF file and specify the calling SWF file's domain. For example, if SWF1 in domainA.com calls a method in SWF2 in domainB, SWF2 must call the `allowDomain()` method and specifically allow SWF files from domainA.com to cross-script the method, as the following example shows:

```
import flash.system.Security;
Security.allowDomain("domainA.com");
```

If the SWF files are in different sandboxes (for example, if one SWF file was loaded from the local file system and the other from a network) they must adhere to the following set of rules:

- Remote SWF files (those served over HTTP and other non-local protocols) can never load local SWF files.
- Local-with-networking SWF files can never load local-with-filesystem SWF files, or vice versa.
- Local-with-filesystem SWF files can never load remote SWF files.
- Local-trusted SWF files can load SWF files from any sandbox.

To facilitate SWF-to-SWF communication, you can also use the LocalConnection class. For more information, see "Using the LocalConnection class" on page 130.

ExternalInterface

You use the ExternalInterface API to let your application call scripts in the wrapper and to allow the wrapper to call functions in your application. The ExternalInterface API consists primarily of the `call()` and `addCallback()` methods in the flash.net package.

This communication relies on the domain-based security restrictions that the `allowScriptAccess` and `allowNetworking` properties define. You set the values of the `allowScriptAccess` and `allowNetworking` properties in the SWF file's wrapper. For more information, see "About the object and embed tags" on page 2564.

By default, the application and the HTML page it is calling must be in the same domain for the `call()` method to succeed. For more information, see "Communicating with the wrapper" on page 226.

The navigateToURL() method

The navigateToURL() method opens or replaces a window in the Flash Player's container application. You typically use it to launch a new browser window, although you can also embed script in the method's call to perform other actions.

This usage of the `navigateToURL()` method relies on the domain-based security restrictions that the `allowScriptAccess` and `allowNetworking` parameters define. You set the values of the `allowScriptAccess` and `allowNetworking` parameters in the SWF file's wrapper. For more information, see "About the object and embed tags" on page 2564.

Caching

Applications reside entirely on the client. If the browser loads the application, the application SWF file, plus externally loaded images and other media files, are stored locally on the client in the browser's cache. These files reside in the cache until cleared.

Storing a SWF file in the browser's cache can potentially expose the file to people who would not otherwise be able to see it. The following table shows some example locations of the browser's cache files:

Browser or operating system	**Cache location**
Internet Explorer on Windows XP	C:\Documents and Settings\username\Local Settings\Temporary Internet Files
Firefox on Windows XP	C:\Documents and Settings\username\Application Data\Mozilla\Firefox\Profiles\username.default\Cache
UNIX	$HOME/.mozilla/firefox/*username*.default/Cache/

These files can remain in the cache even after the browser is closed.

To prevent client browsers from caching the SWF file, try setting the following HTTP headers in the SWF file's wrapper:

```
Cache-control: no-cache, no-store, must-revalidate, max-age=-1
Pragma: no-cache, no-store
Expires: -1
```

Note that in some cases, setting the `Pragma` header to `"no-cache"` can cause a runtime error with GET requests over SSL with the HTTPService class. In this case, setting just the `Cache-control` header should work.

Marc Speck has a blog entry that describes the issue and presents several solutions.

Trusted sites and directories

The browser security model includes levels of trust applied to specific websites. Flash Player interacts with this model by assigning a sandbox based on whether the browser declared the site of the SWF file's origin trusted.

If Flash Player loads a SWF file from a trusted website, the SWF file is put in the local-trusted sandbox. The SWF file can read from local data sources and communicate with the Internet.

You can also assign a SWF file to be in the local-trusted sandbox when you load it from the local file system. To do this, you configure a directory as trusted by Flash Player (which results in the SWF file being put in the local-trusted sandbox) by adding a FlashPlayerTrust configuration file that specifies the directory to trust. This requires administrator access privileges to the client system, so it is typically used in controlled environments. Users can also define a directory as trusted by using the Flash Player User Settings Manager. For more information, see the Flash Player documentation.

Deploying secure applications

When you deploy an application, you make the application accessible to your users. The process of deploying an application is dependent on your application, your application requirements, and your deployment environment. You can employ some of the following strategies to ensure that the application you deploy is secure.

Deploying local SWF files versus network SWF files

Client computers can obtain individual SWF files from a number of sources, such as from an external website or a local file system. When SWF files are loaded into Flash Player, they are individually assigned to security sandboxes based on their origin.

Flash Player classifies SWF files downloaded from the network (such as from external websites) in separate sandboxes that correspond to their website origin domains. By default, these files are authorized to access additional network resources that come from the specific (exact domain name match) site. Network SWF files can be allowed to access additional data from other domains by explicit website and author permissions.

A local SWF file describes any file referenced by using the "file" protocol or a UNC path, which does not include an IP address or a qualifying domain. For example, "\\test\test.swf" and "file:\test.swf" are considered local files, while "\\test.com\test.swf" and "\192.168.0.1\test.swf" are not considered local files.

Local SWF files from local origins, such as local file systems or UNC network paths, are placed into one of three sandboxes: local-with-networking, local-with-filesystem, and local-trusted.

When you compile the application, if you set the `use-network` compiler option to `false`, local SWF files are placed in the local-with-filesystem sandbox. If you set the `use-network` compiler option to `true`, local SWF files are placed in the local-with-networking sandbox.

Local SWF files that are registered as trusted (by users or by installer programs) are placed in the local-trusted sandbox. Users can also reassign (move) a local SWF file to or from the local-trusted sandbox based on their security considerations.

Deploy checklist

Before you deploy your application, ensure that your proxy servers, firewalls, and assets are configured properly. Adobe provides a deployment checklist that you can follow. For more information, see "Deployment checklist" on page 2548.

Remove wildcards

If your application relies on assets loaded from another domain, and that domain has a crossdomain.xml file on it, remove wildcards from that file if possible. For example, change the following:

```
<cross-domain-policy>
    <site-control permitted-cross-domain-policies="all"/>
    <allow-access-from domain="*" to-ports="*"/>
</cross-domain-policy>
```

to this:

```
<cross-domain-policy>
    <site-control permitted-cross-domain-policies="by-content-type"/>
    <allow-access-from domain="*.myserver.com" to-ports="80,443,8100,8080" />
</cross-domain-policy>
```

Also, set the value of the `to-ports` attribute of the `allow-access-from` tag to ensure that you are only allowing necessary ports access to the resources.

Check your application for calls to the `allowDomain()` and `allowInsecureDomain()` methods. During development, you might pass these methods a wildcard character (*), but now restrict those methods to allowing requests only from the necessary domains.

Deploy assets to WEB-INF

In some deployments, you want to make assets such as data files accessible to the application, but not accessible to anyone requesting the file. If you are using a J2EE-based server, you can deploy those files to a subdirectory within the WEB-INF directory. Based on J2EE security constraints, no J2EE server can return a resource from the WEB-INF directory to any client request. The only way to access files in this directory is with server-side code.

Loading assets

The most common task that developers perform that requires an understanding of security is loading external assets.

Data compared to content

The Flash Player security model makes a distinction between loading content and accessing or loading data. Content is defined as media: visual media that Flash Player can display, such as audio, video, or a SWF file that includes displayed media. Data is defined as something that you can manipulate only with ActionScript code.

You can load data in one of two ways: by extracting data from loaded media content, or by directly loading data from an external file (such as an XML file) or socket connection. You can extract data from loaded media by using the `BitmapData.draw()` method, the `Sound.id3` property, or the `SoundMixer.computeSpectrum()` method. You can load data by using classes such as the SWFLoader, URLStream, URLLoader, Socket, and XMLSocket classes.

The Flash Player security model defines different rules for loading content and accessing data. Loading content has fewer restrictions than accessing data. In general, content such as SWF files, bitmaps, MP3 files, and videos can be loaded from anywhere, but if the content is from a domain other than that of the loading SWF file, it will be partitioned in a separate security sandbox.

When you load sub applications into a main application with the SWFLoader control, the sandbox into which you load it determines the level of interoperability between the applications. For more information, see “About security domains” on page 179.

Loading remote assets

Loading remote or network assets relies on three factors:

- Type of asset. If the target asset is a content asset, such as an image file, you do not need any specific permissions from the target domain to load its assets into your application. If the target asset is a data asset, such as an XML file, you must have the target domain's permission to access this asset. For more information on the types of assets, see "Data compared to content" on page 124.
- Target domain. If you are loading data assets from a different web domain, the target domain must provide a crossdomain.xml policy file. This file contains a list of URLs and URL patterns that it allows access from. The calling domain must match one of the URLs or URL patterns in that list. If the target asset is a SWF file, you can also provide permissions by calling the `loadPolicyFile()` method and loading an alternative policy file inside that target SWF file. For more information, see "Using cross-domain policy files" on page 125.
- Loading SWF file's sandbox. To load an asset from a network address, you must ensure that your SWF file is in either the remote or local-with-networking sandbox. To ensure that a SWF file can load assets over the network, you must set the `use-network` compiler option to `true` when you compile the application. This is the default. If the application was loaded from the local file system with `use-network` set to `false`, the application is put in the local-with-filesystem sandbox and it cannot load remote SWF files.

Loading assets from a remote location that you do not control can potentially expose your users to risks. For example, the remote website B contains a SWF file that is loaded by your website A. This SWF file normally displays an advertisement. However, if website B is compromised and its SWF file is replaced with one that asks for a username and password, some users might disclose their login information. To prevent data submission, the loader has a property called `allowNetworking` with a default value of `never`.

Using cross-domain policy files

To make data available to SWF files in different domains, use a *cross-domain policy file*. A cross-domain policy file is an XML file that provides a way for the server to indicate that its data and documents are available to SWF files served from other domains. Any SWF file that is served from a domain that the server's policy file specifies is permitted to access data or assets from that server.

When a Flash document attempts to access data from another domain, Flash Player attempts to load a policy file from that domain. If the domain of the Flash document that is attempting to access the data is included in the policy file, the data is automatically accessible.

The default policy file is named crossdomain.xml and resides at the root directory of the server that is serving the data. The following example policy file permits access to Flash documents that originate from foo.com, friendOfFoo.com, *.foo.com, and 105.216.0.40:

```
<?xml version="1.0"?>
<!-- http://www.foo.com/crossdomain.xml -->
<cross-domain-policy>
    <site-control permitted-cross-domain-policies="by-content-type"/>
    <allow-access-from domain="www.friendOfFoo.com"/>
    <allow-access-from domain="*.foo.com"/>
    <allow-access-from domain="105.216.0.40"/>
</cross-domain-policy>
```

You can also configure ports in the crossdomain.xml file. For more information about crossdomain.xml policy files, see *Security*.

You can use the `loadPolicyFile()` method to access a nondefault policy file.

Loading local assets

In some cases, your SWF file might load assets that reside on the client's local file system. This typically happens when the application is embedded on the client device and loaded from a network. If the application is allowed to access local assets, it cannot access network assets.

To ensure that an application can access assets in the local sandbox, the application must be in the local-with-filesystem or local-trusted sandbox. To ensure this, you set the `use-network` compiler option to `false` when you compile the application. The default value of this option is `true`.

When you load another SWF file that is in the local file system into your application with a class such as SWFLoader, and you want to call methods or access properties of that SWF file, you do not need to explicitly enable cross-scripting.

If the SWF files are in different sandboxes (for example, you loaded the main SWF file into the local-with-network sandbox, but loaded the asset SWF file from the network), you cannot cross-script because they are in different sandboxes. Remote SWF files cannot load local SWF files, and vice versa.

Using J2EE authentication

Applications built with Flex integrates well with any server environment, including J2EE. To effectively implement secure web applications in a J2EE environment, you should understand the following concepts:

Authentication The process of gathering user credentials (user name and password) and validating them in the system. This requires checking the credentials against a user repository such as a database, flat file, or LDAP implementation, and authenticating that the user is who they say they are.

Authorization The process of making sure that the authenticated user is allowed to view or access a given resource. If a user is not authorized to view a resource, the container does not allow access.

Using container-based authentication

J2EE uses the Java Authentication and Authorization Service (JAAS), Java security manager, and policy files to enforce access controls on users and ties this enforcement to web server roles. The authenticating mechanism is role based. That is, all users who access a web application are assigned to one or more roles. Example roles are manager, developer, and customer.

Application developers can assign usage roles to a web application, or to individual resources that make up the application. Before a user is granted access to a web application resource, the container ensures that the user is identified (logged in) and that the user is assigned to a role that has access to the resource. Any unauthorized access of a web application results in an HTTP 401 (Unauthorized) status code.

Authentication requires a website to store information about users. This information includes the role or roles assigned to each user. In addition, websites that authenticate user access typically implement a login mechanism that forces verification of each user's identity by using a password. After the website validates the user, the website can then determine the user's roles.

This logic is typically implemented in one of the following forms:

- JDBC Login Module
- LDAP Login Module
- Windows Login Module
- Custom JAAS Login Module

Authentication occurs on a per-request basis. The container typically checks every request to a web application and authenticates it.

Authentication requires that the roles that the application developer defines for a web application be enforced by the server that hosts the application.

As part of developing and deploying an application, you must configure the following application authentication settings:

- Access roles to applications
- Resource protection
- Application server validation method

The web application's deployment descriptor, web.xml, contains the settings for controlling application authentication. This file is stored in the web application's WEB-INF directory.

Using authentication to control access to applications

To use authentication to prevent unauthorized access to your application, you typically use the container to set up constraints on resources. You then challenge the user who then submits credentials. These credentials determine the success or failure of the user's login attempt, as the container's authentication logic determines.

For example, you can protect the page that the application is returned with, or protect the SWF file itself. You do this in the web.xml file by defining specific URL patterns, as the following example shows:

```
<web-app>
    <security-constraint>
        <web-resource-collection>
            <web-resource-name>Payroll Application</web-resource-name>
                <url-pattern>/payroll/*</url-pattern>
                <http-method>GET</http-method>
                <http-method>POST</http-method>
            </web-resource-collection>
        <auth-constraint>
            <role-name>manager</role-name>
        </auth-constraint>
    </security-constraint>
</web-app>
```

When the browser tries to load a resource that is secured by constraints in the web.xml file, the browser either challenges the user (if you are using BASIC authentication) or forwards the user to a login page (with FORM authentication).

With BASIC authentication, the user enters a username and password in a popup box that the browser creates. To specify that an application uses BASIC authentication, you use the `login-config` element and its `auth-method` subelement in the web application's web.xml file, as the following example shows:

```
<web-app>
    <login-config>
        <auth-method>BASIC</auth-method>
        <realm-name>Managers</realm-name>
    </login-config>
    ...
</web-app>
```

With FORM authentication, you must code the page that accepts the username and password, and submit them as FORM variables named `j_username` and `j_password`. This form can be implemented in HTML or as an application or anything that can submit a form.

When you configure FORM authentication, you can specify both a login form and an error form in the web.xml file, as the following example shows:

```
<web-app>
    <login-config>
        <auth-method>FORM</auth-method>
        <form-login-config>
            <form-login-page>/login.htm</form-login-page>
            <form-error-page>/loginerror.htm</form-error-page>
        </form-login-config>
    </login-config>
</web-app>
```

You submit the results of the form validation to the `j_security_check` action. The server executing the application recognizes this action and processes the form.

A simple HTML-based form might appears as follows:

```
<form method="POST" action="j_security_check">
    <table>
        <tr><td>User</td><td><input type=text name="j_username"></tr>
        <tr><td>Password</td><td><input type=password name="j_password"></tr>
    </table>
    <input type=submit>
</form>
```

The results are submitted to the container's JAAS system with base-64 encoding, which means they can be read by anyone that can view the TCP/IP traffic. Use encryption to prevent these so-called "man-in-the-middle" attacks. In both BASIC and FORM authentication, if the user accessed the resource through SSL, the username and password submission are encrypted, as is all traffic during that exchange.

After it is complete, the container populates the browser's security context and provides or denies access to the resource. Flash Player inherits the security context of the underlying browser. As a result, when you make a data service call, the established credentials are used.

When a user fails an authentication attempt with invalid credentials, be sure not to return information about which item was incorrect. Instead, use a generic message such as "Your login information was invalid."

Using RPC services

You can use the RPC services classes—RemoteObject, HTTPService, and WebService—not only to control access to the data that goes into an application, but also to control the data and actions that flow out of it. You can also use service authentication to allow only certain users to perform certain actions. For example, if you have an application that allows employee data to be modified through a RemoteObject call, use RemoteObject authentication to make sure that only managers can change the employee data.

A service-based architecture makes it easy to implement several different security models for your application. You can use programmatic security to limit access to services, or you can apply declarative security constraints to entire services.

When accessing RPC services with Flex tags such as the `<mx:WebService>` and `<mx:HTTPService>` tags, your application's SWF file must connect to the service directly, which means that it can encounter security-based limitations. When using RPC services, one of the following must be true:

- The RPC is in the same domain as the application that calls it.
- The RPC's host system has a crossdomain.xml file that explicitly allows access from the application's domain.

Using secured services

Secured services are services that are protected by resource constraints. The service itself behaves as a resource that needs authentication and the container defines its URL pattern as requiring authorization.

You might have a protected application that calls a protected resource. In this case, with BASIC authentication and a proxied destination, the user's credentials are passed through to the service. The user only has to log on once when they first start the application, and not when the application attempts to access the service.

Without a proxy, the user is challenged to enter their credentials a second time when the application attempts to access the service.

When you use secured services, keep the following in mind:

- If possible, use HTTPS for your services when you use authentication. In BASIC and custom authentication, user names and passwords are sent in a base-64 encoding. Using base-64 encoding hides the data only from plain view; HTTPS actually encrypts the data. You can use HTTPS in these cases by making sure HTTPS is set up on your server and by adding a protocol attribute with the value `https` on the service, and by adding a crossdomain.xml file.
- To ensure that the WebService and HTTPService endpoints are secure, use a browser window to access the URL you are trying to secure. This should always bring up a BASIC authentication prompt.
- If the BASIC or custom login box appears but you can't log in, make sure that the users and roles were added correctly to your application server. This is often an error-prone task that is overlooked as the source of the problem.

Making other connections

Flash Player can connect to servers, services, and load data from sources other than RPC services. Some of these sources have security issues that you should consider.

Using RTMP

Flash Player uses the Real-Time Messaging Protocol (RTMP) for client-server communication. This is a TCP/IP protocol designed for high-performance transmission of audio, video, and data messages. RTMP sends unencrypted data, including authentication information (such as a name and a password).

Although RTMP in and of itself does not offer security features, Flash communications applications can perform secure transactions and secure authentication through an SSL-enabled web server.

RTMPT connections are HTTP connections for the client to the server over which RTMP data is tunneled. When a direct RTMP connection is unavailable, the standard and secure channels use RTMPT and tunneled RTMPS connections, respectively, on the RTMP endpoint.

Use the secure RTMP channel to connect to the RTMP endpoint over Transport Layer Security (TLS). This channel supports real-time messaging and server-pushed broadcasts. This channel falls back to tunneled RTMPS when a direct connection is unavailable.

Using sockets

Sockets let you read and write raw binary or XML data with a connected server. Sockets transmit over TCP. Because of this, Flash Player cannot take advantage of the built-in encryption capabilities of the browser. However, you can use encryption algorithms written in ActionScript to protect the data that is being communicated.

Cross-domain access to socket and XML socket connections is disabled by default. Access to socket connections in the same domain of the SWF file on ports lower than 1024 is also disabled by default. You can permit access to these connections by serving a cross-domain policy file from any of the following locations:

- The same port as the main socket connection
- A different port
- The HTTP server on port 80 in the same domain as the socket server

For more information, see the Socket and XMLSocket classes in ActionScript 3.0 Reference for the Adobe Flash Platform.

Using the LocalConnection class

The LocalConnection class lets you develop SWF files that can send instructions to each other. LocalConnection objects can communicate only among SWF files that are running on the same client computer, but they can be running in different applications—for example, a SWF file running in a browser and a SWF file running in a projector. (A projector is a SWF file saved in a format that can run as a stand-alone application—that is, the projector doesn't require Flash Player to be installed since it is embedded inside the executable file.)

For every LocalConnection communication, there is a sender SWF file and a listener SWF file. The simplest way to use a LocalConnection object is to allow communication only between LocalConnection objects located in the same domain because you won't have security issues.

Applications served from different domains that need to be able to make LocalConnection calls to each other must be granted cross-domain LocalConnection permissions. To do this, the listener must allow the sender permission by using the `LocalConnection.allowDomain()` or `LocalConnection.allowInsecureDomain()` methods.

Adobe does not recommend using the `LocalConnection.allowInsecureDomain()` method because allowing non-HTTPS documents to access HTTPS documents compromises the security offered by HTTPS. It is best that all Flash SWF files that make LocalConnection calls to HTTPS SWF files are served over HTTPS.

For more information about using the LocalConnection class, see *ActionScript 3.0 Developer's Guide*.

To facilitate SWF-to-SWF communication, you can also use cross-scripting. For more information, see "Cross-scripting" on page 121.

Using SSL

A SWF file playing in a browser has many of the same security concerns as an HTML page being displayed in a browser. This includes the security of the SWF file while it is being loaded into the browser, as well as the security of communication between Flash and the server after the SWF file has loaded and is playing in the browser. In particular, data communication between the browser and the server is susceptible to being intercepted by third parties. The solution to this issue in HTML is to encrypt the communication between the client and server to make any data captured by third parties undecipherable and thus unusable. This encryption is done by using an SSL-enabled browser and server.

Because a SWF file running within a browser uses the browser for almost all of its communication with the server, it can take advantage of the browser's built-in SSL support. This lets communication between the SWF file and the server be encrypted. Furthermore, the actual bytes of the SWF file are encrypted while they are being loaded into the browser. Thus, by playing a SWF file within an SSL-enabled browser through an HTTPS connection with the server, you can ensure that the communication between Flash Player and the server is encrypted and secure.

The one exception to this security is the way Flash Player uses persistent sockets (through the ActionScript XMLSocket object), which does not use the browser to communicate with the server. Because of this, SWF files that use sockets cannot take advantage of the built-in encryption capabilities of the browser. However, you can use one-way encryption algorithms written in ActionScript to encrypt the data being communicated.

MD5 is a one-way encryption algorithm described in RFC 1321. This algorithm has been ported to ActionScript, which enables developers to secure one-way data by using the MD5 algorithm before it is sent from the SWF file to the server. For more information about RFC 1321, see www.faqs.org/rfcs/rfc1321.html.

Using secure endpoints

To access HTTP services or web services through HTTPS, you can specify the protocols using “https” in the `wsdl` or `url` properties; for example:

```
<mx:WebService url="https://myservice.com" .../>
<mx:HTTPService wsdl="https://myservice.com" .../>
```

By default, a SWF file served over an unsecure protocol, such as HTTP, cannot access other documents served over the secure HTTPS protocol, even when those documents come from the same domain. As a result, if you loaded the SWF file over HTTP but want to connect to the service through HTTPS, you must add `secure="false"` in the crossdomain.xml file on the services’s server, as the following example shows:

```
<cross-domain-policy>
    <site-control permitted-cross-domain-policies="by-content-type"/>
    <allow-access-from domain="*.mydomain.com" secure="false"/>
</cross-domain-policy>
```

If you loaded the SWF file over HTTPS, you do not have to make any changes.

Writing secure applications

When you code an application, keep the following topics in mind to ensure that the application you write is as secure as possible.

MXML tags with security restrictions

Some MXML tags trigger operations that require security settings. Operations that trigger security checks include:

- Referencing a URL that is outside the exact domain of the application that makes a request.
- Referencing an HTTPS URL when the application that makes the request is not served over HTTPS.
- Referencing a resource that is in a different sandbox.

In these cases, access rights must be granted through one of the permission-granting mechanisms such as the `allowDomain()` method or a crossdomain.xml file.

MXML tags that can trigger security checks include:

- Any class that extends the Channel class.
- RPC-related tags that use channels such as `<mx:WebService>`, `<mx:RemoteObject>`, and `<mx:HTTPService>`.
- Messaging tags such as `<mx:Producer>` and `<mx:Consumer>`.
- The `<mx:DataService>` tag.
- Tags that load SWF files such as `<mx:SWFLoader>` and `<s:ModuleLoader>`.

In addition to these tags and their underlying classes, many Flash classes trigger security checks including ExternalInterface, Loader, NetStream, SoundMixer, URLLoader, and URLRequest.

Disabling viewSourceURL

If you enabled the view source feature by setting the value of the `viewSourceURL` property on the `<s:Application>` tag, you must be sure to remove it before you put your application into production.

This functionality applies only to Flash Builder users.

Remove sensitive information from SWF files

Applications built with Flash share many of the same concerns and issues as web pages when it comes to protecting the security of data. Because the SWF file format is an open format, you can extract data and algorithms contained within a SWF file. This is similar to how HTML and JavaScript code can be easily viewed by users. However, SWF files make viewing the code more difficult. A SWF file is compiled and is not human-readable like HTML or JavaScript.

But security is not obtained through obscurity. A number of third-party tools can extract data from compiled SWF files. As a result, do not consider that any data, variables, or ActionScript code compiled into an application are secure. You can use a number of techniques to secure sensitive information and still make it available for use in your SWF files.

To help ensure a secure environment, use the following general guidelines:

- Do not include sensitive information, such as user names, passwords, or SQL statements in SWF files.
- Do not use client-side username and password checks for authentication.
- Remove debug code, unused code, and comments from code before compiling to minimize the amount of information about your application that is available to someone with a decompiler or a debugger version of Flash Player.
- If your SWF file needs access to sensitive information, load the information into the SWF file from the server at run time. The data will not be part of the compiled SWF file and thus cannot be extracted by decompiling the SWF file. Use a secure transfer mechanism, such as SSL, when you load the data.
- Implement sensitive algorithms on the server instead of in ActionScript.
- Use SSL whenever possible.
- Only deploy your web applications from a trusted server. Otherwise, the server-side aspect of your application could be compromised.

Input validation

Input validation means ensuring that input is what it says it is or is what it is supposed to be. If your application is expecting name and address information, but it gets SQL commands, have a validation mechanism in your application that checks for and filters out SQL-specific characters and strings before passing the data to the execute method.

In many cases, you want users to provide input in TextInput, TextArea, and other controls that accept user input. If you use the input from these controls in operations inside the application, make sure that the input is free of possible malicious characters or code.

One approach to enforcing input validation is to use the validator classes. Validators ensure that the input conforms to a predetermined pattern. For example, the NumberValidator class ensures that a string represents a valid number. This validator can ensure that the input falls within a given range (specified by the `minValue` and `maxValue` properties), is an integer (specified by the `domain` property), is non-negative (specified by the `allowNegative` property), and does not exceed the specified precision.

In typical client-server environments, data validation occurs on the server after data is submitted to it from the client. One advantage of using validators in Flex is that they execute on the client, which lets you validate input data before transmitting it to the server. By using validators, you eliminate the need to transmit data to and receive error messages back from the server, which improves the overall responsiveness of your application.

You can also write your own ActionScript filters that remove potentially harmful code from input. Common approaches include stripping out dollar sign ($), quotation mark ("), semi-colon (;) and apostrophe (') characters because they have special meaning in most programming languages. Because Flex also renders HTML in some controls, also filter out characters that can be used to inject script into HTML, such as the left and right angle brackets ("<" and ">"), by converting these characters to their HTML entities "&lt;" and "&gt;". Also filter out the left and right parentheses ("("and ")") by translating them to "&#40;" and "&#41;", and the pound sign ("#") and ampersand ("&") by translating them to "&#35" (#) and "&#38" (&).

Another approach to enforcing input validation is to use strongly-typed, parameterized queries in your SQL code. This way, if someone tries to inject malicious SQL code into text that is used in a query, the SQL server will reject the query.

For more information on potentially harmful characters and conversion processes, see http://www.cert.org/tech_tips/malicious_code_mitigation.html.

For more information about validators, see "Validating Data" on page 1964.

ActionScript

Use some of the following techniques to try to make your use of ActionScript more secure.

Handling errors

The SecurityError exception is thrown when some type of security violation takes place. Security errors include:

- An unauthorized property access or method call was made across a security sandbox boundary.
- An attempt was made to access a URL not permitted by the security sandbox.
- A socket connection was attempted to an unauthorized port number, for example, a port below 1024, without a policy file present.
- An attempt was made to access the user's camera or microphone, and the request to access the device was denied by the user.

Flash Player dispatches SecurityErrorEvent objects to report the occurrence of a security error. Security error events are the final events dispatched for any target object. This means that any other events, including generic error events, are not dispatched for a target object that experiences a security error.

Your event listener can access the SecurityErrorEvent object's `text` property to determine what operation was attempted and any URLs that were involved, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- security/SecurityErrorExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script><![CDATA[
        import flash.net.URLLoader;
        import flash.net.URLRequest;
        import flash.events.SecurityErrorEvent;
        import mx.controls.Alert;
        private var loader:URLLoader = new URLLoader();

        private function triggerSecurityError():void {
            var request:URLRequest = new URLRequest("c:/temp/feeds.txt");

            // Triggers a security exception if you run this SWF from a server without
            // explicitly allowing local file-access permissions.
           try {
                loader.load(request);
           } catch (error:SecurityError) {
                Alert.show(error.name + ": " + error.message);
           }
        }
    ]]></fx:Script>
    <s:Button id="b1" label="Click Me To Trigger Security Error"
click="triggerSecurityError()"/>
</s:Application>
```

If no event listeners are present, the debugger version of Flash Player automatically displays an error message that contains the contents of the text property.

In general, try to wrap methods that might trigger a security error in a try/catch block. This prevents users from seeing information about destinations or other properties that you might not want to be visible.

Suppressing debug output

Flash Player writes debug output from a `trace()` method or the Logging API to a log file on the client. Any client can be running the debugger version of Flash Player. As a result, remove calls to the `trace()` method and Logging API calls that produce debugging output so that clients cannot view your logged information.

If you use the Logging API in your custom components and classes, set the value of the LogEventLevel to `NONE` before compilation, as the following example shows:

```
myTraceTarget.level = LogEventLevel.NONE;
```

For more information about the Logging API, see “Using the logging API” on page 2229.

Using host-based authentication

IP addresses and HTTP headers are sometimes used to perform host-based authentication. For example, you might check the `Referer` header or the client IP address to ensure that a request comes from a trusted source.

However, request headers such as Referer can be spoofed easily. This means that clients can pretend to be something they are not by settings headers or faking IP addresses. The solution to the problem of client spoofing is to not use HTTP header data as an authentication mechanism.

Using passwords

Using passwords in your application is a common way to protect resources from unauthorized access. Test the validity of the password on the server rather than the client, because the client has access to all the logic in the local SWF file.

Never store passwords locally. For example, do not store username and password combinations in local SharedObjects. These are stored in plain-text and unencrypted, just as cookie files are. Anyone with access to the user's computer can access the information inside a SharedObject.

To ensure that passwords are transmitted from the client to the server safely, enforce the use of SSL or some other secure transport-level protocol.

When you ask for a password in a TextArea or TextInput control, set the displayAsPassword property to true. This displays the password as asterisks as it is typed. This also prevents copy/paste operations from accessing the underlying characters in the text field.

Storing persistent data with the SharedObject class

Flash Player supports persistent shared objects through the SharedObject class. The SharedObject class stores data on users' computers. This data is usually local, meaning that it was obtained with the SharedObject.getLocal() method. You can also create persistent remote data with the SharedObject class; this requires Adobe® Flash® Media Server.

Each remote sandbox has an associated store of persistent SharedObject directory on the client. For example, when any SWF from domain1.com reads or writes data with the SharedObject class, Flash Player reads or writes that object in the domain1.com object store. Likewise for a SWF from domain2.com, Flash Player uses the domain2.com store. To avoid name collisions, the directory path defaults to the full path in the URL of the creating SWF file. This process can be shortened by using the localPath parameter of the SharedObject.getLocal() method, which allows other SWF files from the same domain to access a shared object after it is created.

Every domain has a maximum amount of data that a SharedObject class can save in the object store. This is an allocation of the user's disk space in which applications from that domain can store persistent data. Users can change the quota for a domain at any time by choosing Settings from the Flash Player context menu. When an application tries to store data with a SharedObject class that causes Flash Player to exceed its domain's quota, a dialog box appears, asking the user whether to increase the domain quota.

Configuring client security settings

Some security control features in Flash Player target user choices, and some target the modern corporate and enterprise environments, such as when the IT department would like to install Flash Player across the enterprise but has concerns about IT security and privacy. To help address these types of requirements, Flash Player provides various installation-time configuration choices. For example, some corporations do not want Flash Player to have access to the computer's audio and video hardware; other environments do not want Flash Player to have any read or write access to the local file system.

Three groups can make security choices: the application author (using developer controls), the administrative user (using administrator controls), and the local user (with user controls).

About the mm.cfg file

You configure the debugger version of Flash Player by using the settings in the mm.cfg text file. You must create this file when you first configure the debugger version of Flash Player.

The settings in this file let you enable or disable `trace()` logging, set the location of the `trace()` file's output, and configure client-side error and warning logging.

For more information, see "Editing the mm.cfg file" on page 2224.

About the mms.cfg file

The primary purpose for the security configuration file (mms.cfg) is to support the corporate and enterprise environments where the IT department wants to install Flash Player across the enterprise, while enforcing some common global security and privacy settings (supported with installation-time configuration choices).

On operating systems that support the concept of user security levels, the file is flagged as requiring system administrator (or root) permissions to modify or delete it. The following table shows the location of the mms.cfg file, depending on the operating system:

Operating System	**Location of mms.cfg file**
Macintosh OS X	/Library/Application Support/Macromedia
Windows XP/Vista	C:\WINDOWS\system32\Macromed\Flash
Windows 2000	C:\WINNT\System32\Macromed\Flash
Windows 95/98/ME	C:\WINDOWS\System\Macromed\Flash
Linux	/etc/adobe

You can use this file to configure security settings that deal with data loading, privacy, and local file access. The settings include:

- `FileDownloadDisable`
- `FileUploadDisable`
- `LocalStorageLimit`
- `AVHardwareDisable`

For a complete list of options and their descriptions, see http://www.adobe.com/go/fp9_admin.

About FlashPlayerTrust files

Flash Player provides a way for administrative users to register certain local files so that they are always loaded into the local-trusted sandbox. Often an installer for a native application or an application that includes many SWF files will do this. Depending on whether Flash Player will be embedded in a nonbrowser application, one of two strategies can be appropriate: register SWF files and HTML files to be trusted, or register applications to be trusted. Only applications that embed the browser plug-ins can be trusted—the stand-alone players and standard browsers do not check to see if they were trusted.

The installer creates files in a directory called FlashPlayerTrust. These files list paths of trusted files. This directory, known as the Global Flash Player Trust directory, is alongside the mms.cfg file, in the following location, which requires administrator access:

- Windows: system\Macromed\Flash\FlashPlayerTrust (for example, C:\winnt\system32\Macromed\Flash\FlashPlayerTrust)

- OS X: app support/Macromedia/FlashPlayerTrust (for example, /Library/Application Support/Macromedia/FlashPlayerTrust)

These settings affect all users of the computer. If an installer is installing an application for all users, the installer can register its SWF files as trusted for all users.

For more information about FlashPlayerTrust files, see http://www.adobe.com/devnet/flashplayer/articles/flash_player10_security_wp.html.

About the Settings Manager

The Settings Manager allows the individual user to specify various security, privacy, and resource usage settings for applications executing on their client computer. For example, the user can control application access to select facilities (such as their camera and microphone), or control the amount of disk space allotted to a SWF file's domain. The settings it manages are persistent and controlled by the user.

The user can indicate their personal choices for their Flash Player settings in a number of areas, either globally (for Flash Player itself and all applications built with Flash) or specifically (applying to specific domains only). To designate choices, the user can select from the six tab categories along the top of the Settings Manager dialog box:

- Global Privacy Settings
- Global Storage Settings
- Global Security Settings
- Flash Player Update Settings
- Privacy Settings for Individual Websites
- Storage Settings for Individual Websites

Access the Settings Manager for your Flash Player

1. Open an application in Flash Player.
2. Right-click and select Settings.

   The Adobe Flash Player Settings dialog box appears.
3. Select the Privacy tab (on the far left).
4. Click the Advanced button.

   Flash Player launches a new browser window and loads the Settings Manager help page.

Other resources

The following table lists resources that are useful in understanding the Flash Player security model and implementing security in your applications:

Modular applications

Modules quick start

Modules are SWF files that are similar to applications. You use modules to externalize functionality and load it only when it is needed. Applications can load and unload modules at run time, which can save start up time and memory because the applications can be smaller and download faster.

The most common use of modules is in a navigator container. Typically, each view in a navigator container is a module. When the user navigates to a new view, a new module is loaded.

You compile modules just as you would any application file. On the command line, you create a new module and compile it with the mxmlc compiler. In Flash Builder, you create a new module by selecting File > New > MXML Module.

Modules are MXML documents with `<s:Module>` as the root tag. Within that tag, you can use any child tags that you can use in a `<s:Application>` tag. The following examples shows two modules:

HorizontalLayoutModule.mxml:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- modules/mxmlmodules/HorizontalLayoutModule.mxml -->
<s:Module xmlns:fx="http://ns.adobe.com/mxml/2009"
          xmlns:s="library://ns.adobe.com/flex/spark"
          xmlns:mx="library://ns.adobe.com/flex/mx"
          minWidth="955" minHeight="600"
          >
    <fx:Declarations>
    </fx:Declarations>
    <fx:Style>
    </fx:Style>

    <fx:Script>
        <![CDATA[
        ]]>
    </fx:Script>
    <s:layout>
        <s:HorizontalLayout />
    </s:layout>
    <s:Label text="label three"/>
    <s:Button label="button three"/>
    <s:Label text="label four"/>
    <s:Button label="button four"/>
</s:Module>
```

VerticalLayoutModule.mxml:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- modules/mxmlmodules/VerticalLayoutModule.mxml -->
<s:Module xmlns:fx="http://ns.adobe.com/mxml/2009"
          xmlns:s="library://ns.adobe.com/flex/spark"
          xmlns:mx="library://ns.adobe.com/flex/mx"
          minWidth="955" minHeight="600">
    <fx:Declarations>
    </fx:Declarations>
    <fx:Style>
    </fx:Style>

    <fx:Script>
        <![CDATA[
        ]]>
    </fx:Script>
    <s:layout>
        <s:VerticalLayout />
    </s:layout>
    <s:Label text="label one"/>
    <s:TextInput />
    <s:Label text="label two"/>
    <s:TextArea/>
</s:Module>
```

To load modules in an application, you use a `<s:ModuleLoader>` tag inside a container. The container can be an MX container (such as a TabNavigator container), or a Spark container (such as a Group). The following example application uses a TabNavigator container:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- modules/SimpleLoader.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
               xmlns:s="library://ns.adobe.com/flex/spark"
               xmlns:mx="library://ns.adobe.com/flex/mx"
               minWidth="955" minHeight="600">

    <mx:TabNavigator width="500" height="300">
        <s:ModuleLoader label="Tab One" url="mxmlmodules/VerticalLayoutModule.swf"/>
        <s:ModuleLoader label="Tab Two" url="mxmlmodules/HorizontalLayoutModule.swf"/>
    </mx:TabNavigator>
</s:Application>
```

When the application first loads, Flash Player loads the first module in the first view of the container. When the user navigates to the second view of the container, Flash Player loads the second module.

The Spark ModuleLoader class implements the INavigatorContent interface. As a result, it provides some convenience properties for working with navigator containers. For example, you can use the `label` property to set a label on the tab in a TabNavigator container, or you can use the `icon` property to instead add an icon to the tab.

The ModuleLoader class also provides a `creationPolicy` property. You can use this property to instruct the application when to load the module.

Modular applications overview

About modules

Modules are SWF files that can be loaded and unloaded by an application. They cannot be run independently of an application, but any number of applications can share the modules.

Modules let you split your application into several pieces, or modules. The main application, or shell, can dynamically load other modules that it requires, when it needs them. It does not have to load all modules when it starts, nor does it have to load any modules if the user does not interact with them. When the application no longer needs a module, it can unload the module to free up memory and resources.

Modular applications have the following benefits:

- Smaller initial download size of the SWF file.
- Less memory use of overall application when modules are unloaded.
- Shorter load time due to smaller SWF file size.
- Better encapsulation of related aspects of an application. For example, a “reporting” feature can be separated into a module that you can then work on independently.

Modules and sub-applications are similar in many ways. Before deciding on an architecture for your applications, see the comparison of these two approaches in “Comparing loaded applications to modules” on page 187.

Benefits of modules

A module is a special type of dynamically loadable SWF file that contains an IFlexModuleFactory class factory. This allows an application to load code at run time and create class instances without requiring that the class implementations be linked into the main application.

Modules are similar to Runtime Shared Libraries (RSLs) in that they separate code from an application into separately loaded SWF files. Modules are very flexible because modules can be loaded and unloaded at run time and compiled without the application.

Two common scenarios in which using modules is beneficial are a large application with different user paths and a portal application.

An example of the first common scenario is an enormous insurance application that includes thousands of screens, for life insurance, car insurance, health insurance, dental insurance, travel insurance, and veterinary pet insurance.

By using a traditional approach to Rich Internet Application (RIA) design, you might build a monolithic application with a hierarchical tree of MXML classes. Memory use and start-up time for the application would be significant, and the SWF file size would grow with each new set of functionality.

When using this application, however, any user accesses only a subset of the screens. By refactoring the screens into small groups of modules that are loaded on demand, you can improve the perceived performance of the main application and reduce the memory use. Also, when the application is separated into modules, developers’ productivity may increase due to better encapsulation of design. When rebuilding the application, the developers also have to recompile only the single module instead of the entire application.

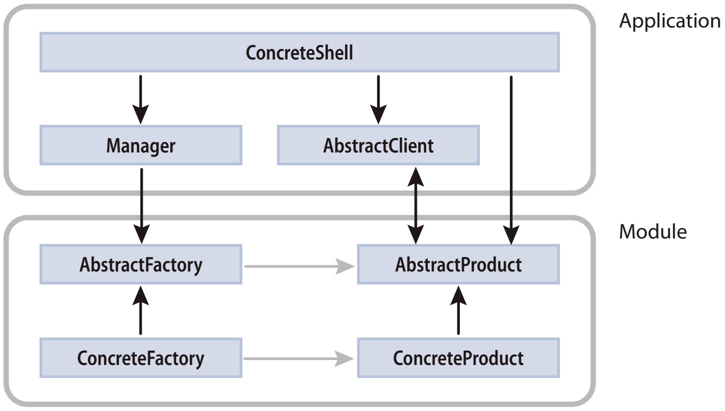
An example of the second common scenario is a system with a main portal application, written in ActionScript 3.0, that provides services for numerous portlets. Portlets are configured based on data that is downloaded on a per-user basis. By using the traditional approach, you might build an application that compiles in all known portlets. This is inefficient, both for deployment and development.

By using modules, you can establish an interface that contains portal services, and a generic portlet interface. You can use XML data to determine which modules to load for a given session. When the module is loaded, you obtain a handle to a class factory inside the module, and from that you create an instance of a class that implements the portlet interface. In this scenario, full recompilation is necessary only if the interfaces change.

Module API details

Modules implement a class factory with a standard interface. The product of that class factory implements an interface known to the shell, or the shell implements an interface known to the modules. These shared interfaces reduce hard dependencies between the shell and the module. This provides type-safe communication and enforces an abstraction layer without adding significantly to the SWF file size.

The following image shows the relationship between the shell and the module's interfaces:



The ModuleManager manages the set of loaded modules, which are treated as a map of Singletons that are indexed by the module URL. Loading a module triggers a series of events that let clients monitor the status of the module. Modules are only ever loaded once, but subsequent reloads also dispatch events so that client code can be simplified and rely on using the `READY` event to know that the module's class factory is available for use.

The ModuleLoader class is a thin layer on top of the ModuleManager API that is intended to act similarly to the mx.controls.SWFLoader class for modules that only define a single visual UIComponent. The ModuleLoader class is the easiest class to use when implementing a module-based architecture, but the ModuleManager provides greater control over the modules.

The ModuleLoader class implements the INavigatorContent interface so that it can be used directly by MX-based navigator containers (such as TabNavigator). The ModuleLoader class does not have any UI associated with it. All UI is defined by the module that it loads.

The Spark Module class extends the SkinnableContainer class. This means you can skin it and add visual components, including graphics, as children.

Module domains and sharing class libraries

By default, a module is loaded into a child domain of the current application domain. You can specify a different application domain by using the `applicationDomain` property of the ModuleLoader class.

Because a module is loaded into a child domain, it owns class definitions that are not in the main application's domain. For example, the first module to load the PopUpManager class becomes the owner of the PopUpManager class for the entire application because it registers the manager with the SingletonManager. If another module later tries to use the PopUpManager, Adobe ® Flash® Player throws an exception.

One solution is to use framework RSLs when compiling your applications and modules (RSLs are enabled by default). The definitions of the manager classes will be loaded in the framework RSL by the main application. Then, all the modules and sub-applications can share it. For more information about using framework RSLs with modules, see "Using RSLs with modules" on page 145.

If you do not use RSLs, the solution is to ensure that managers such as PopUpManager and DragManager and any other shared services are defined by the main application (or loaded late into the shell's application domain). When you promote one of those classes to the main application, the class can then be used by all modules. Typically, this is done by adding the following to a script block in the main application:

```
import mx.managers.PopUpManager;
import mx.managers.DragManager;
import mx.managers.ToolTipManager;
import mx.managers.CursorManager;
import mx.core.EmbeddedFontRegistry;

private var popUpManager:PopUpManager;
private var dragManager:DragManager;
private var tooltipManager:ToolTipManager;
private var cursorManager:CursorManager;
private var embeddedFontRegistry:EmbeddedFontRegistry;
```

You should only define these classes in your main application if your modules use the related functionality. For example, define the EmbeddedFontRegistry class in your main application if one or more of your modules uses embedded fonts.

This technique also applies to components. The module that first uses the component owns that component's class definition in its domain. As a result, if another module tries to use a component that has already been used by another module, its definition will not match the existing definition.

To avoid a mismatch of component definitions, create an instance of the component in the main application. The result is that the definition of the component is owned by the main application and can be used by modules in any child domain.

By default, modules do not share the main application's StyleManager, however. They have their own instances of the IStyleManager2 class. As a result, modules can define their own styles. For example, style properties set on a Button control in one module are not applied to the Button control in another module or to the main application.

Because a module must be in the same security domain as the application (SWF) that loads it, when you're using modules in an AIR application, any module SWF must be located in the same directory as the main application SWF or one of its subdirectories, which ensures that, like the main application SWF, the module SWF is in the AIR application security sandbox. One way to verify this is to ensure that a relative URL for the module's location doesn't require "../" ("up one level") notation to navigate outside the application directory or one of its subdirectories.

For more information about application domains, see "Developing and loading sub-applications" on page 176.

Create a modular application

To create a modular application, you create separate classes for each module, and an application that loads the modules. Adobe® Flash® Builder™ provides some mechanisms for making module use easier.

1 Create any number of modules. An MXML-based module file's root tag is `<s:Module>`. ActionScript-based modules extend either the Module or ModuleBase class.

2 Compile each module as if it were an application. You can do this by using the mxmlc command-line compiler or the compiler built into Adobe Flash Builder.

3 Create an Application class. This is typically an MXML file whose root tag is `<s:Application>`, but it can also be an ActionScript-only application.

4 In the Application file, use an `<s:ModuleLoader>` tag to load each of the modules. You can also load modules by using methods of the spark.modules.ModuleLoader and mx.modules.ModuleManager classes in ActionScript.

Using styles with modules

When you set styles on modules, the style properties are set on the local StyleManager. Each module has its own instance of the IStyleManager2 class. This means that each module can load its own set of styles, and its styles do not necessarily affect the styles of other modules.

After an application finishes loading a module, the module's styles are merged with the styles of the application. The module's StyleManager walks the chain of parent modules and applications, up to the top-level StyleManager, and merges its styles with those set on the StyleManagers above it.

If during a style merge, a module encounters a style that it already sets on itself, the style is ignored. If the module encounters a style not set on itself, the style is added to the merged style definition. The styles set on the StyleManager that is closest to the module wins.

The following example loads two modules. The main application sets the `color` and `cornerRadius` style properties on the Button control type selector. The modules each set the `color` property on the Button control type selector. The merged styles result in the Buttons having a corner radius of 10, with colors set by each module. This shows how style merges work.

```
<?xml version="1.0"?>
<!-- modules/StyleModLoaderApp.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Style>
        @namespace s "library://ns.adobe.com/flex/spark";
        s|Button {
            color:blue;
            cornerRadius:10;
        }
    </fx:Style>
    <s:VGroup>
        <s:Label id="l1" text="Module 1"/>
        <s:ModuleLoader id="ml1" url="mxmlmodules/StyleMod1.swf"/>
    </s:VGroup>
    <s:VGroup>
        <s:Label id="l2" text="Module 2"/>
        <s:ModuleLoader id="ml2" url="mxmlmodules/StyleMod2.swf"/>
    </s:VGroup>
    <s:Button id="myButton" label="Main App Button"/>
</s:Application>
```

Module 1:

```
<?xml version="1.0"?>
<!-- modules/mxmlmodules/StyleMod1.mxml -->
<s:Module
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Style>
        @namespace s "library://ns.adobe.com/flex/spark";
        s|Button {
            color:red;
        }
    </fx:Style>

    <s:Button label="StyleMod1"/>
</s:Module>
```

Module 2:

```
<?xml version="1.0"?>
<!-- modules/mxmlmodules/StyleMod2.mxml -->
<s:Module
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Style>
        @namespace s "library://ns.adobe.com/flex/spark";
        s|Button {
            color:green;
        }
    </fx:Style>

    <s:Button label="StyleMod2"/>
</s:Module>
```

To prevent style merges, set the `isolate-styles` compiler argument to `false`. By doing this, you might trigger type coercion errors when loading skins. Modules also might not be properly garbage collected when they are unloaded. This is because the main application's StyleManager will maintain references to the module even after is is unloaded. When you set `isolate-styes` to `false`, if more than one module loads a style, the first one loaded wins. In this case, styles set on modules can be overridden by those set on other modules.

In the previous example, if you set the `isolate-styles` compiler argument to `false`, the color of the Button controls' labels in both modules would be red, because that is definition that is first loaded.

The `getStyleDeclarations()` method returns only the local style definitions. To get the merged style definitions, you can use the `getMergedStyleDeclaration()` method. All methods that modify style definitions affect only the local style definitions and not the merged style definitions.

Style properties are merged when the module is loaded. This means that style properties set on the main application and all child applications and modules are set on the module if the module does not override that style. Merged styles are set on a per-property basis, starting with the closest StyleManager and working upwards to the top-level StyleManager.

Even when using merged styles, child modules still inherit their parent module or application's inheritable style properties when those settings are applied at runtime. Their StyleManager is not changed, but the values of the properties are inherited and applied where applicable. If you set a property at run time on the main application, the modules inherit that style immediately, as the following example shows:

```
<?xml version="1.0"?>
<!-- modules/StyleModLoaderApp2.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        /* When you set this style in the main application, the modules immediately
           inherit the value. */
        private function changeStyle():void {
            styleManager.getStyleDeclaration("spark.components.Button").setStyle("fontSize",
15);
        }
    </fx:Script>
    <fx:Style>
        @namespace s "library://ns.adobe.com/flex/spark";
        s|Button {
            color:blue;
            cornerRadius:10;
        }
    </fx:Style>
    <s:VGroup>
        <s:Label id="l1" text="Module 1"/>
        <s:ModuleLoader id="ml1" url="mxmlmodules/StyleMod1.swf"/>
    </s:VGroup>
    <s:VGroup>
        <s:Label id="l2" text="Module 2"/>
        <s:ModuleLoader id="ml2" url="mxmlmodules/StyleMod2.swf"/>
    </s:VGroup>
    <s:Button label="Change Styles" click="changeStyle()"/>
</s:Application>
```

For information on using run-time style sheets with modules, see “Using run-time style sheets with modules and sub-applications” on page 1554.

If you use run-time resource bundles with loaded modules, you should consider setting the `addResourceBundle()` method’s `useWeakReferences` parameter to `true`. For more information, see “Preventing memory leaks in modules and sub-applications” on page 2118.

Using RSLs with modules

Starting with Flex 4.5, modules work much more efficiently with RSLs. Modules will not load RSLs that the main application has already loaded, and modules can share RSLs with other modules.

The application only loads those framework RSLs that are needed at startup, and creates placeholders for all remaining framework RSLs. When a module is loaded, it does not try to load RSLs that are already loaded by the main application. If the module needs a framework RSL that is not initially loaded by the main application (and has a placeholder), then the module loads the RSL.

In addition, when a module loads an RSL, you can specify which domain the RSL is loaded into with the `application-domain` compiler argument. This lets you load an RSL into the parent, current, or top-level application domains. This applies to both framework RSLs and custom RLSs.

For more information about using modules and RSLs, see “Using RSLs with modules and sub-applications” on page 258.

Using pop-ups with modules

When using modules as pop-ups, you might not be able to click or drag the pop-up. The solution is to create a subclass of the pop-up (such as a TitleWindow container) that you use as the top-level MXML tag in the Module.

For more information, see Alex's Flex Closet.

Writing modules

Modules are classes just like application files. You can create them either in ActionScript or by extending a Flex class by using MXML tags. You can create modules in MXML and in ActionScript.

After you compile a module, you can load it into an application or another module. Typically, you use one of the following techniques to load MXML-based modules:

- ModuleLoader — The ModuleLoader class provides the highest-level API for handling modules. For more information, see “Using the ModuleLoader class to load modules” on page 150.
- ModuleManager — The ModuleManager class provides a lower-level API for handling modules than the ModuleLoader class does. For more information, see “Using the ModuleManager class to load modules” on page 152.

Creating MXML-based modules

To create a module in MXML, you extend the spark.modules.Module class by creating a file whose root tag is `<s:Module>`. In that tag, ensure that you add any namespaces that are used in that module. You must also include an XML type declaration tag at the beginning of the file, such as the following:

```
<?xml version="1.0"?>
```

The following example is a module that includes a Chart control:

```
<?xml version="1.0"?>
<!-- modules/ColumnChartModule.mxml -->
<s:Module
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    width="100%" height="100%" >

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script><![CDATA[
        import mx.collections.ArrayCollection;
        [Bindable]
        public var expenses:ArrayCollection = new ArrayCollection([
            {Month:"Jan", Profit:2000, Expenses:1500},
            {Month:"Feb", Profit:1000, Expenses:200},
            {Month:"Mar", Profit:1500, Expenses:500}
        ]);
    ]]></fx:Script>
    <mx:ColumnChart id="myChart" dataProvider="{expenses}">
        <mx:horizontalAxis>
           <mx:CategoryAxis
                dataProvider="{expenses}"
                categoryField="Month"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:ColumnSeries
                xField="Month"
                yField="Profit"
                displayName="Profit"/>
           <mx:ColumnSeries
                xField="Month"
                yField="Expenses"
                displayName="Expenses"/>
        </mx:series>
     </mx:ColumnChart>
     <mx:Legend dataProvider="{myChart}"/>
</s:Module>
```

After you create a module, you compile it as if it were an application. For more information on compiling modules, see “Compiling modules” on page 148.

Creating ActionScript-based modules

To create a module in ActionScript, you can create a file that extends either the spark.modules.Module class or the mx.modules.ModuleBase class.

Extending the Module class is the same as using the `<s:Module>` tag in an MXML file. You should extend this class if your module interacts with the framework; this typically means that it adds objects to the display list or otherwise interacts with visible objects.

To see an example of an ActionScript class that extends the Module class, create an MXML file with the root tag of `<s:Module>`. When you compile this file, set the value of the `keep-generated-actionscript` compiler property to `true`. The Flex compiler stores the generated ActionScript class in a directory called generated. You will notice that this generated class contains code that you probably will not understand. As a result, you should not write ActionScript-based modules that extend the Module class; instead, you should use MXML to write such modules.

If your module does not include any framework code, you can create a class that extends ModuleBase. If you use the ModuleBase class, your module will typically be smaller than if you use a module based on the Module class because it does not have any framework class dependencies.

The following example creates a simple module that does not contain any framework code and therefore extends the ModuleBase class:

```
// modules/asmodules/SimpleModule.as
package {
    import mx.modules.ModuleBase;
    public class SimpleModule extends ModuleBase {
        public function SimpleModule() {
            trace("SimpleModule created");
        }

        public function computeAnswer(a:Number, b:Number):Number {
            return a + b;
        }
    }
}
```

To call the `computeAnswer()` method on the ActionScript module, you can use one of the techniques shown in "Accessing modules from the parent application" on page 173.

Compiling modules

The way you compile modules is similar to the way you compile applications. On the command line, you use the mxmlc command-line compiler; for example:

```
mxmlc MyModule.mxml
```

In Flash Builder, you compile all modules in a project when you compile the main application in that project.

The result of compiling a module is a SWF file that you load into your application. You cannot run the module-based SWF file as a stand-alone application or load it into a browser window. It must be loaded by an application as a module. Modules should not be opened directly by Adobe® Flash® Player or Adobe® AIR,™ or requested through a browser directly.

When you compile your module, you should try to remove redundancies between the module and the application that uses it. To do this on the command line, you create a link report for the application, and then externalize any assets in the module that appear in that report. Flash Builder can do this for you automatically. For more information, see "Reducing module size" on page 148.

Reducing module size

Module size varies based on the components and classes that are used in the module. By default, a module externalizes all framework code that its components depend on by using RSLs. However, other custom classes and libraries are not externalized by default, which can cause modules to be larger than necessary by linking classes that overlap with the application's classes.

To reduce the size of the modules, you can optimize the module by instructing the compiler to externalize classes that are included by the application. This includes custom classes and framework classes. The result is that the module includes only the classes it requires, while the framework code and other dependencies are included in the application.

By default, Flash Builder optimizes modules by externalizing classes against the default application in the module's project. If your project has multiple applications, you might need to change the application that a module is compiled against. Otherwise, if you try to load a module that was compiled against one application into another application, you could get run time errors claiming that classes are not found.

If you want to use a module with more than one application, you might want to optimize it for no applications so that it contains all the class references necessary to run, regardless of the parent application.

Change the application that a module is optimized for in Flash Builder

1 Select Project > Properties.

2 Select Flex Modules.

3 Select the module in the list and click the Edit button.

4 To change the application that a module is optimized for, select the Optimize For Application option, and select the new application from the drop down list.

To not optimize the module for any application, select the Do Not Optimize option.

Create and use a linker report with the command-line compiler

To externalize framework classes with the command-line compiler, you generate a linker report from the application that loads the modules. You then use this report as input to the module's `load-externs` compiler option. The compiler externalizes all classes from the module for which the application contains definitions. This process is also necessary if your modules are in a separate project from your main application in Flash Builder.

1 Generate the linker report and compile the application:

```
mxmlc -link-report=report.xml MyApplication.mxml
```

The default output location of the linker report is the same directory as the compiler. In this case, it would be in the bin directory.

2 Compile the module and pass the linker report to the `load-externs` option:

```
mxmlc -load-externs=report.xml MyModule.mxml
```

Recompiling modules

If you change a module, you do not have to recompile the application that uses the module if that module is in the same project. This is because the application loads the module at run time and does not check against it at compile time. Similarly, if you make changes to the application, you do not have to recompile the module. Just as the application does not check against the module at compile time, the module does not check against the application until run time.

If the module is in a separate project than the application that loads it, you must recompile the module separately.

However, if you make changes that might affect the linker report or common code, you should recompile both the application and the modules.

***Note:** If you externalize the module's dependencies by using the `load-externs` or `optimize` option, your module might not be compatible with future versions of Adobe Flex. You might be required to recompile the module. To ensure that a future application can use a module, compile that module with all the classes it requires. This also applies to applications that you load inside other applications.*

Debugging modules

To debug an application that uses modules, you set the `debug` compiler option to `true` for the modules when you compile them. Otherwise, you will not be able to set breakpoints in the modules or gather other debugging information from them. In Flash Builder, debugging is enabled by default. On the command line, debugging is disabled by default. You must also set the `debug` option to `true` when you compile the application that loads the modules that you want to debug.

A common issue that occurs when using multiple modules is that modules sometimes own the class definitions that the other modules want to use. Because they are in sibling application domains, the module that loaded the class definition first owns the definition for that class, but other modules will experience errors when they try to use that class. The solution is to promote the class definition to the main application domain so that all modules can use the class. For more information, see "Module domains and sharing class libraries" on page 141.

Loading and unloading modules

There are several techniques you can use to load and unload modules in your applications. These techniques include:

- ModuleLoader — The ModuleLoader class provides the highest-level API for handling modules. For more information, see "Using the ModuleLoader class to load modules" on page 150.
- ModuleManager — The ModuleManager class provides a lower-level API for handling modules than the ModuleLoader class does. For more information, see "Using the ModuleManager class to load modules" on page 152.

When you're using modules in an AIR application, the module SWF file must be located in the same directory as the main application SWF file or one of its subdirectories.

Using the ModuleLoader class to load modules

You can use the ModuleLoader class to load a module in an application or other module. The easiest way to do this in an MXML application is to use the `<s:ModuleLoader>` tag. You set the value of the `url` property to point to the location of the module's SWF file. The following example loads the module when the application first starts:

```
<?xml version="1.0"?>
<!-- modules/MySimplestModuleLoader.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <s:ModuleLoader url="ColumnChartModule.swf"/>
</s:Application>
```

You can change the timing of when the module loads by setting the value of the `url` property at some other time, such as in response to an event. Setting the target URL of a ModuleLoader object triggers a call to the `loadModule()` method. This occurs when you first create a ModuleLoader object with the `url` property set. It also occurs if you change the value of that property.

If you set the value of the `url` property to an empty string (`""`) or `null`, the ModuleLoader object unloads the current module by calling the `release()` method.

You can have multiple instances of the ModuleLoader class in a single application. The following example loads the modules when the user navigates to the appropriate tabs in the TabNavigator container:

```
<?xml version="1.0"?>
<!-- modules/URLModuleLoaderApp.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:Panel title="Module Example" width="100%" height="100%">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>

        <mx:TabNavigator id="tn"
            paddingTop="10"
            paddingLeft="10"
            paddingRight="10"
            paddingBottom="10"
            width="100%" height="100%"
            creationPolicy="auto">
            <s:ModuleLoader id="ml1"
                label="ColumnChart Module"
                url="ColumnChartModule.swf"/>
            <s:ModuleLoader id="ml2"
                label="BarChart Module"
                url="BarChartModule.swf"/>
        </mx:TabNavigator>
    </s:Panel>
</s:Application>
```

You can also use the ModuleLoader API to load and unload modules with the `loadModule()` and `unloadModule()` methods. These methods take no parameters; the ModuleLoader class loads or unloads the module that matches the value of the current `url` property.

The following example loads and unloads the module when you click the button:

```
<?xml version="1.0"?>
<!-- modules/ASModuleLoaderApp.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
        import spark.modules.ModuleLoader;
        public function createModule(m:ModuleLoader, s:String):void {
            if (!m.url) {
                m.url = s;
            }
            m.loadModule();
        }

        public function removeModule(m:ModuleLoader):void {
            m.unloadModule();
        }
        ]]>
    </fx:Script>
    <s:Panel title="Module Example" width="100%" height="100%">
        <mx:TabNavigator id="tn"
            paddingTop="10"
            paddingLeft="10"
            paddingRight="10"
            paddingBottom="10"
            width="100%" height="100%"
            creationPolicy="auto">
            <s:NavigatorContent label="ColumnChartModule">
                <s:layout>
                    <s:VerticalLayout paddingTop="10" paddingLeft="5"/>
                </s:layout>
                <s:Button label="Load"
                    click="createModule(chartModuleLoader, l1.text)"/>
                <s:Button label="Unload"
                    click="removeModule(chartModuleLoader)"/>
                <s:Label id="l1" text="ColumnChartModule.swf"/>
                <s:ModuleLoader id="chartModuleLoader"/>
            </s:NavigatorContent>
            <s:NavigatorContent label="FormModule">
                <s:layout>
                    <s:VerticalLayout paddingTop="10" paddingLeft="5"/>
                </s:layout>
                <s:Button label="Load"
                    click="createModule(formModuleLoader, l2.text)"/>
                <s:Button label="Unload"
                    click="removeModule(formModuleLoader)"/>
                <s:Label id="l2" text="FormModule.swf"/>
                <s:ModuleLoader id="formModuleLoader"/>
            </s:NavigatorContent>
        </mx:TabNavigator>
    </s:Panel>
</s:Application>
```

When you load a module, Flex ensures that there is only one copy of a module loaded, no matter how many times you call the `load()` method for that module.

Using the ModuleManager class to load modules

You can use the ModuleManager class to load the module. This technique is less abstract than using the `<s:ModuleLoader>` tag, but it does provide you with greater control over how and when the module is loaded.

To use the ModuleManager to load a module in ActionScript:

1 Get a reference to the module's IModuleInfo interface by using the ModuleManager `getModule()` method.

2 Call the interface's `load()` method.

The application that loads the module should pass in its `moduleFactory` property. This lets the module know who its parent style manager is. When using the `load()` method, you can specify the application's `moduleFactory` with the fourth parameter, as the following example shows:

```
info.load(null, null, null, moduleFactory);
```

3 Use the `factory` property of the interface to call the `create()` method and cast the return value as the module's class. If you are adding the module to a container, you can cast the return value as an IVisualElement (for Spark containers) or a DisplayObject (for MX containers) so that they can be added to the display list.

The following example shell application loads the ColumnChartModule.swf file. The example then adds the modules to the display list so that it appears when the application starts:

```
<?xml version="1.0"?>
<!-- modules/ModuleLoaderApp.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    creationComplete="initApp()">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
        import mx.events.ModuleEvent;
        import mx.modules.ModuleManager;
        import mx.modules.IModuleInfo;
        import mx.core.IVisualElement;
        public var info:IModuleInfo;

        private function initApp():void {
            info = ModuleManager.getModule("ColumnChartModule.swf");
            info.addEventListener(ModuleEvent.READY, modEventHandler);
            /* Load the module into memory. Calling load() makes the
               IFlexModuleFactory available. You can then get an
               instance of the class using the factory's create()
               method. */
            info.load(null, null, null, moduleFactory);
        }
        /* Add an instance of the module's class to the display list. */
        private function modEventHandler(e:ModuleEvent):void {
            /* For MX containers, cast to a DisplayObject. */
            vb1.addChild(info.factory.create() as DisplayObject);
            /* For Spark containers, cast to a UIComponent. */
            vg1.addElement(info.factory.create() as IVisualElement);
        }
        ]]>
    </fx:Script>
    <!-- MX container -->
    <mx:VBox id="vb1">
        <s:Label text="Module loaded in MX VBox container:"/>
    </mx:VBox>
    <!-- Spark container -->
    <s:VGroup id="vg1">
        <s:Label text="Module loaded in Spark VGroup container:"/>
    </s:VGroup>
</s:Application>
```

The IModuleInfo class's `load()` method also optionally takes an ApplicationDomain and a SecurityDomain as arguments. If you do not specify either of these (or set them to `null`), then the module is loaded into a new child domain.

MXML-based modules can load other modules. Those modules can load other modules, and so on.

Be sure to define the module instance outside of a function, so that it is not in the function's local scope. Otherwise, the object might be garbage collected and the associated event listeners might never be invoked.

If you remove all references to the module, it will be garbage collected. You do not need to call the `unload()` method when adding and removing modules using the IModuleInfo class. You just need to set the IModuleInfo instance to `null`.

Loading modules from different servers

To load a module from one server into an application running on a different server, you must establish trust between the module and the application that loads it.

Access applications across domains

1 In your loading application, you must call the `allowDomain()` method and specify the target domain from which you load a module. So, specify the target domain in the preinitialize event handler of your application to ensure that the application is set up before the module is loaded.

2 In the cross-domain file of the remote server where your module is, add an entry that specifies the server on which the loading application is running.

3 Load the cross-domain file on the remote server in the preinitialize event handler of your loading application.

4 In the loaded module, call the `allowDomain()` method so that it can communicate with the loader.

The following example shows the `init()` method of the loading application:

```
public function setup():void {
    Security.allowDomain("remoteservername");
    Security.loadPolicyFile("http://remoteservername/crossdomain.xml");
    var request:URLRequest = new URLRequest("http://remoteservername/crossdomain.xml");
    var loader:URLLoader = new URLLoader();
    loader.load(request);
}
```

The following example shows the loaded module's `init()` method:

```
public function initMod():void {
    Security.allowDomain("loaderservername");
}
```

The following example shows the cross-domain file that resides on the remote server:

```
<!-- crossdomain.xml file located at the root of the server -->
<cross-domain-policy>
    <site-control permitted-cross-domain-policies="all"/>
    <allow-access-from domain="loaderservername" to-ports="*"/>
</cross-domain-policy>
```

For more information about using the cross-domain policy file, see "Security" on page 117.

Preloading modules

When you first start an application that uses modules, the application's file size should be smaller than a similar application that does not use modules. As a result, there should be a reduction in wait time because the application can be loaded into memory and run before the modules' SWF files are even transferred across the network. However, there will be a delay when the user navigates to a part in the application that uses the module. This is because the modules are not by default preloaded, but rather loaded when they are first requested.

When a module is loaded by the application for the first time, the module's SWF file is transferred across the network and stored in the browser's cache. If the application unloads that module, but then later reloads it, there should be less wait time because Flash Player loads the module from the cache rather than across the network.

Module SWF files, like all SWF files, reside in the browser's cache unless and until a user clears them. As a result, modules can be loaded by the main application across several sessions, reducing load time; but this depends on how frequently the browser's cache is flushed.

You can preload modules at any time so that you can have the modules' SWF files in memory even if the module is not currently being used.

To preload modules on application startup, use the IModuleInfo class `load()` method. This loads the module into memory but does not create an instance of the module.

The following example loads the BarChartModule.swf module when the application starts up, even though it will not be displayed until the user navigates to the second pane of the TabNavigator container. Without preloading, the user would wait for the SWF file to be transferred across the network when they navigated to the second pane of the TabNavigator.

```
<?xml version="1.0"?>
<!-- modules/PreloadModulesApp.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    creationComplete="preloadModules()">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
        import mx.events.ModuleEvent;
        import mx.modules.ModuleManager;
        import mx.modules.IModuleInfo;

        private function preloadModules():void {
            /* Get a reference to the module's interface. */
            var info:IModuleInfo =
                ModuleManager.getModule("BarChartModule.swf");
            info.addEventListener(ModuleEvent.READY, modEventHandler);

            /* Load the module into memory. The module will be
               displayed when the user navigates to the second
               tab of the TabNavigator. */
            info.load();
        }
        private function modEventHandler(e:ModuleEvent):void {
            trace("module event: " + e.type); // "ready"
        }
        ]]>
    </fx:Script>
    <s:Panel title="Module Example" width="100%" height="100%">
        <mx:TabNavigator id="tn"
            paddingTop="10"
            paddingLeft="10"
            paddingRight="10"
            paddingBottom="10"
            width="100%" height="100%"
            creationPolicy="auto">
            <s:ModuleLoader label="ColumnChartModule"
                url="ColumnChartModule.swf"/>
            <s:ModuleLoader label="BarChartModule"
                url="BarChartModule.swf"/>
        </mx:TabNavigator>
    </s:Panel>
</s:Application>
```

Using ModuleLoader events

The ModuleLoader class triggers several events, including `setup`, `ready`, `loading`, `unload`, `progress`, `error`, and `urlChanged`. You can use these events to track the loading process, and find out when a module has been unloaded or when the ModuleLoader target URL has changed.

The following example uses a custom ModuleLoader component. This component reports all the events of the modules as they are loaded by the main application.

Custom ModuleLoader:

```
<?xml version="1.0" encoding="iso-8859-1"?>
<!-- modules/CustomModuleLoader.mxml -->
<s:ModuleLoader
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns="*"
    creationComplete="init()">

  <fx:Script>
    <![CDATA[
        import mx.core.UIComponent;

        public var standin:UIComponent;
        public function init():void {
            addEventListener("urlChanged", onUrlChanged);
            addEventListener("loading", onLoading);
            addEventListener("progress", onProgress);
            addEventListener("setup", onSetup);
            addEventListener("ready", onReady);
            addEventListener("error", onError);
            addEventListener("unload", onUnload);
            standin = panel;
            removeElement(standin);
        }
```

```
public function onUrlChanged(event:Event):void {
    if (url == null) {
        if (contains(standin))
            removeElement(standin);
    } else {
        if (!contains(standin))
            addElement(standin);
    }
    progress.indeterminate=true;
    unload.enabled=false;
    reload.enabled=false;
}
public function onLoading(event:Event):void {
    progress.label="Loading module " + url;
    if (!contains(standin))
        addElement(standin);
    progress.indeterminate=true;
    unload.enabled=false;
    reload.enabled=false;
}
public function onProgress(event:Event):void {
    progress.label="Loaded %1 of %2 bytes...";
    progress.indeterminate=false;
    unload.enabled=true;
    reload.enabled=false;
}
public function onSetup(event:Event):void {
    progress.label="Module " + url + " initialized!";
    progress.indeterminate=false;
    unload.enabled=true;
    reload.enabled=true;
}
public function onReady(event:Event):void {
    progress.label="Module " + url + " successfully loaded!";
    unload.enabled=true;
    reload.enabled=true;
    if (contains(standin))
        removeElement(standin);
}
public function onError(event:Event):void {
    progress.label="Error loading module " + url;
    unload.enabled=false;
    reload.enabled=true;
}
public function onUnload(event:Event):void {
    if (url == null) {
        if (contains(standin))
            removeElement(standin);
    } else {
        if (!contains(standin))
```

```
                    addElement(standin);
            }
            progress.indeterminate=true;
            progress.label="Module " + url + " was unloaded!";
            unload.enabled=false;
            reload.enabled=true;
        }
    ]]>
  </fx:Script>
  <s:Panel id="panel" width="100%" title="Status &amp; Operations">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <mx:ProgressBar width="100%" id="progress" source="{this}"/>
    <s:HGroup width="100%">
      <s:Button id="unload" label="Unload Module" click="unloadModule()"/>
      <s:Button id="reload" label="Reload Module" click="unloadModule();loadModule()"/>
    </s:HGroup>
  </s:Panel>
</s:ModuleLoader>
```

Main application:

```
<?xml version="1.0"?>
<!-- modules/EventApp.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns="*">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            [Bindable]
            public var selectedModule:Object;
        ]]>
    </fx:Script>
    <s:ComboBox width="215" labelField="label" prompt="Select Coverage"
        close="selectedModule=ComboBox(event.target).selectedItem">
        <s:dataProvider>
            <s:ArrayCollection>
```

```
                <fx:Object label="Life Insurance"
                    module="insurancemodules/LifeInsurance.swf"/>
                <fx:Object label="Auto Insurance"
                    module="insurancemodules/AutoInsurance.swf"/>
                <fx:Object label="Home Insurance"
                    module="insurancemodules/HomeInsurance.swf"/>
            </s:ArrayCollection>
        </s:dataProvider>
    </s:ComboBox>
    <s:Panel width="100%" height="100%" title="Custom Module Loader">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <CustomModuleLoader id="mod" width="100%" url="{selectedModule.module}"/>
    </s:Panel>
    <s:HGroup>
        <s:Button label="Unload" click="mod.unloadModule()"/>
        <s:Button label="Nullify" click="mod.url=null"/>
    </s:HGroup>
</s:Application>
```

The insurance modules used in this example are simple forms, such as the following:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- modules/insurancemodules/AutoInsurance.mxml -->
<s:Module
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    backgroundColor="#ffffff"
    width="100%" height="100%">
    <s:Label x="147" y="50" text="Auto Insurance"
        fontSize="28" fontFamily="Myriad Pro"/>
    <s:Form left="47" top="80">
        <s:FormHeading label="Coverage"/>
        <s:FormItem label="Latte Spillage">
            <s:TextInput id="latte" width="200"/>
        </s:FormItem>
        <s:FormItem label="Shopping Cart to the Door">
            <s:TextInput id="cart" width="200"/>
        </s:FormItem>
        <s:FormItem label="Irate Moose">
            <s:TextInput id="moose" width="200"/>
        </s:FormItem>
        <s:FormItem label="Color Fade">
            <mx:ColorPicker/>
        </s:FormItem>
    </s:Form>
</s:Module>
```

Using the error event

The `error` event gives you an opportunity to gracefully fail when a module does not load for some reason. In the following example, you can load and unload a module by using the Button controls. To trigger an `error` event, change the URL in the TextInput control to a module that does not exist. The error handler displays a message to the user and writes the error message to the trace log.

```
<?xml version="1.0"?>
<!-- modules/ErrorEventHandler.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout
                paddingTop="10"
                paddingLeft="10"
                paddingRight="10"
                paddingBottom="10"/>
    </s:layout>
    <fx:Script>
        <![CDATA[
        import mx.events.ModuleEvent;
        import spark.modules.ModuleLoader;
        import spark.modules.Module;
        import mx.controls.Alert;

        private function errorHandler(e:ModuleEvent):void {
            Alert.show("There was an error loading the module." +
                " Please contact the Help Desk.\n" +
                e.errorText);
        }

        public function createModule():void {
            if (chartModuleLoader.url == ti1.text) {
                /* If they are the same, call the loadModule() method. */
                chartModuleLoader.loadModule();
            } else {
                /* If they are not the same, then change the url,
                   which then triggers a call to the loadModule() method. */
                chartModuleLoader.url = ti1.text;
            }
        }

        public function removeModule():void {
            chartModuleLoader.unloadModule();
        }
        ]]>
    </fx:Script>
    <s:Panel title="Module Example" height="90%" width="90%">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <s:HGroup>
            <s:Label text="URL:"/>
            <s:TextInput width="200" id="ti1" text="ColumnChartModule.swf"/>
            <s:Button label="Load" click="createModule()"/>
            <s:Button label="Unload" click="removeModule()"/>
        </s:HGroup>
        <s:ModuleLoader id="chartModuleLoader" error="errorHandler(event)"/>
    </s:Panel>
</s:Application>
```

Using the progress event

You can use the progress event to track the progress of a module as it loads. When you add a listener for the progress event, Flex calls that listener at regular intervals during the module's loading process. Each time the listener is called, you can look at the bytesLoaded property of the event. You can compare this to the bytesTotal property to get a percentage of completion.

The following example reports the level of completion during the module's loading process. It also produces a simple progress bar that shows users how close the loading is to being complete.

```
<?xml version="1.0"?>
<!-- modules/SimpleProgressEventHandler.mxml -->
<s:Application
    creationComplete="initApp()"
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
        import mx.events.ModuleEvent;
        import flash.events.ProgressEvent;
        import spark.modules.Module;
        import spark.modules.ModuleLoader;

        [Bindable]
        public var progBar:String = "";
        [Bindable]
        public var progMessage:String = "";

        private function progressEventHandler(e:ProgressEvent):void {
            progBar += ".";
            progMessage =
                "Module " +
                Math.round((e.bytesLoaded/e.bytesTotal) * 100) +
                "% loaded";
        }
        public function initApp():void {
            chartModuleLoader.url = "ColumnChartModule.swf";
        }
        public function createModule():void {
            chartModuleLoader.loadModule();
        }

        public function removeModule():void {
            chartModuleLoader.unloadModule();
            progBar = "";
            progMessage = "";
        }
        ]]>
    </fx:Script>
    <s:Panel title="Module Example" height="90%" width="90%">
        <s:layout>
            <s:VerticalLayout
                paddingTop="10" paddingLeft="10"
                paddingRight="10" paddingBottom="10"/>
        </s:layout>
        <s:HGroup>
            <s:Label id="l2" text="{progMessage}"/>
            <s:Label id="l1" text="{progBar}"/>
        </s:HGroup>
        <s:Button label="Load" click="createModule()"/>
        <s:Button label="Unload" click="removeModule()"/>
        <s:ModuleLoader id="chartModuleLoader"
            progress="progressEventHandler(event)"/>
    </s:Panel>
</s:Application>
```

You can also connect a module loader to a ProgressBar control. The following example creates a custom component for the ModuleLoader that includes a ProgressBar control. The ProgressBar control displays the progress of the module loading.

```
<?xml version="1.0"?>
<!-- modules/MySimpleModuleLoader.mxml -->
<s:ModuleLoader
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            private function clickHandler():void {
                if (!url) {
                    url="ColumnChartModule.swf";
                }
                loadModule();
            }
        ]]>
    </fx:Script>
    <mx:ProgressBar id="progress" width="100%" source="{this}"/>
    <s:HGroup width="100%">
      <s:Button id="load" label="Load" click="clickHandler()"/>
      <s:Button id="unload" label="Unload" click="unloadModule()"/>
      <s:Button id="reload" label="Reload" click="unloadModule();loadModule();"/>
    </s:HGroup>
</s:ModuleLoader>
```

You can use this module in a simple application, as the following example shows:

```
<?xml version="1.0"?>
<!-- modules/ComplexProgressEventHandler.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:local="*">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:Panel title="Module Example" height="90%" width="90%">
        <s:layout>
            <s:VerticalLayout
                paddingTop="10" paddingLeft="10"
                paddingRight="10" paddingBottom="10"/>
        </s:layout>
        <s:Label text="Use the buttons below to load and unload the module."/>
        <local:MySimpleModuleLoader id="customLoader"/>
    </s:Panel>

</s:Application>
```

This example does not change the ProgressBar `label` property for all events. For example, if you load and then unload the module, the `label` property remains at "LOADING 100%". To adjust the label properly, you must define other event handlers for the ModuleLoader events, such as `unload` and `error`.

Passing data to modules

Communication between modules and the parent application, and among modules, is possible. You can use the following approaches to facilitate inter-module, application-to-module, and module-to-application communication:

- Interfaces — You can create ActionScript interfaces that define the methods and properties that modules and applications can access. This gives you greater control over module and application interaction. It also prevents you from creating dependencies between modules and applications. For more information, see “Using interfaces for module communication” on page 164.
- Query string parameters — Modules are loaded with a URL; you can pass parameters on this URL and then parse those parameters in the module. This is only a way to pass simple data, and is not appropriate for complex data. For more information, see “Passing data to modules with the query string” on page 166.
- ModuleLoader`'s child`, ModuleManager ‘s `factory`, and Application’s `parentApplication` properties — You can use these properties to access modules and applications. However, by using these properties, you create a tightly-coupled design that prevents code reuse and is easily broken. In addition, you also create dependencies among modules and applications that cause class sizes to be bigger. For more information, see “Accessing modules from the parent application” on page 173, “Accessing the parent application from modules” on page 169, and “Accessing modules from other modules” on page 171.

The following techniques for accessing methods and properties apply to parent applications as well as modules. Modules can load other modules, which makes the loading module similar to the parent application in the simpler examples.

Using interfaces for module communication

You can use an interface to provide module-to-application communication. Your modules implement the interface and your application calls its methods or sets its properties. The interface defines stubs for the methods and properties that you want the application and module to share. The module implements an interface known to the application, or the application implements an interface known to the module. This lets you avoid so-called hard dependencies between the module and the application.

In the main application, when you want to call methods on the module, you cast the ModuleLoader class's `child` property to an instance of the custom interface.

The following example application lets you customize the appearance of the module that it loads by calling methods on the custom IModuleInterface interface. The application also calls the `getModuleName()` method. This method returns a value from the module and sets a local property to that value.

```
<?xml version="1.0"?>
<!-- modules/interfaceexample/MainModuleApp.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns="*">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import mx.events.ModuleEvent;
            import mx.modules.ModuleManager;

            [Bindable]
            public var selectedItem:Object;
            [Bindable]
            public var currentModuleName:String;

            private function applyModuleSettings(e:Event):void {
                /* Cast the ModuleLoader's child to the interface.
                   This child is an instance of the module.
                   You can now call methods on that instance. */
                var ichild:* = mod.child as IModuleInterface;
                if (mod.child != null) {
                    /* Call setters in the module to adjust its
                       appearance when it loads. */
                    ichild.setAdjusterID(myId.text);
                    ichild.setBackgroundColor(myColor.selectedColor);
                } else {
                    trace("Uh oh. The mod.child property is null");
                }
                /* Set the value of a local variable by calling a method
                   on the interface. */
                currentModuleName = ichild.getModuleName();
            }

            private function reloadModule():void {
                // Reset the ColorPicker control:
                myColor.selectedColor = 0xFFFFFF;
                // Reload the module:
                mod.unloadModule();
                mod.loadModule();
            }
        ]]>
    </fx:Script>

    <s:Form>
        <s:FormItem label="Current Module:">
            <s:Label id="l1" text="{currentModuleName}"/>
        </s:FormItem>
        <s:FormItem label="Adjuster ID:">
            <s:TextInput id="myId" text="Enter your ID"/>
        </s:FormItem>
        <s:FormItem label="Background Color:">
            <mx:ColorPicker id="myColor"
                selectedColor="0xFFFFFF"
                change="applyModuleSettings(event)"/>
        </s:FormItem>
    </s:Form>

    <s:Label text="Long Shot Insurance" fontSize="24"/>
    <s:ComboBox labelField="label" prompt="Select Module"
        close="selectedItem=ComboBox(event.target).selectedItem">
        <s:dataProvider>
            <s:ArrayList>
                <fx:Object label="Auto Insurance" module="AutoInsurance2.swf"/>
            </s:ArrayList>
        </s:dataProvider>
    </s:ComboBox>
    <s:Panel width="100%" height="100%">
        <s:ModuleLoader id="mod"
            width="80%" height="80%"
            url="{selectedItem.module}"
            ready="applyModuleSettings(event)"/>
    </s:Panel>
    <s:Button id="b1" label="Reload Module" click="reloadModule()"/>
</s:Application>
```

The following example defines a simple interface that has two getters and one setter. This interface is used by the application in the previous example.

```
// modules/interfaceexample/IModuleInterface.as
package
{
    import flash.events.IEventDispatcher;
    public interface IModuleInterface extends IEventDispatcher {

        function getModuleName():String;
        function setAdjusterID(s:String):void;
        function setBackgroundColor(n:Number):void;
    }
}
```

The following example defines the module that is loaded by the previous example. It implements the custom IModuleInterface interface.

```
<?xml version="1.0"?>
<!-- modules/interfaceexample/AutoInsurance2.mxml -->
<s:Module
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    width="100%" height="100%" implements="IModuleInterface">

    <s:Panel id="p1" title="Auto Insurance"
        width="100%" height="100%"
        backgroundColor="{bgcolor}">
        <s:Label id="myLabel" text="ID: {adjuster}"/>
    </s:Panel>
    <fx:Script>
        <![CDATA[
            [Bindable]
            private var adjuster:String;
            [Bindable]
            private var bgcolor:Number;
            public function setAdjusterID(s:String):void {
                adjuster = s;
            }

            public function setBackgroundColor(n:Number):void {
                /* Use a bindable property to set values of controls
                   in the module. This ensures that the property will be set
                   even if Flex applies the property after the module is
                   loaded but before it is rendered by the player. */
                bgcolor = n;

                /* Don't do this. The backgroundColor style might not be set
                   by the time the ModuleLoader triggers the READY
                   event: */
                // p1.setStyle("backgroundColor", n);
            }

            public function getModuleName():String {
                return "Auto Insurance";
            }
        ]]>
    </fx:Script>
</s:Module>
```

In general, if you want to set properties on controls in the module by using external values, you should create variables that are bindable. You then set the values of those variables in the interface's implemented methods. If you try to set properties of the module's controls directly by using external values, the controls might not be instantiated by the time the module is loaded and the attempt to set the properties might fail.

Passing data to modules with the query string

One way to pass data to a module is to append query string parameters to the URL that you use to load the module. You can then parse the query string by using ActionScript to access the data.

In the module, you can access the URL by using the `loaderInfo` property. This property points to the LoaderInfo object of the loading SWF (in this case, the main application). The information provided by the LoaderInfo object includes load progress, the URLs of the loader and loaded content, the file size of the application, and the height and width of the application.

The following example application builds a unique query string for the module that it loads. The query string includes a `firstName` and `lastName` parameter.

```
<?xml version="1.0"?>
<!-- modules/QueryStringApp.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    height="500" width="400">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            public function initModule():void {
                // Build query string so that it looks something like this:
                // "QueryStringModule.swf?firstName=Nick&lastName=Danger"
                var s:String = "QueryStringModule.swf?" + "firstName=" +
                    ti1.text + "&lastName=" + ti2.text;
                // Changing the url property of the ModuleLoader causes
                // the ModuleLoader to load a new module.
                m1.url = s;
            }
        ]]>
    </fx:Script>
    <s:Form>
        <s:FormItem id="fi1" label="First Name:">
            <s:TextInput id="ti1"/>
        </s:FormItem>
        <s:FormItem id="fi2" label="Last Name:">
            <s:TextInput id="ti2"/>
        </s:FormItem>
    </s:Form>
    <s:ModuleLoader id="m1"/>

    <s:Button id="b1" label="Submit" click="initModule()"/>
</s:Application>
```

The following example module parses the query string that was used to load it. If the `firstName` and `lastName` parameters are set, the module prints the results in a TextArea. The module also traces some additional information available through the LoaderInfo object:

```
<?xml version="1.0"?>
<!-- modules/QueryStringModule.mxml -->
<s:Module
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    creationComplete="parseString()">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import mx.utils.*;
            [Bindable]
            private var salutation:String;

            public var o:Object = {};

            public function parseString():void {
                try {
                    /* Remove everything before the question mark, including
                       the question mark. */
                    var myPattern:RegExp = /.*\?/;
                    var s:String = this.loaderInfo.url.toString();
                    s = s.replace(myPattern, "");
                    /* Create an Array of name=value Strings. */
                    var params:Array = s.split("&");

                    /* Print the params that are in the Array. */
                    var keyStr:String;
                    var valueStr:String;
                    var paramObj:Object = params;
                    for (keyStr in paramObj) {
                        valueStr = String(paramObj[keyStr]);
                        ta1.text += keyStr + ":" + valueStr + "\n";
                    }
                    /* Set the values of the salutation. */
                    for (var i:int = 0; i < params.length; i++) {
                        var tempA:Array = params[i].split("=");
                        if (tempA[0] == "firstName") {
                            o.firstName = tempA[1];
                        }
                        if (tempA[0] == "lastName") {
                            o.lastName = tempA[1];
                        }
                    }
                    if (StringUtil.trim(o.firstName) != "" &&
                        StringUtil.trim(o.lastName) != "") {
                            salutation = "Welcome " +
                            o.firstName + " " + o.lastName + "!";
                    } else {
                        salutation = "Full name not entered."
                    }
                } catch (e:Error) {
                    trace(e);
                }
                /* Show some of the information available through loaderInfo: */
               ta2.text = "AS version: " + this.loaderInfo.actionScriptVersion;
               ta2.text += "\nApp height: " + this.loaderInfo.height;
               ta2.text += "\nApp width: " + this.loaderInfo.width;
               ta2.text += "\nApp bytes: " + this.loaderInfo.bytesTotal;
            }
        ]]>
    </fx:Script>
    <s:Label text="{salutation}"/>
    <s:TextArea height="75" width="250" id="ta1"/>
    <s:TextArea height="200" width="250" id="ta2"/>
</s:Module>
```

This example uses methods of the String and StringUtil classes, plus a for-in loop to parse the URLs. You can also use methods of the URLUtil and URLVariables classes to do this.

Modules are cached by their URL, including the query string. As a result, you will load a new module if you change the URL or any of the query string parameters in the URL. This can be useful if you want multiple instances of a module based on the parameters that you pass in the URL with the ModuleLoader.

Accessing the parent application from modules

Modules can access properties and methods of the parent application by using a reference to the `parentApplication` property. In most cases, you should avoid doing this as it creates a close coupling between the module and the application. Having this coupling directly negates some of the benefits of using modules.

The following example accesses the `expenses` property of the parent application when the module first loads. The module then uses this property, an ArrayCollection, as the source for its chart's data. When the user clicks the button, the module calls the `getNewData()` method of the parent application that returns a new ArrayCollection for the chart:

```
<?xml version="1.0"?>
<!-- modules/ChartChildModule.mxml -->
<s:Module
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    width="100%" height="100%"
    creationComplete="getDataFromParent()">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;
            [Bindable]
            private var expenses:ArrayCollection;
            // Access properties of the parent application.
            private function getDataFromParent():void {
                expenses = parentApplication.expenses;
            }
        ]]>
    </fx:Script>

    <mx:ColumnChart id="myChart" dataProvider="{expenses}">
        <mx:horizontalAxis>
           <mx:CategoryAxis dataProvider="{expenses}" categoryField="Month"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:ColumnSeries xField="Month" yField="Profit"
                displayName="Profit"/>
           <mx:ColumnSeries xField="Month" yField="Expenses"
                displayName="Expenses"/>
        </mx:series>
     </mx:ColumnChart>
     <mx:Legend dataProvider="{myChart}"/>

     <s:Button id="b1"
        click="expenses = parentApplication.getNewData();"
        label="Get New Data"/>

</s:Module>
```

The following example shows the parent application that the previous example module uses:

```
<?xml version="1.0"?>
<!-- modules/ChartChildModuleLoader.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;
            [Bindable]
            public var expenses:ArrayCollection = new ArrayCollection([
                {Month:"Jan", Profit:2000, Expenses:1500},
                {Month:"Feb", Profit:1000, Expenses:200},
                {Month:"Mar", Profit:1500, Expenses:500}
            ]);
            public function getNewData():ArrayCollection {
                return new ArrayCollection([
                    {Month:"Apr", Profit:1000, Expenses:1100},
                    {Month:"May", Profit:1300, Expenses:500},
                    {Month:"Jun", Profit:1200, Expenses:600}
                ]);
            }
        ]]>
    </fx:Script>

    <s:ModuleLoader url="ChartChildModule.swf" id="m1"/>
</s:Application>
```

You can also call methods and access properties on other modules. For more information, see "Accessing modules from other modules" on page 171.

The drawback to this approach is that it can create dependencies on the parent application inside the module. In addition, the modules are no longer portable across multiple applications unless you ensure that you replicate the behavior of the applications.

To avoid these drawbacks, you should use interfaces that secure a contract between the application and its modules. This contract defines the methods and properties that you can access. Having an interface lets you reuse the application and modules as long as you keep the interface updated. For more information, see "Using interfaces for module communication" on page 164.

Accessing modules from other modules

You can access properties and methods of other modules by using references to the other modules through the parent application. You do this by using the ModuleLoader class's `child` property. This property points to an instance of the module's class, which lets you call methods and access properties. In most cases, you should avoid doing this as it creates a close coupling among the modules. Having this coupling directly negates some of the benefits of using modules in the first place.

The following example defines a single application that loads two modules. The InterModule1 module defines a method that returns a String. The InterModule2 module calls that method and sets the value of its Label to the return value of that method.

Main application:

```
<?xml version="1.0"?>
<!-- modules/InterModuleLoader.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
        ]]>
    </fx:Script>

    <s:ModuleLoader url="InterModule1.swf" id="m1"/>

    <s:ModuleLoader url="InterModule2.swf" id="m2"/>
</s:Application>
```

Module 1:

```
<?xml version="1.0"?>
<!-- modules/InterModule1.mxml -->
<s:Module
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    width="100%" height="100%">

    <fx:Script>
        <![CDATA[
            /* Defines the method that the other module calls. */
            public function getNewTitle():String {
                return "New Title";
            }
        ]]>
    </fx:Script>
</s:Module>
```

Module 2:

```
<?xml version="1.0"?>
<!-- modules/InterModule2.mxml -->
<s:Module
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    width="100%" height="100%">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            [Bindable]
            private var title:String = "Original Title";
            // Call method of another module.
            private function changeTitle():void {
                title = parentApplication.m1.child.getNewTitle();
            }
        ]]>
    </fx:Script>
    <s:HGroup>
        <s:Label id="l1" text="Title: "/>
        <s:Label id="myTitle" text="{title}"/>
    </s:HGroup>
    <s:Button id="b1" label="Change Title" click="changeTitle()"/>
</s:Module>
```

The application in this example lets the two modules communicate with each other. You could, however, define methods and properties on the application that the modules could access. For more information, see "Accessing the parent application from modules" on page 169.

As with accessing the parent application's properties and methods directly, using the technique described in this section can make your modules difficult to reuse and also can create dependencies that can cause the module to be larger than necessary. Instead, you should use interfaces to define the contract between modules. For more information, see "Using interfaces for module communication" on page 164.

Accessing modules from the parent application

You can access the methods and properties of a module from its parent application by getting an instance of the module's class. Referencing a module by its class name in an application causes the whole module and all of its dependencies to be linked into the application. This defeats the purpose of using modules. However, using this technique can be useful for debugging and testing.

You should only use interfaces to access the methods and properties of a module unless you want to create these dependencies. For more information, see "Using interfaces for module communication" on page 164.

If you use the ModuleLoader to load the module, you can call methods on a module from the parent application by referencing the ModuleLoader class's `child` property, and casting it to the module's class. The `child` property is an instance of the module's class. In this case, the module's class is the name of the MXML file that defines the module.

The following example calls the module's `getTitle()` method from the parent application:

Parent Application:

```
<?xml version="1.0"?>
<!-- modules/ParentApplication.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script><![CDATA[
        [Bindable]
        private var s:String;

        private function getTitle():void {
            s = (m1.child as ChildModule1).getModTitle();
        }
    ]]></fx:Script>

    <s:Label id="l1" text="{s}"/>
    <s:ModuleLoader id="m1"
        url="ChildModule1.swf"
        ready="getTitle()"/>
</s:Application>
```

Module:

```
<?xml version="1.0"?>
<!-- modules/ChildModule1.mxml -->
<s:Module
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    width="100%" height="100%">
    <fx:Script><![CDATA[
        /* Defines the method that the application calls. */
        public function getModTitle():String {
            return "Child Module 1";
        }
    ]]></fx:Script>
</s:Module>
```

If you load the module that you want to call by using the ModuleManager API, there is some additional coding in the shell application. You use the ModuleManager `factory` property to get an instance of the module's class. You can then call the module's method on that instance.

The following module example defines a single method, `computeAnswer()`:

```
<?xml version="1.0"?>
<!-- modules/mxmlmodules/SimpleModule.mxml -->
<s:Module
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
            public function computeAnswer(a:Number, b:Number):Number {
                return a + b;
            }
        ]]>
    </fx:Script>
</s:Module>
```

The following example gets an instance of the SimpleModule class by using the `factory` property to call the `create()` method. It then calls the module’s `computeAnswer()` method on that instance:

```
<?xml version="1.0"?>
<!-- modules/mxmlmodules/SimpleMXMLApp.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    creationComplete="initApp()">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <fx:Script>
    <![CDATA[
        import mx.modules.IModuleInfo;
        import mx.modules.ModuleManager;
        public var assetModule:IModuleInfo;
        public var sm:Object;

        [Bindable]
        public var answer:Number = 0;
        public function initApp():void {
            /* Get the IModuleInfo interface for the specified URL. */
            assetModule = ModuleManager.getModule("SimpleModule.swf");
            assetModule.addEventListener("ready", getModuleInstance);
            assetModule.load(null, null, null, moduleFactory);
        }
        public function getModuleInstance(e:Event):void {
            /* Get an instance of the module. */
            sm = assetModule.factory.create() as SimpleModule;
        }

        public function addNumbers():void {
            var a:Number = Number(ti1.text);
            var b:Number = Number(ti2.text);
            /* Call a method on the module. */
            answer = sm.computeAnswer(a, b).toString();
        }
    ]]>
  </fx:Script>
   <s:Form>
        <s:FormHeading label="Enter values to sum."/>
        <s:FormItem label="First Number">
            <s:TextInput id="ti1" width="50"/>
        </s:FormItem>
        <s:FormItem label="Second Number">
            <s:TextInput id="ti2" width="50"/>
        </s:FormItem>
        <s:FormItem label="Result">
            <s:Label id="ti3" width="100" text="{answer}"/>
        </s:FormItem>
        <s:Button id="b1" label="Compute" click="addNumbers()"/>
    </s:Form>
</s:Application>
```

In this example, you should actually create a module that extends the ModuleBase class in ActionScript rather than an MXML-based module that extends the Module class. This is because the example module does not have any visual elements and contains only a single method that computes and returns a value. A module that extends the ModuleBase class would be more lightweight than a class that extends Module. For more information on writing ActionScript-based modules that extend the ModuleBase class, see “Creating ActionScript-based modules” on page 147.

Developing and loading sub-applications

About loading sub-applications

Flex lets you load and unload sub-applications in a main application. Reasons to use sub-applications as part of your overall application architecture include the following:

- Reduce the size of the main application
- Encapsulate related functionality into a sub-application
- Create reusable sub-applications that can be loaded into different applications
- Integrate third-party applications into your main application

The way in which a sub-application is loaded defines the level of interoperability between the main application and the sub-application. Consider the following factors when loading a sub-application in your main application:

Trusted applications What level of trust do the applications have? A trusted sub-application has a greater amount of interoperability with the main application. An untrusted sub-application, while limited, can still interoperate with the main application in some ways. In general, though, if you do not have complete control over the development and deployment of a loaded sub-application, consider that application to be untrusted.

Versioning Are the main application and sub-application compiled with the same version of the Flex framework? The default method of loading a sub-application assumes that all applications are compiled by the same version of the framework. However, Flex can load a sub-application that was compiled with an older version of the framework. This type of application is known as a *multi-versioned* application. A multi-versioned application has some restrictions on its level of interoperability with the main application that loads it. It is, however, more flexible to use in a large application.

The level of trust and use of versioning are determined by the application domain and the security domain into which a sub-application is loaded.

There are three main types of loaded sub-applications in Flex:

Single-versioned applications are guaranteed to have been compiled with the same version of the compiler as the main application. They have the greatest level of interoperability with the main application, but they also require that you have complete control over the source of the sub-applications.

Multi-versioned applications can be compiled with older versions of the Flex framework than the main application that loads them. Their interoperability with the main application and other sub-applications is more limited than single-versioned applications.

Sandboxed applications are loaded into their own security domains, and can be multi-versioned. Using sandboxed applications is the recommended practice for loading third-party applications. In addition, if your sub-applications use RPC or DataServices-related functionality, you should load them as sandboxed.

When compiling each of these types of applications, you should include the MarshallingSupport class into the main application and sub-applications. You do this with the `includes` compiler argument, as the following example shows:

```
-includes=mx.managers.systemClasses.MarshallingSupport
```

Using sub-applications is in some ways like using modules. For a comparison of the two approaches, see "Comparing loaded applications to modules" on page 187.

About application domains

An application domain is a container for class definitions. Applications have a single, top-level application domain called the system domain. Application domains are then defined as child nodes of the system domain. When you load a sub-application into another, main application, you can load it into one of three application domains: sibling, child, and current. When you load a sub-application into a *sibling* application domain, the sub-application's application domain has the same parent as the main application's application domain. In addition, it is a peer of all other sibling applications.

When you load a sub-application into a *child* application domain, the sub-application's application domain is a child of the main application's application domain. When you load a sub-application into a *current* application domain, the sub-application is loaded into the same application domain as the main application. Each of these locations defines where the sub-application can get its class definitions from.

The default behavior of the SWFLoader and Loader controls is to load a sub-application into a *child* application domain. If the sub-application and the main application are compiled with different versions of the Flex framework, runtime errors can result. These errors occur because the applications are sometimes compiled against different definitions of the same classes.

You can specify that the main application loads a multi-versioned sub-application. It does this by loading the sub-application into a *sibling* application domain. This means that the sub-application defines its own class definitions and does not get them from its parent. It is possible for two applications to work together, even if they are compiled with different versions of the Flex framework.

***Note:** In a multi-versioned application, the sub-applications must be compiled with the same or older version of the compiler that the main application was compiled with.*

You specify the application domain of a sub-application by setting the value of the `loadForCompatibility` property on the SWFLoader. If you set the value of this property to `true`, then the sub-application is loaded into a sibling application domain. If you set the value of this property to `false`, then the sub-application is loaded into a child application domain. The default value of this property is `false`, so by default, sub-applications are not multi-versioned.

You can also specify the application domain on the LoaderContext object. You do this if you specify the value of the `loaderContext` property when using the SWFLoader control. For more information, see "Specifying a LoaderContext" on page 195.

The system domain

Classes defined by Flash Player are in the system domain. The system domain parents all other application domains. The main application's application domain is a child of the system domain. If you load sub-applications into sibling application domains, then they are also children of the system domain. Classes defined in the system domain are never redefined in sub-applications or main applications. Those applications all share the common definitions of Flash Player. These definitions include classes such as DisplayObject, Event, and Sprite. The definitions of these shared classes are contained in the playerglobal.swc file.

Sibling application domains

The application domain that a sub-application is in determines where the sub-application gets its class definitions from. If the main application loads a sub-application into a sibling application domain, the sub-application defines its own non-player class definitions. This is the configuration for multi-versioned applications. Applications that are loaded into a sibling application domain can load other applications into a sibling application domain.

sub-applications that are in sibling application domains of the main application can communicate with the main application. Sub-applications can call methods and access properties on the applications, as long as they meet these criteria:

- Only strong types that are defined in Flash Player are used.
- The sub-applications are not in different security domains.

The ability for a sub-application in a sibling application domain to communicate with the main application is not as seamless as when the sub-application is in a child application domain. For example, if the sub-application launches a pop-up control, it passes an event to the main application that actually launches the control. This event passing limits their communication somewhat, but does provide some measure of interoperability. For more information about developing this type of application, see "Developing multi-versioned applications" on page 213.

Applications that are in separate security domains are automatically in separate, sibling application domains. As a result, if you load an untrusted sub-application into a main application, that sub-application has its own class definitions.

More Help topics

"Developing multi-versioned applications" on page 213

Child application domains

If a main application loads a sub-application into a child application domain of its application domain, the sub-application gets its class definitions from the main application. This behavior is the default for application loading. It can result in runtime errors if the applications are compiled with different versions of the Flex framework. As the SWF file sets up its classes, classes that are already defined are not added to the application domain. First in wins, which means that the first class defined becomes the only definition of that class. Subsequent definitions loaded into that application domain are ignored.

Sub-applications that are in child application domains of the main application can communicate with the main application. They have the highest level of possible interoperability with the main application. This situation is typical of a large application that is not multi-versioned, and it is the default behavior for the SWFLoader.

"Creating and loading sub-applications" on page 191

The current application domain

If you load a sub-application into the current application domain (rather than a separate, sibling application domain or a child application domain), the sub-application's class definitions are often ignored. This behavior is because the first definition in a domain is used. Subsequent definitions loaded into that domain are ignored. If new class definitions are added, the main application can use them.

Using the current application domain is typical of RSLs and other specially compiled resources, and is not typically used when loading sub-applications.

About security domains

Security domains define the level of trust between applications. The greater the trust between applications, the greater the amount of possible interoperability between those applications. In general, if a sub-application is loaded into the same security domain as the main application, then the applications have the highest level of interoperability.

If a sub-application is loaded into a different security domain (as is the case with many remote or multi-versioned applications), then the sub-application is allowed a limited amount of interaction with the main application. Sub-applications in separate security domains are also restricted in their ability to communicate with one another. They are known as sandboxed applications.

You determine whether a sub-application is loaded into the same security domain as the main application when you load it. You can set the value of the `trustContent` property to `true` to load a remote sub-application into the same security domain as the main application. This behavior only applies if that application is loaded from a different web domain or subdomain than the main application. If the sub-application is loaded from the same web domain as the main application, then it is by default loaded into the same security domain. Setting the value of the `loadForCompatibility` property does not affect the `trustContent` property.

In some cases, you want to load a sub-application that is on the same domain as the main application into a separate security domain. This might be because the sub-application is from a third party or you want you applications to have the same level of interoperability as a sandboxed application. One way to do this is to set up a different sub domain name on the same server, and load the sub-application from that sub domain. For more information, see "Loading same-domain and cross-domain applications" on page 189.

When using AIR, you cannot set the value of the `trustContent` property to `true`.

If you do not set the value of the `trustContent` property to `true`, then a sub-application on a remote server is loaded into a separate security domain by default.

You can also specify the security domain on the LoaderContext object. You do this if you specify the value of the `loaderContext` property when using the SWFLoader control. You can only do this if you want to load the sub-application into the same security domain. For more information, see "Specifying a LoaderContext" on page 195.

Sandboxed applications have the greatest number of limitations on application interoperability. These restrictions include the following:

Stage Access to the stage from the sub-application is limited to some stage properties and methods.

Mouse You cannot receive mouse events from objects in other security domains.

Pixels Applications cannot access the pixels drawn in applications that are in other security domains.

Properties While applications can get references to objects in other security domains, avoid doing this for security reasons. Some properties are restricted, such as the Stage or any parent of a DisplayObject that another application instantiates. In addition to these restrictions, applications that are in separate security domains are also in separate application domains by definition. As a result, they are subject to all restrictions of that architecture. However, they can also benefit from this situation because they can then be multi-versioned.

For more information about working with sandboxed applications, see "Developing sandboxed applications" on page 205

Common types of applications that load sub-applications

Common types of applications that load sub-applications include:

- Large applications that are or are not multi-versioned
- Mashups
- Portals
- Dashboards

About sandboxed applications

A sandboxed application is a common type of application that loads sub-applications. In general, sandbox applications load applications that are compiled and hosted by third parties. The main application does not necessarily trust the third party that developed those sub-applications. In addition, the developer of the main application does not know the version of the Flex framework that was used to compile the sub-applications (it must have been compiled with an older version or the same version of the compiler). As a result, sandboxed applications have the least amount of interoperability between the main application and the sub-applications, but they are typically multi-versioned. A common type of sandboxed application is a portal.

Sandboxed applications require the least amount of additional coding when using RPC classes and DataServices-related functionality. Trusted multi-versioned applications often require a bootstrap loader so that RPC classes work across applications. Sandboxed applications do not have this requirement. As a result, with many multi-versioned applications, using sandboxed applications is actually the recommended approach.

The following image shows the boundaries of a sandboxed application. The sub-applications are loaded into separate, sibling application domains. This means that each application contains its own class definitions so they can interoperate with applications that were compiled with different versions of the framework. The sub-applications are also in separate security domains. This separation means that they do not trust each other, and therefore have limited interoperability.

"Developing sandboxed applications" on page 205

About large, multi-versioned applications

A large, multi-versioned application is typically made up of many different components that are developed by different groups within an organization. For example, a form manager.

Multi-versioned applications load the sub-applications into a sibling application domain that is alongside the main application's application domain. They also load sub-applications into the same security domain as the main application.

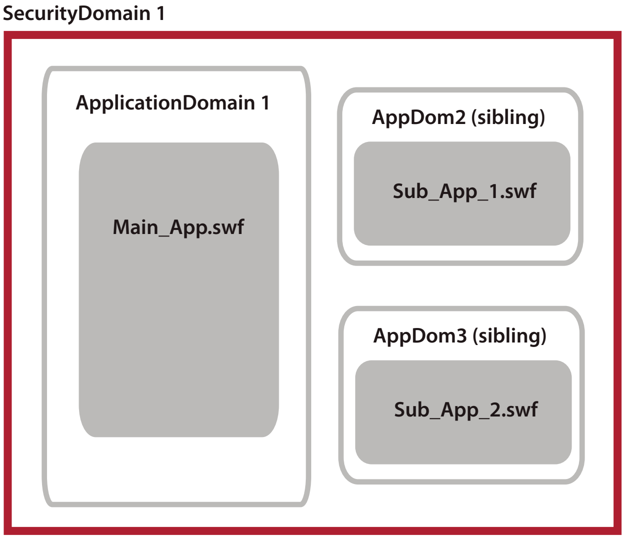
The sub-applications loaded by the main application in a multi-versioned architecture must have compiled with the same or older version of the compiler. You cannot load a sub-application into a main application if the sub-application was compiled with a newer version of the compiler.

Multi-versioned applications have many of the benefits of sandboxed applications, but can require additional coding to work with RPC classes and DataServices-related functionality. In general, if your sub-applications use these classes, use the sandboxed application approach for loading sub-applications, even if they are trusted. For more information, see "Using RPC and DataServices classes with multi-versioned applications" on page 214.

In deployment, the main application and the sub-applications are typically all in the same web domain, and so they have a trusted relationship. Even if they are deployed on different web domains, the applications are typically loaded into the same security domain to maintain the trusted relationship. This process of loading cross-domain applications into the same security domain is known as *import loading*. Use this process only under rare circumstances where you know that you can trust the source of the loaded sub-applications.

Sometimes third parties compile the sub-applications that the main application loads. In this case, developers sometimes don't know the version of the Flex framework that was used to compile the sub-applications. The sub-applications must be compiled with older versions of the compiler, or the same version of the compiler, but the developers of the main application do not need to know which version. They might not have access to the source code of the sub-applications. As a result, they would not necessarily be able to recompile them with the same version of the framework as the main application.

The following image shows the boundaries of a large, multi-versioned application. The sub-applications are loaded into separate, sibling application domains. This means that each application contains its own class definitions so they can be compiled with different versions of the framework (as long as the sub-applications are compiled with the same or older versions of the compiler that the main application was compiled with). All the applications are loaded into the same security domain and therefore trust each other.



Sub-applications in a sibling application domain store their own class definitions, apart from the class definitions in the main application. The following image shows the class definitions of a large, multi-versioned application. You can see that the sub-application uses its own definitions, which were compiled with Flex 3.2). The main application uses its own definitions, which were compiled with Flex 4.

"Developing multi-versioned applications" on page 213

About large, single-versioned applications

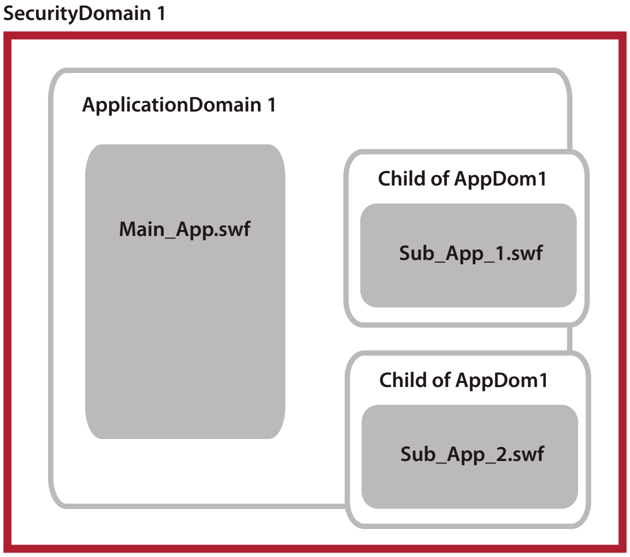
A large application without versioning support is an application that loads sub-applications that must have been compiled with the same version of the Flex framework. A single group within an organization typically creates these applications. It is possible for that group to enforce Flex framework versions and other standards during the development process.

Large, single-versioned applications are the default type of application loaded by the SWFLoader control. If you accept the SWFLoader's default settings when you load sub-applications into your main application, the sub-applications are not multi-versioned. They are loaded into child application domains of the main application.

It can be difficult to maintain large, single-versioned applications. This is because all sub-applications must be recompiled whenever any of the applications are recompiled with a new version of the framework. In addition, it is more difficult to add third-party sub-applications because they might have been compiled with different versions of the framework. In many cases, you do not have access to the source code to recompile them.

Large, single-versioned applications and all their sub-applications are usually deployed in the same web domain. This is because the same group within an organization typically develops and maintains them. As a result, they have a trusted relationship. Even if the applications are deployed on different web domains, the applications would be import loaded into the same security domain. This results in the applications having a trusted relationship.

The following image shows the boundaries of a large application that does not support multi-versioning. Each sub-application is loaded into a child application domain of the main application's application domain. As a result, all the applications use the same class definitions. If one of these applications is compiled with a different version of the framework, then runtime errors are likely to occur when a call is made to an API that is different. All the applications are inside the same security domain and therefore trust each other.



Sub-applications in a child application domain inherit their class definitions from the application in the parent application domain. If a sub-application defines one of the classes that is already defined in the main application, the child's definition is ignored. If multiple sub-applications define the same class that isn't defined in the main application, each sub-application uses its own definition.

The following image shows the class definitions of a large, single-versioned application. In this image, you can see that the sub-application gets its definitions from the main application, which was compiled with Flex 4. The class definitions in the sub-application, which was also compiled with Flex 4, are ignored.

About the manager classes

The manager classes handle various tasks of the application. For example, the DragManager handles all the drag-and-drop functionality; this manager class is responsible for marshaling data, creating the DragProxy, and triggering drag-related events.

When sub-applications are loaded into the same application domain as the main application, the application domain contains only a single instance of each manager. When applications are in different application domains, though, there can be more than one instance of a manager in the system domain.

Depending on the type of task, the manager classes are sometimes allowed to communicate through event passing when a main application loads a sub-application. For example, the FocusManager in a sub-application receives control from the FocusManager in the main application when the focus shifts to the sub-application. When the focus shifts away from the sub-application, the sub-application's FocusManager passes control back to the main application's FocusManager.

In other cases, there can only be one active instance of a manager in the system domain. Flex ensures that the sub-application's manager is disabled. For example, the BrowserManager cannot have multiple instances. Only the main application can access it, and only the main application can communicate with it, unless the sub-application is in a child application domain of the main application. If a sub-application in a separate application domain wants to communicate with the BrowserManager, it must do so through the main application.

In this case you would have to create custom logic that handles interaction with manager classes. For example, if you want a sub-application to use the main application's deep linking, you can create a custom class. This custom class passes messages from the sub-application to the main application, where the BrowserManager can be communicated with.

What typically happens is that the top-level manager handles the user interaction. This manager receives messages from the sub-application's manager that instructs it on what to do.

The following manager classes are linked in by all applications:

- SystemManager
- LayoutManager
- StyleManager
- EffectManager

- ResourceManager (which links in ModuleManager)
- FocusManager
- CursorManager
- ToolTipManager

The following manager classes are linked in only when used in an application:

- DragManager
- BrowserManager
- HistoryManager (deprecated)
- PopUpManager (note that if a sub-application uses pop-up controls, the main application must include a definition of this manager)

If a main application loads sub-applications that are compiled with the same version of the framework, only one definition of each manager is stored in the SWF file. However, if you have a sandboxed or multi-versioned sub-application, both the main application and the sub-application store their own definitions. In many cases, the manager classes in the sub-application pass messages to the main application's instance of the manager. The main application's manager can then handle the task.

With sandboxed or multi-versioned applications, both the main application and the sub-application have their own versions of the manager classes. In single-versioned applications, only one version of most manager classes is necessary. You can externalize the definition of a manager in many cases for applications that are not multi-versioned.

About the SystemManager class

All applications have an instance of the SystemManager class. If an application is loaded into another application, a SystemManager for the sub-application is still created. The SystemManager still manages the sub-application's application window, but it might not manage pop-up controls, tool tips, and cursors, depending on the way in which the sub-application was loaded. The content of the SWFLoader that loaded the sub-application contains a reference to the sub-application.

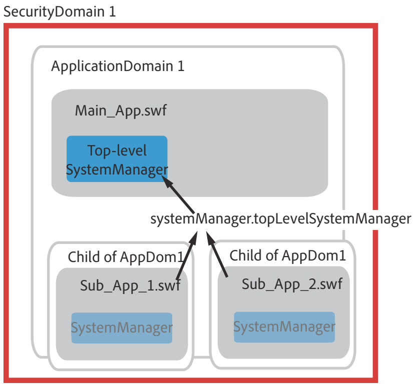
The SystemManager of the main application is important because it gives you access to many aspects of the entire application. For example, the top-level SystemManager does the following:

- Parents all pop-up controls, ToolTip objects, and cursors in the main application and all trusted sub-applications
- Handles focus for all applications that are trusted

You can use a reference to the top-level SystemManager to register to listen for events in a sub-application. For example, your sub-application can listen for mouse events that are outside its application domain by adding listeners to the top-level SystemManager.

The way you access the top-level SystemManager from a sub-application depends on the type of sub-application that you are using.

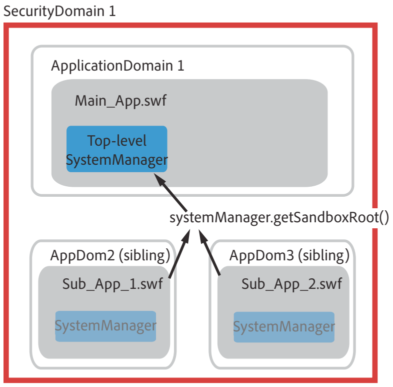
To get access to the top-level SystemManager in an architecture where sub-applications are loaded into child application domains, you use the `topLevelSystemManager` property of the SystemManager. The following image shows that the sub-applications use the `systemManager.topLevelSystemManager` to access the SystemManager in the main application.



For a code example that uses the `topLevelSystemManager` property to access the main application's SystemManager, see "Listening for mouse events with loaded applications" on page 201.

For single-versioned applications, the `topLevelSystemManager` property always refers to the top-level SystemManager in an application domain. If your applications are in separate application domains (as sandboxed or multi-versioned applications are), use the `getSandboxRoot()` method to get the top-level SystemManager for that security domain.

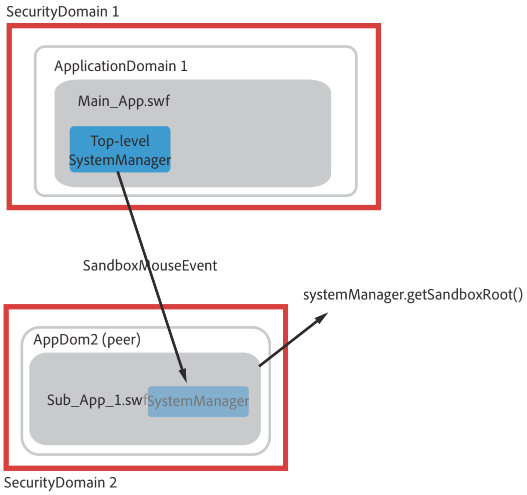
The following image shows that the sub-applications use the `systemManager.getSandboxRoot()` to get a reference to the main application's SystemManager, which is in a separate application domain.



For a code example that uses the `getSandboxRoot()` method to access the main application's SystemManager, see "Listening for mouse events in multi-versioned applications" on page 216.

When a sub-application is in a different security domain as the main application (or *not trusted*, such as in a sandboxed application), you cannot get a reference to the main application's SystemManager from the sub-application. In this case, you can listen for a SandboxMouseEvent and InterDragManagerEvent for inter-application communication. Any application can trigger these events. The sub-application's SystemManager gets notification of them, at which point you can handle them in the sub-application.

The following image shows an architecture where two applications, in separate security domains, communicate through event passing. The sub-application calls the `getSandboxRoot()` method to get a reference to its own SystemManager. The SystemManager can then listen for events that the main application's SystemManager dispatched.



The properties of a SandboxMouseEvent object are not the same as the properties in a typical event object. For example, the `target` and `currentTarget` properties are the SandboxBridge that dispatched the event, or the SystemManager that redispatched it. These properties are not the specific object that dispatched the event. Untrusted child applications should not be able to get references to objects that are typically specified by these properties. Similarly, the `stageX`, `stageY`, `localX`, and `localY` properties are not available.

For an example that uses the SandboxMouseEvent object to handle mouse events outside a sub-application's security domain, see "Listening for mouse events with sandboxed applications" on page 209.

Comparing loaded applications to modules

When you design a large application, give some consideration to its architecture. If the application has one main application that loads and unloads subordinate applications, then weigh the benefits of using either modules or sub-application when deciding which approach to take.

Consider the example of an application composed of many forms. In a modular application, a main application loads each form as a module with the ModuleManager. In an application that uses sub-applications, each form is a separate application that the SWFLoader loads into the main application. These two approaches are similar in many ways, but also have many differences.

Many of the reasons to use modules also apply to sub-applications. Main applications usually load sub-applications rather than embed their functionality. The result is generally a smaller initial download size and shorter load time for the main application. In addition, this promotes better encapsulation of related functionality, which can make development and maintenance easier.

Modules and sub-applications have the following similarities:

- Are compiled SWF files
- Can be loaded and unloaded at run time
- Promote encapsulation of related functionality
- Allow for an asynchronous development environment

- Can be recompiled without having to recompile the main application
- Support debugging
- Can be loaded locally or remotely (with the appropriate permissions)
- Are cached by the browser
- Can be preloaded
- Support progress events for getting the status while loading
- Can dynamically access methods and properties of the main application

Modules and sub-applications are also different. The main difference is that modules typically share classes with their host application. This sharing of classes creates a dependency between the module and the main application. Sub-applications, on the other hand, typically have their own versions of the classes, so less dependency exists between them and the main application.

Other differences between modules and sub-applications include the following:

File size Modules and their host applications are often smaller in file size because you can externalize shared classes. You can't always externalize shared classes for sub-applications. In cases where the versions of the applications are different, each application must have its own set of classes.

Reuse Modules are more tightly bound to the host application. They use interfaces to communicate with the loading application. This means that as your application changes, if your application uses modules, you'll probably need to recompile all of them if you move the main application to a later version of Flex.

Versioning Modules do not support multi-versioning. The main application and all modules must be compiled by the same version of the Flex framework. In a mult-versioned application, the sub-applications can be compiled with different versions of the compiler, as long as the compiler is the same or older than the compiler used to compile the main application.

Manager classes Modules and their host applications typically share manager classes. The modules are in a child application domain, whereas sub-applications often have their own instance of the manager class so that they can be multi-versioned. An exception is the StyleManager class; modules each define their own instance of type IStyleManager2.

ActionScript-only Modules can be either MXML-based or ActionScript-only; applications and sub-applications are not typically pure ActionScript.

Application domains sub-applications can be loaded into sibling application domains or child application domains, whereas modules must be loaded into a child application domain of the host application.

Security domains Modules must be loaded into the same security domain as their host application. Sub-applications can be loaded into either the same security domain or a different security domain.

For more information about modules, see "Modular applications" on page 138.

Comparing the SWFLoader and Loader controls

You can use the SWFLoader and Loader classes to load sub-applications into a main application. In most circumstances, use the SWFLoader class. This class wraps the Loader class and provides additional functionality that makes it easier to use for loading sub-applications into main applications.

The SWFLoader control has the following features:

- Supports Flex styles and effects; the Loader class does not have any inherent support for styles and effects.
- Lets you monitor the progress of a load inherently (if you use the Loader class, you have to first get a reference to a LoaderInfo object).

- Is a UIComponent. As a result, the SWFLoader control participates in the display list and adds children to the display list without having to write additional code.
- Resizes and scales the contents automatically.
- Does not require that the SWF file be an instance of the Application class, it just checks if an Application exists, and handles sizing differently.
- Can be multi-versioned. The Loader class does not have built-in support for multi-versioning.

Communicating across domains

Whenever you have a main application and sub-applications that are in different application domains, the recommended way to communicate between the applications is through event passing. If something that happens in the sub-application affects the main application, the sub-application triggers an event. This event can be caught in the main application. The event defines the properties necessary to respond to the event. For example, suppose a user moves the mouse pointer over a control in a sub-application that has a ToolTip. The sub-application's ToolTipManager creates the ToolTip and sends an event that requests the main application's ToolTipManager to display it. This interaction works across application domains that are within the same security domain.

Communication across security domains use the LoaderInfo.sharedEvents dispatcher and custom events. This process is largely transparent to you; you only need to know which events to register with event listeners. The LoaderInfo.sharedEvents class dispatches events in a sub-application that should be handled by a manager in the main application. The event contains data that define it, and that data is marshaled across the security domain. It is important to note that custom event classes cannot be strongly typed across the security domain by the receiver. Only classes defined by Flash Player can be strongly typed.

In many cases, communicating across security domains is transparent to the developer. The Flex framework handles the details of event passing and data marshaling for you. For example, when using functionality managed by the FocusManager or PopUpManager, you do not generally write additional code to make application interoperability work. The underlying Flex classes trigger the events and marshal the data across the domains so that the experience is seamless. In some cases, such as when you use custom classes to define objects, you must write custom code to marshal the data across the security domain.

Loading same-domain and cross-domain applications

The level of interaction that a main application and sub-application have depends on the level of trust between them. They can be trusted or untrusted. By default, applications that are loaded from a different web domain are untrusted, and applications that are loaded from the same web domain are trusted. You can, however, make a cross-domain application trusted.

Same-domain applications are applications that are loaded into the main application from the same web domain as the main application. By default, they are loaded into the same security domain and are trusted. Trusted applications can be loaded into the same application domain as the main application, which means they share their class definitions with the main application. They can also be loaded into a different, sibling application domain, which means that they contain their own definitions for all their classes and can be multi-versioned (as long as they are compiled with the same or older version of the compiler that the main application was compiled with).

Cross-domain applications are applications that are loaded into a main application from a different web domain as the main application. For example, if the main application is located at domainA.com, and the sub-application is located at domainB.com, then the sub-application is a cross-domain application. Cross-domain applications are often known as untrusted applications, although you can specify that a remote application be trusted (except when using AIR).

When loading cross-domain SWF files, consider these points:

- The main application might have to call the `Security.allowDomain()` method.

- The sub-application's server might require a crossdomain.xml if you try to load data from the target application.
- The main application can define the level of trust between the main application and the sub-application by setting the value of the `trustContent` property (if the crossdomain.xml file permits it, and you are not using AIR).

Untrusted applications are loaded into a different security domain as the main application. As a result, Flash Player provides only limited interoperability between applications that do not trust each other because of the security concerns.

You can load the content of any SWF file from any web domain regardless of whether target web server has a policy file, but you need permissions to read the SWF file's data. To load a cross-domain application and access its data, the target server that hosts the remote sub-application must have a policy file called crossdomain.xml on it. This file must specifically allow access from the source server. In the previous example, if you wanted to access the loaded application's data, domainB must have a policy file on it that lets domainA load from it. Without a policy file, Flash Player throws a security error if it tries to access the application's data. A policy file must be in the root of the domain, or its location must be specified explicitly in the loading application. For more information about the crossdomain.xml file, see "Using cross-domain policy files" on page 125.

Sub-domains that are not the same, such as www1.domainA.com and www2.domainA.com, also apply when deciding if a sub-application is cross-domain or not. In this example, if the main application is on www1.domainA.com, and the sub-application is on www2.domainA.com, then the sub-application is considered untrusted by default. To load data from the sub-application, the sub-application's domain would require a policy file.

You cannot test loading cross-domain applications directly in Flash Builder because the sub-applications must be loaded from a separate domain. As a result, to build the main application and the sub-application in Flash Builder, set up the compilation process to deploy the applications to separate servers for testing.

Cross-domain applications can be "import loaded," which means that they are loaded into the same security domain as the main application. You do this by setting the `trustContent` flag to `true` on the SWFLoader, or by specifying that the application load into the same security domain domain on the LoaderContext. You should only import load a cross-domain application if you know for sure that it can be trusted. For more information on using the LoaderContext to load sub-applications, see "Specifying a LoaderContext" on page 195.

Another way to load cross-domain applications into the same security domain is to use the `Security.allowDomain()` method. You first load the application as a sandboxed application (from a different web domain, without setting the `trustContent` property to `true`). In the main application, you call the `allowDomain()` method on the sub-application's domain in the SWFLoader control's `complete` event handler. In the sub-application, you call the `allowDomain()` method on the main application's domain. You must make this call early in the sub-application's lifecycle. For example, in the application's `preinitialize` event. If you use the `allowDomain()` method to load applications, you do not need a crossdomain.xml file on the target domain.

You can load a local (or same-domain) application into a different security domain. To do this, you can use a URL string for the SWFLoader's `source` property that is different from the path to the main application. For example, you could specify an IP address for the `source` property. When Flash Player compares the domain names, they are recognized as different, and the sub-application loads as an untrusted application. This is a common approach if you want to the loaded application to be sandboxed, but deploy the applications into the same web domain. You could also create separate sub domains on the same server to ensure that the sub-application is loaded into a separate security domain.

Sub-applications access remote data based on the way that they were loaded. If you import load an application, the sub-application is effectively running from within the main application's security domain. As a result, it would now need permissions to access data on its domain of origin. If you load a sub-application into a separate security domain, it runs within its original domain and can access resources on that domain as normal.

Creating and loading sub-applications

You use the SWFLoader control to load sub-applications into your main application. The default behavior of the SWFLoader control assumes that the application you are developing loads trusted sub-applications that were compiled with the same version of the Flex framework. These applications are typically loaded from the same web domain as the main application.

You can load the following other types of applications:

Sandboxed applications Sandboxed applications contain sub-applications that are loaded into separate security domains. As a result, they can be multi-versioned, but are untrusted. This is the recommended approach for any third-party application, or for many multi-versioned applications that use RPC classes or DataServices-related functionality. For more information, see “Developing sandboxed applications” on page 205.

Multi-versioned applications Multi-versioned applications are typically very large applications that load trusted sub-applications. The sub-applications might or might not have been compiled with the same version of the Flex framework as the main application. They must be loaded by the same or older version of the compiler that is used for the main application. For more information, see “Developing multi-versioned applications” on page 213.

When compiling each of these types of applications, you should include the MarshallingSupport class into the main application and sub-applications. You do this with the `includes` compiler argument, as the following example shows:

```
-includes=mx.managers.systemClasses.MarshallingSupport
```

When developing large, single-versioned applications, you might consider using modules instead of sub-applications. For more information, see “Comparing loaded applications to modules” on page 187.

Sub-applications can run independently of the main application and other sub-applications. There should be no dependencies on the main application or other sub-applications for a sub-application to run.

When developing sub-applications in Flash Builder, you cannot just compile the main application and expect the sub-application to also recompile. You must compile them separately. Using Ant or some other automated build process can help. This process is different from developing modules, where if you compile the application that loads a module, Flash Builder also compiles the module.

Loading applications with the SWFLoader control

The SWFLoader control lets you load one application into another application. It has properties that let you scale its contents. It can also resize itself to fit the size of its contents. By default, content is scaled to fit the size of the SWFLoader control. The SWFLoader control can also load content on demand programmatically, and monitor the progress of a load operation.

To load a SWF file into a SWFLoader control, you set the value of the SWFLoader control’s `source` property. This property defines the location of the sub-application’s SWF file. After you set the value of the `source` property, Flex imports the specified SWF file and runs it. For simple examples of using the SWFLoader tag in an application, see “Creating a SWFLoader control” on page 716.

In addition to SWF files, the SWFLoader control can also load several types of images (such as JPG, PNG, and GIF files) as SWF files. You cannot load a module, RSL, or style module with the SWFLoader control.

The default behavior for the SWFLoader control depends on the location of the loaded SWF file. If the loaded application is loaded locally, the default is to load the SWF file into the same security domain, and a child application domain. This loads an application that is trusted but single-versioned.

If the loaded application is loaded from a different server or in a separate sub domain than the main application, then the default is to load the application into a separate security domain and a separate, sibling application domain. The result is a multi-versioned application, but one that has some restrictions on it because it is untrusted by default. This is the recommended approach for all third-party applications, or any multi-versioned applications that use RPC classes or DataServices-related functionality.

When loading any application, you can explicitly set the values of properties on the SWFLoader control that set the application domain and the security domain. These properties define the trust level between the main application and the sub-application, and determine whether the applications are multi-versioned. The following table describes these properties of the SWFLoader control.

Property	**Description**
`loadForCompatibility`	Determines if the loaded SWF file is a multi-versioned application. Set this property to `true` to indicate that the loaded application might be compiled with a different version of the Flex framework and you want your application to be able to interact with it. Setting the value of the `loadForCompatibility` property to `true` also causes the LoaderContext of the Loader to load the sub-application into a sibling application domain of the main application, rather than a child application domain. ***Note:** The sub-application must be compiled with the same or older version of the compiler than the version that the main application was compiled with.* Set this property to `false` to disallow any version compatibility. If the loaded application was compiled with an older version of the framework, then the application will likely experience errors at run time (if the two applications use a shared resource whose API has changed between versions of the Flex framework). If the application was compiled with the same version of the framework, then it will load and interact with the main application as normal. The value of the `loadForCompatibility` property is ignored if you explicitly set the value of the `loaderContext` property. Setting this property has no impact on the sub-application's security domain. The default value of the `loadForCompatibility` property is `false`. If you set `loadForCompatibility` to `true` when developing your applications, use this method of loading consistently in the future. If you change an application from one that is multi-versioned to one that is single-versioned, or vice versa, you should not expect the application to work the same way. For more information, see SWFLoader.loadForCompatibility.
`loaderContext`	Defines the context into which the child SWF file is loaded. The context defines the application domain and the security domain of the application. With the `loaderContext` property, you can set the security domain into which the application is loaded. You can also require that a policy file is in place before the SWF file is loaded. The default for a local application is to load the sub-application into the same security domain as the main application. For a remote (or cross-domain) application, the default is to load the sub-application into a different security domain. With the `loaderContext` property, you can also specify the application domain for the context. The default is a child of the Loader's application domain. If you want to load a multi-versioned application, change this to a sibling application domain. In general, use the `loadForCompatibility` property rather than the `loaderContext` property to specify the application domain. If you explicitly set the value of the `loaderContext` property, then the SWFLoader control ignores the value of its `loadForCompatibility` and `trustContent` properties. The default value of the `loaderContext` property is `null`. You can only specify a LoaderContext in ActionScript. There are some restrictions on using the `loaderContext` property. For more information, see "Specifying a LoaderContext" on page 195. For more information, see SWFLoader.loaderContext.

Property	Description
trustContent	Determines whether the SWF file is loaded into the main application's security domain. Set to true to load the SWF file into the main application's security domain. Regardless of whether the SWF file is same-domain or cross-domain, the SWF file is now considered trusted (assuming that the policy file permits it to be). This means that it can access properties and methods of the main application, and vice versa. You should not set this to true for any third-party application unless you can absolutely trust the source of that application. Set this property to false to load a cross-domain SWF file into a separate security domain. It is now considered untrusted. The SWF file cannot access properties and methods of the main application, nor can the main application access the SWF file's properties and methods. The value of the trustContent property is ignored if you explicitly set the value of the loaderContext property. The default value of the trustContent property is false. For more information, see SWFLoader.trustContent.

Specifying a LoaderContext

Specifying a loader context for the sub-application gives you control over the security domain and application domain that the application is loaded into. You specify the loader context by setting the values of the `securityDomain` and `applicationDomain` properties on the LoaderContext object.

You can only specify a loader context in ActionScript. You cannot set its value as an attribute in the `<mx:SWFLoader>` tag.

The following example assigns a custom LoaderContext to the SWFLoader. It defines the current security domain and a sibling application domain for the loader. This is only applicable to sub-applications that are single-versioned. For multi-versioned applications or sandboxed applications, you should use calls to the `allowDomain()` method to establish trust between the main application and the sub-application.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- apploading/MainAppCustomLoaderContext.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    creationComplete="initApp()">
     <fx:Script>
          <![CDATA[
               import flash.system.SecurityDomain;
               import flash.system.ApplicationDomain;

               private function initApp():void {
                    var context:LoaderContext = new LoaderContext();

                    /* Specify the current application's security domain. */
                    context.securityDomain = SecurityDomain.currentDomain;
                    /* Specify a new ApplicationDomain, which loads the sub-app into a
                      peer ApplicationDomain. */
                    context.applicationDomain = new ApplicationDomain();
                    contentLoader.loaderContext = context;
                    contentLoader.source = "http://yourdomain.com/SubApp3.swf";
               }
          ]]>
     </fx:Script>
     <mx:SWFLoader id="contentLoader"/>

</s:Application>
```

This example triggers the `initApp()` method on the Application object's `creationComplete` event. If you had instead set the `source` property of the SWFLoader control in MXML, you would use the `preinitialize` event to set the loader context. Waiting for the application's `creationComplete` event to set the loader context would occur too late in the application startup.

Setting the `context.securityDomain` property to the `currentDomain` makes the SWF file trusted by loading it into the same security domain as the main application. To do this, though, the sub-application's server must have a policy file that allows you to load it. The result is that the SWF file becomes trusted, and acts as if it was loaded locally. In AIR, you cannot specify any value for the `context.securityDomain` property.

You can only specify the value `SecurityDomain.currentDomain` for the `context.securityDomain` property. Attempting to pass any other security domain results in a SecurityError exception. If you do not specify any value for the `currentDomain` property, then a remote SWF file is loaded into its own security domain. This occurs unless you set the security domain in some other way, such as setting the value of the SWFLoader's `trustContent` property to `true`.

When specifying an application domain for the `context.applicationDomain` property, you can add a sub-application to a sibling application domain, a child application domain, or the same application domain as the loading application. The following table describes each of these methods.

Value of context.applicationDomain	Result
`new ApplicationDomain()`	Loads the sub-application into a sibling application domain that is rooted on the same domain as the loading application. If the loading application is the top-level application, then both the loading application and the sub-application's application domain will be children of the system domain. You do this if you want to use compatibility mode, because applications that are in sibling application domains can each have their own class definitions. As a result, they can be compiled by different versions of the Flex framework, as long as the sub-applications are compiled with the same or older version of the compiler than the main application.
`new ApplicationDomain( ApplicationDomain.currentDomain)`	Loads the sub-application into an application domain that is a child of the main application's application domain. All class conflicts are resolved when the application is loaded; the first class definition wins. Do not use this method if you want to load a multi-versioned application. That is because applications that are loaded into the same application domains must be compiled by the same version of the Flex framework.
`application.currentDomain`	Loads the sub-application into the same application domain as the main application. You typically do not use this setting when loading sub-applications. It is generally only used for RSLs and other specially compiled resources.

If you specify a loader context when loading a sub-application, do not load more than one application into the same application domain. In other words, do not use the same loader context for more than one sub-application.

Unloading applications with the SWFLoader control

To unload a sub-application that you loaded with the SWFLoader control, call the SWFLoader control's `unloadAndStop()` method, as the following example shows:

```
myLoader.unloadAndStop(true);
```

You can also set the SWFLoader's `source` property to `null`. This results in a call to the `SWFLoader.content.loaderInfo.loader.unload()` method. You can call this method explicitly, but only for trusted applications.

To free up the memory that was used by the loaded sub-application, ensure that no references to objects or classes in the sub-application exist. The `unload()` method frees the loader's reference to the sub-application's bytes, but if code in the sub-application is still in use, then it is not garbage collected.

Flash Player also unloads a sub-application when the same SWFLoader control loads a new sub-application. The original content is removed before the new application is loaded.

Typically, you load a style module into the main application's application domain. If the sub-application contains any user interface classes (such as skins) that are not in the main application, the styles for those classes are loaded into the main application's StyleManager. When you unload the sub-application, the sub-application's memory is not freed up. In this case, load style modules into the sub-application's application domain.

Accessing the main application from sub-applications

There are several ways to access the methods and properties of the main application from the sub-application. These ways only work for sub-applications that are loaded as children into a main application's application domain. You cannot use these for sandboxed applications, or for multi-versioned applications.

These methods include:

- Using the `application` property of the Application class. This property accesses the root application from anywhere in the application. For more information, see "Accessing document and application scopes" on page 404.

- Using the parentDocument property of the Application class. This is useful if you have multiple applications embedded and want to just access the immediate parent. For more information, see "Accessing document and application scopes" on page 404.

Be aware that you might encounter security errors if you try to access members that should not be accessed.

Accessing sub-applications from the main application

Although you can access the sub-application from the main application, you cannot directly reference methods and properties. This is because the members of the sub-application, unless it is embedded at compile-time, are not known by the compiler when the main application compiles.

You can, however, get a reference to the sub-application's SystemManager. You can then treat members of the sub-application as dynamic properties and methods of the sub-application's object.

The following example loads a remote sub-application into the SWFLoader. It sets the value of the trustContent property to true so that the sub-application is loaded into the same security domain as the main application. It casts the content property of the SWFLoader to a SystemManager so that the application's members can be accessed dynamically. It then calls a method and accesses a property of the sub-application.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- apploading/MainAppUsingSubAppMembers.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
     <fx:Script>
          <![CDATA[
               import mx.managers.SystemManager;
               private function getValueFromSubApp():void {
                    /* Cast the SWFLoader's content as a SystemManager
                      to access the sub-application. */
                    var subApp:SubApp2 =
                         (contentLoader.content as SystemManager).application as SubApp2;
                    /* Call a method and access a property of the
                      sub-application. */
                    label1.text = subApp.doSomething() + subApp.answer;
               }
          ]]>
     </fx:Script>

     <mx:SWFLoader id="contentLoader" visible="false"
          height="0" width="0"
          trustContent="true"
          source="http://yourdomain.com/SubApp2.swf"/>
     <mx:Panel id="myPanel2"
          paddingLeft="10" paddingBottom="10"
          paddingTop="10" paddingRight="10">
          <s:Label id="label1"/>
          <s:Button id="b2" label="Call SubApp2" click="getValueFromSubApp()"/>
     </mx:Panel>

</s:Application>
```

The following example shows the sub-application that is loaded by the main application in the previous example. It defines a public property, `answer`, as well as a public method, `doSomething()`, that returns a String.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- apploading/SubApp2.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Script>
          <![CDATA[
               // Define a public property.
               public var answer:int = 42;

               // Define a public method that returns a String.
               public function doSomething():String {
                    return "The answer is ";
               }
          ]]>
     </fx:Script>
</s:Application>
```

For more information about accessing sub-applications from the main application, see "SWFLoader control" on page 715.

If the sub-application is loaded remotely, you can access its members only if it is in the same security domain as the main application, or if you and the sub-application call the `Security.allowDomain()` method. In this case, you must call the `Security.allowDomain()` method from the main application on the sub-application's domain, and the sub-application must call this method on the main application's domain. You must also call the `allowDomain()` method early in the sub-application's lifecycle. For example, call it in a `preinitialize` event handler.

Creating class instances from loaded applications

You can create instances in a main application of classes that are defined in a loaded sub-application. You can then add these objects to your main application and interact with them as you would interact with any other object in the display list. To access class definitions in a sub-application, you get the definitions from the sub-application's application domain.

Each application domain contains definitions of all the classes within it. There is an applicationDomain object that you access with a reference to the loaded application's LoaderContext. The ApplicationDomain object has two methods, `hasDefinition()` and `getDefiniton()`. The `hasDefinition()` method lets you detect if a class definition exists. If a class definition exists, the `getDefinition()` method lets you create an instance of that class in your main application.

You can't add a UIComponent that is defined in another application domain to the main application's display list. As a result, to create an instance of a class that is defined in another application domain, the sub-application must be loaded into a child application domain of the main application's application domain (you cannot set the value of the SWFLoader's `loadForCompatibility` property to `true`). The sub-application must also be in the same security domain as the main application (`trustContent` must be `true`).

You can only create the instance of the class dynamically when the class is defined in an application that is loaded at run time. This is because the compiler does not have access to classes in loaded applications at compile time, so it cannot check linkages. If the sub-application was embedded at compile time, then you would not have to create the instance dynamically, the class definition would be available to the compiler. In this case, you could instead use the `new` keyword with the specific class type rather than a generic Class type.

The following example main application loads a sub-application with the SWFLoader control. It sets the value of the `trustContent` property to `true` and defines a method, `createClassInstance()`. This method gets the definition of the custom class from its loaded application's application domain. The example then creates an instance of this class and sets a property on it before adding it to the display list.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- apploading/MainAppUsingSubAppDefinitions.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
     <fx:Script>
          <![CDATA[
               import mx.core.UIComponent;
               public function createClassInstance():void {
                    // Check that the definition exists.
                    if
(contentLoader.loaderContext.applicationDomain.hasDefinition('MyRedButton')) {
                         var objClass:Class =
contentLoader.loaderContext.applicationDomain.getDefinition('MyRedButton') as Class;
                         if (objClass != null) {
                              var newObject:UIComponent = UIComponent(new objClass());
                              // Set properties on the custom class as an associative array.
                              newObject["label"] = "Click Me";

                             // Add the new instance to the second panel in this application.
                              myPanel2.addChild(newObject);
                         }
                    }
               }
          ]]>
     </fx:Script>
     <!-- The SWFLoader in the first panel loads the
           sub-application that contains a definition of MyRedButton. -->
     <mx:Panel id="myPanel" title="SubApp1 Loaded by main application">
          <mx:SWFLoader id="contentLoader"
            trustContent="true"
            source="SubApp1.swf"/>
     </mx:Panel>
     <!-- This application adds an instance of the MyRedButton
           class to the second panel after the content is loaded. -->
     <mx:Panel id="myPanel2" title="Instance of a Class Defined By SubApp1"/>

</s:Application>
```

In this case, the `hasDefinition()` method returns a boolean to tell if a class is present in the loaded SWF file. If it is present, the sub-application can obtain the Class using the `getDefinition()` method. You can then create instances by using the `new` keyword with the returned class.

Also notice that the `createClassInstance()` method is public. If it were private, the sub-application would not be able to call it.

The sub-application, SubApp1.swf, statically links a custom class called MyRedButton. It also calls the parent application's method when it is done. You cannot call that method in the parent application's `applicationComplete` event, because that event will likely be triggered too early in the initialization process. Wait for the sub-application to complete its loading and initialization before you create an instance of a class that is defined in it.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- apploading/SubApp1.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:custom="*"
    creationComplete="initApp()"
    applicationComplete="mx.core.FlexGlobals.topLevelApplication.createClassInstance()">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

     <fx:Script>
          <![CDATA[
               private function initApp():void {
                    var child:DisplayObject = getChildAt(0);
                    var childClassName:String = getQualifiedClassName(child);

                   // Show that the qualified class name of the custom button is MyRedButton.
                    trace(childClassName);
               }
          ]]>
     </fx:Script>
     <custom:MyRedButton id="myRedButtonId" label="Click Me"/>
</s:Application>
```

The MyRedButton class is a simple MXML component that extends Button and defines its color as red. The following example shows this custom class:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- apploading/MyRedButton.mxml -->
<s:Button
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    color="red">
</s:Button>
```

Listening for mouse events with loaded applications

It is possible to listen for mouse events in a main application from a loaded sub-application that is in a child application domain. To listen for these events, you listen for events such as `MOUSE_UP` and `MOUSE_MOVE` on the sub-application's `systemManager.topLevelSystemManager`. When the sub-application is in a child application domain, the `topLevelSystemManager` property refers to the main application's SystemManager.

The following application shows how to access mouse events on the `topLevelSystemManager` in a sub-application that was loaded into a child application domain. If the sub-application is not in a child application domain, then you must handle access to the SystemManagers differently. For more information, see the examples in "Listening for mouse events with sandboxed applications" on page 209 and "Listening for mouse events in multi-versioned applications" on page 216.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- apploading/ZoomerPattern2.mxml -->
<s:Application
    creationComplete="setup()"
    height="250"
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
     <fx:Script>
     <![CDATA[
          import mx.core.UIComponent;
          import mx.managers.PopUpManager;
          [Bindable]
          public var data1:Array = ["Ice Cream", "Fudge", "Whipped Cream", "Nuts"];
          public var zoomTool:UIComponent;
          public function setup():void {
               // Draw the zoom rectangle.
               zoomWidget.graphics.lineStyle(1);
               zoomWidget.graphics.beginFill(0, 0);
               zoomWidget.graphics.drawRect(0, 0, 17, 17);
               zoomWidget.graphics.endFill();
               // Listen for mouse down events.
               zoomWidget.addEventListener(MouseEvent.MOUSE_DOWN, zoom_mouseDownHandler);
          }
          private var lastX:int;
          private var lastY:int;
          private function zoom_mouseDownHandler(event:MouseEvent):void {
               // When the mouse is down, listen for the move and up events.
               systemManager.topLevelSystemManager.addEventListener(
                    MouseEvent.MOUSE_MOVE, zoom_mouseMoveHandler, true);
               systemManager.topLevelSystemManager.addEventListener(
                    MouseEvent.MOUSE_UP, zoom_mouseUpHandler, true);
               // Update the last position of the mouse.
               lastX = event.stageX;
               lastY = event.stageY;
               // Create and pop up the zoomTool. This is what is dragged around.
               // It must be a popup so that it can float over other content.
               zoomTool = new UIComponent();
               PopUpManager.addPopUp(zoomTool, this);
               var pt:Point = new Point(zoomWidget.transform.pixelBounds.x,
                    zoomWidget.transform.pixelBounds.y);
               pt = zoomTool.parent.globalToLocal(pt);
               zoomTool.x = pt.x;
               zoomTool.y = pt.y;
               zoomTool.graphics.lineStyle(1);
               zoomTool.graphics.beginFill(0, 0);
               zoomTool.graphics.drawRect(0, 0, 17, 17);
               zoomTool.graphics.endFill();
               // Hide the rectangle that was the target.
               zoomWidget.visible = false;
          }
          private function zoom_mouseMoveHandler(event:MouseEvent):void {
               // Update the position of the dragged rectangle.
               zoomTool.x += event.stageX - lastX;
```

```
                zoomTool.y += event.stageY - lastY;
                lastX = event.stageX;
                lastY = event.stageY;
                var bm:BitmapData = new BitmapData(16, 16);

                // Capture the bits on the screen.
                bm.draw(DisplayObject(systemManager.topLevelSystemManager), new
                     Matrix(1, 0, 0, 1,  -zoomTool.transform.pixelBounds.x - 2,
                     -zoomTool.transform.pixelBounds.y - 2));
                // Create a Bitmap to hold the bits.
                if (zoomed.numChildren == 0) {
                     var bmp:Bitmap = new Bitmap();
                     zoomed.addChild(bmp);
                } else
                     bmp = zoomed.getChildAt(0) as Bitmap;
                // Set the bits.
                bmp.bitmapData = bm;
                // Zoom in on the bits.
                bmp.scaleX = bmp.scaleY = 8;
           }
           private function zoom_mouseUpHandler(event:Event):void {
                // Remove the listeners.
                systemManager.topLevelSystemManager.removeEventListener(
                     MouseEvent.MOUSE_MOVE, zoom_mouseMoveHandler, true);
                systemManager.topLevelSystemManager.removeEventListener(
                     MouseEvent.MOUSE_UP, zoom_mouseUpHandler, true);
                // Replace the target rectangle.
                zoomWidget.visible = true;
                // Remove the dragged rectangle.
                PopUpManager.removePopUp(zoomTool);
           }
     ]]>
     </fx:Script>

     <mx:HBox>
          <mx:HBox backgroundColor="0x00eeee" height="140" paddingTop="4" paddingRight="4">
               <mx:Label text="Drag Rectangle"/>
               <mx:UIComponent id="zoomWidget" width="17" height="17"/>
               <mx:Canvas id="zoom"
                    borderStyle="solid"
                    width="132"
                    height="132"
               >
                    <mx:UIComponent id="zoomed" width="128" height="128"/>
               </mx:Canvas>
          </mx:HBox>
          <mx:List dataProvider="{data1}"/>
     </mx:HBox>
</s:Application>
```

The following example main application loads the previous example application. It uses the default settings to load the sub-application.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- apploading/MainZoomerPattern2.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
     <mx:Text text="Default (trusted application in child ApplicationDomain):"/>

     <mx:SWFLoader id="swf1" source="ZoomerPattern2.swf"/>

</s:Application>
```

In this example, you cannot drag the rectangle outside the sub-application's boundaries, and the `mouseUp` event does not get triggered.

This example application uses the `systemManager.topLevelSystemManager` property to get a reference to the main application's SystemManager. If the application were a stand-alone application, you could use the `systemManager` property to register event listeners, as the following example shows:

```
systemManager.addEventListener(MouseEvent.MOUSE_MOVE, zoom_mouseMoveHandler, true);
systemManager.addEventListener(MouseEvent.MOUSE_UP, zoom_mouseUpHandler, true);
```

This works when the application is a stand-alone application, but not when the application is loaded as a child. The top-level SystemManager, which is not the sub-application's SystemManager, parents the zoomTool class.

Embedded fonts in loaded applications

Applications and modules in the same application domain are able to use the same embedded fonts by specifying the font name. For example, a font embedded in the main application can be used by a sub-application, as long as the applications are in the same application domain.

Models and singletons in loaded applications

Models that are implemented as singletons, and other singletons that the main application and its sub-applications share, do not work if the sub-application and main application are in separate application domains.

To share models and other singletons, you can write your own marshaling code or create a bootstrap loader that stores definitions of those classes.

Adobe recommends not sharing data models and other singletons with untrusted applications.

"Bootstrap loading" on page 219

Using RSLs with sub-applications

Single-versioned applications can share RSLs with other sub-applications and the main application to minimize the number of classes that are loaded. This results in faster load times and smaller file sizes. Multi-versioned or sandboxed applications cannot share RSLs.

Starting with Flex 4.5, sub-applications work much more efficiently with RSLs. The main application only loads those framework RSLs that are needed at startup, and creates placeholders for all remaining framework RSLs. The sub-application does not try to load RSLs that are already loaded by the main application. If the sub-application needs one of the framework RSLs that are not initially loaded by the main application, then the sub-application loads the RSL.

In addition, when a sub-application loads an RSL, you can specify which domain the RSL is loaded into with the `application-domain` compiler argument. This applies to both framework RSLs and custom RLSs. This lets you load an RSL into the parent, current, or top-level application domains.

When you develop sandboxed or multi-versioned applications, you cannot always externalize overlapping class definitions, because the class definitions might be different. For example, if two applications are compiled with different versions of the Flex framework, then each application must have its own definition of the manager classes (such as the LayoutManager or the CursorManager) and other classes in the framework. As a result, do not externalize those classes by compiling the applications against the same RSLs.

In previous versions of Flex, you were required to initialize certain manager classes such as the FocusManager if you loaded a module or sub-application into a main application that did not use those manager classes. You are no longer required to do this if you load the sub-application into a sibling application domain where each application has its own class definitions. However, each security domain must include a definition of the PopUpManager class in case an untrusted sub-application displays a modal dialog box.

For information on using RSLs with sub-applications, see “Using RSLs with modules and sub-applications” on page 258.

Developing sandboxed applications

Sandboxed applications contain sub-applications that are loaded into separate security domains. By definition, they are therefore loaded into separate application domains as well. As a result, they can be multi-versioned, but are untrusted. Because they are untrusted, their interoperability with the main applications is limited. Types of sandboxed applications include portals, mashups, and dashboards.

Sandboxed applications must be compiled with the same or older version of the compiler that the main application is compiled with.

When compiling sandboxed applications, you should include the MarshallingSupport class into the main application and sub-applications. You do this with the `includes` compiler argument, as the following example shows:

```
-includes=mx.managers.systemClasses.MarshallingSupport
```

If you are using any third-party applications, you should load them as sandboxed applications. In addition, if you are using multi-versioned applications that use RPC classes or DataServices-related functionality, you should also consider loading them as sandboxed applications. Otherwise, you might be required to provide additional code such as a bootstrap loader.

In a sandboxed configuration, loaded sub-applications are typically not on the same domain as the main application. This means that the applications might not necessarily trust the loaded applications by default. In addition, all sub-applications are not necessarily always visible at the same time, so the main sandboxed application must be able to load and unload sub-applications at any time.

In sandboxed applications, each sub-application is loaded into a separate application domain and a separate security domain. The interoperability across security domains is very limited. The sub-application cannot access most stage properties, methods, and events. It cannot get mouse and keyboard events from other security domains. It also cannot perform drag and drop operations to or from the main application, and pop-up controls are clipped at the boundaries of the sub-application. Data sharing between the main application and sub-application requires marshaling.

If you try to use the parent chain of an application object to access properties of the main application from a sub-application in a different security domain, you will encounter security errors at run-time. In addition, you cannot access the application through the SWFLoader.content object.

For details about the architecture of a sandboxed application, see “About sandboxed applications” on page 180.

Pop-up controls in sandboxed applications

Pop-up controls are parented by the application at the sandbox root of their security domain. This is because the sandbox root handles requests to display a modal window from its children.

Because pop-up controls are parented by the sandbox root, centering a popup in a sandboxed application centers it in the area of the screen occupied by the sub-application and not the entire application. It also means that pop-up controls are sometimes clipped by scroll bars and masks on the sub-application.

A sub-application in a separate security domain from the main application has the following behavior:

- Launching a modal dialog box dims the entire application, but the pop-up can only be dragged within the boundaries of the sub-application.
- Centering a pop-up centers it over the sub-application, not the main application.
- Dragging pop-up controls works over the sub-application only. If you drag a pop-up outside the sub-application, it is clipped.
- Focus shifts to the pop-up control when you first launch a pop-up.

A sandboxed application cannot display a window or dialog box outside the bounds of its application. This rule prevents an untrusted application from phishing for passwords by displaying a dialog box on top of all the applications. When displaying a popup window, the PopUpManager checks if the parent application trusts it and if it trusts the parent application before asking the parent to host the window. If the parent hosts a window it is displayed over the parent's content as well as the child's content. If no mutual trust exists between a main and sub-application, then the PopUpManager hosts the dialog box locally so that it can only be displayed over the content of the application itself. But if the parent trusts the child, the dialog box is not clipped by the boundaries of the child’s application.

When a main application does not trust a sub-application, the main application’s SWFLoader uses masking with a scrollRect and scroll bars to keep the sandboxed application’s content restricted to its own application space.

Pop-up-related controls such as ColorPicker, ComboBox, DateField, PopUpButton, PopUpMenuButton, and Menu sometimes display their contents in unexpected ways if their normal position would cause them to be clipped.

Alert controls in sandboxed applications

Alerts, like other pop-up controls in sandboxed applications, are clipped at the edge of the loaded application. When an Alert is being displayed, the main application and all sub-applications are covered with a modal dialog box to prevent interaction with their controls. The blur effect only applies to the sub-application that launched the Alert box, and its child applications. The blur effect is not applied to the parent application or sibling applications.

Styles and style modules in sandboxed applications

The StyleManager does not pass styles from a parent application to a child in a different application domain or security domain. Similarly, a main application does not inherit styles from a sub-application. Therefore, either define styles within your sub-application and do not depend on the sub-application inheriting styles from the main application, or load a style module into the main application’s application domain.

Sub-applications each have their own StyleManager. When you load a style module in a sub-application, the classes themselves should be loaded into the child ApplicationDomain. The styles are loaded into the sub-application’s StyleManager.

If you want a main application and a sub-application to use the same runtime style sheets, load the style module into the main application’s application domain. Sub-application’s styles are merged with the main application’s styles. Main applications do not inherit styles that are defined in style modules that are loaded into sub-applications.

A style module must be compiled with the same version of the Flex framework as the application into which it is loaded. The main application and sub-application might not be able to load the same style module, unless they are compiled with the same version of the framework.

When loading a style module into a sub-application, if you don't specify an application domain, the module is loaded into a *sibling* application domain of the sub-application. This can result in an error when the sub-application tries to use classes that are defined in the style module.

To load a style module into a sub-application, load the style module into a *child* application domain of the sub-application. The `loadStyleDeclarations()` method has two optional parameters, `applicationDomain` and `securityDomain`. You use these properties to control the application domain and the security domain into which style modules get loaded.

The following example loads a style module into a child application domain of the sub-application:

```
private function loadStyle():void {
    /* Load style module into a child ApplicationDomain by specifying
       ApplicationDomain.currentDomain. */
    var eventDispatcher:IEventDispatcher = styleManager.loadStyleDeclarations(
        currentTheme + ".swf", true, false, ApplicationDomain.currentDomain);
    eventDispatcher.addEventListener(StyleEvent.COMPLETE, completeHandler);
}
```

For more information on using style modules, see "Loading style sheets at run time" on page 1547.

Fonts in sandboxed applications

Applications that are in the same application domain are able to use the same embedded fonts by specifying the font name. However, if the sub-application is loaded into a different application domain (as is the case with sandboxed applications), then the sub-application must embed the font to use it.

Focus in sandboxed applications

The FocusManager class in the main application and sub-application integrate to create a seamless focus scheme. Users can "tab through" the sub-application, regardless of whether the application is in the same or a different security domain as the main application. Shift tabbing also works. The FocusManager class is one of the few manager classes that supports interoperability even across security domains.

When an application is loaded, the main application keeps track of that SWF file in a list of focus candidates. When the user moves focus into the sub-application, the sub-application's FocusManager takes over focus duties until the user moves focus outside the sub-application. At that time, the main application's FocusManager resumes control.

When a pop-up is dismissed, the focus is moved to the last place that had focus. This behavior can be another pop-up or it can be in the main application.

When focus is on a control that is in a different security sandbox, calls to the `getFocus()` method on that application's FocusManager return `null`. Calls to the `UIComponent.getFocus()` method also return `null`.

The FocusManager's `moveFocus()` method lets you programmatically transfer focus to a control under the jurisdiction of another FocusManager. It also lets you transfer the control of focus to another FocusManager.

Focus management across application domains works even with modal dialog boxes. When a different top-level window is activated, the SystemManager deactivates the FocusManager in the formerly active top-level window. The SystemManager also activates the FocusManager in the other window and changes the depth level (z-order) of the windows.

Cursors in sandboxed applications

If the applications are in different security domains, then a custom cursor in the sub-application only appears over the area of the screen that is allocated to that sub-application. Moving the mouse outside the bounds of the sub-application passes control of the cursor to the main application's CursorManager.

These rules apply to the busy cursor as well. If a busy cursor is visible and you move the cursor to the main application that is in a different security domain, the cursor changes back to the last used cursor in the main application.

Localizing sandboxed applications

As with style modules, the main application cannot access resource modules used in a sub-application, and vice versa. Each sub-application must load its own resource modules.

Each multi-versioned application has its own ResourceManager instance. As a result, each sub-application has its own `localeChain`.

If more than one sub-application has resource bundles for the same locale with the same name, then the first one in wins. The contents of all resource bundles of that name in other sub-applications are ignored. Those sub-applications use the one that was defined first.

Like style modules, load resource modules into the child application domain of a sub-application. You control the application domain and the security domain into which resource bundles are loaded. The `loadResourceModule()` method of IResourceManager has two optional parameters, `applicationDomain` and `securityDomain`.

Also like style modules, all resource modules in an application must be compiled with the same version of the Flex framework. Do this whether that application is a main application or a sub-application. You cannot use multiple resource modules that were compiled with two different versions of the framework in the same main application or sub-application.

The following example loads a resource module into a child application domain of the sub-application:

```
private function loadBundle():void {
    /* Load resource module into a child ApplicationDomain by specifying
       ApplicationDomain.currentDomain. */
    var eventDispatcher:IEventDispatcher = ResourceManager.loadResourceModule(
        "MyBundle.swf", true, false, ApplicationDomain.currentDomain);
    eventDispatcher.addEventListener(StyleEvent.COMPLETE, completeHandler);
}
```

If you use run-time resource bundles with sub-applications, you should consider setting the `addResourceBundle()` method's `useWeakReferences` parameter to `true`. For more information, see "Preventing memory leaks in modules and sub-applications" on page 2118.

ToolTip objects in sandboxed applications

When in a different security domain, ToolTip objects are parented by the sub-application's SystemManager and are therefore clipped and masked by the main application. The ToolTipManager styles and positions the tip in a sub-application so that it fits within the sub-application's area of the screen only. If the ToolTip object is larger than the area of the sub-application, the ToolTip object is clipped.

ToolTip styles in the main application are not inherited by ToolTip objects in the sub-application.

This applies to error tips and data tips on List objects in sandboxed sub-applications as well.

Layouts in sandboxed applications

For controls that have pop-up or drop-down menus, when they are in a separate security domain, they are initially displayed unclipped. These controls are restricted to the sub-application's space, so if they try to go outside that bounding area, they are clipped.

Deep linking in sandboxed applications

The BrowserManager controls deep linking support in applications built with Flex. It is a singleton within its security domain. Sub-applications in sibling application domains cannot access the main application's BrowserManager, regardless of whether a sub-application is trusted or untrusted. As a result, a sub-application in a separate security domain or application domain cannot modify the URL nor can it access the URL.

If the sub-application is untrusted, do not give it access to the URL. If the sub-application is trusted (such as with a multi-versioned application that is not sandboxed), you can write custom code that handles the interaction between the sub-application and the main application's BrowserManager. Typically, you call this method in the main application that accesses the URL, or create an interface that acts as a gatekeeper for this interaction.

If you try to get an instance of the BrowserManager from within a sub-application, Flash Player throws an error.

Dragging and dropping in sandboxed applications

When the sub-application is in a different security domain from the main application, the user cannot drag data between the applications. The DragProxy lets the user drag an item to the edge of the sub-application's area of the screen. At that point, the mouse cursor changes back to whatever mouse cursor is correct for the new security domain.

The proxy for the item stays at the boundary of the sub-application, and might be clipped.

Listening for mouse events with sandboxed applications

Mouse interaction between sub-applications and main applications can be confusing, especially when those events occur in different application domains. This interaction is further muddied when the applications are in different security domains. To listen for mouse events outside the security domain, you use the SandboxMouseEvent object. You can listen for this event in a main application for a mouse event that is triggered from the sub-application, and vice versa.

The following application is like the application in the topic, "Listening for mouse events in multi-versioned applications" on page 216, with some exceptions. For example, while the `MouseEvent.MOUSE_MOVE` and `MouseEvent.MOUSE_UP` events are registered, the `SandboxMouseEvent.MOUSE_UP_SOMEWHERE` event is also registered. This event can be registered by any SystemManager within the security domain. All applications can then receive notification if this event is triggered. To get the mouse position, this application uses the `globalToLocal()` method. You can see how to determine the absolute position of an object in a sub-application when you don't have access to the stage.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- apploading/ZoomerPattern4.mxml -->
<s:Application
    creationComplete="setup()"
    height="250"
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
     <fx:Script>
     <![CDATA[
          import mx.core.UIComponent;
          import mx.events.SandboxMouseEvent;
          import mx.managers.PopUpManager;
          [Bindable]
          public var data1:Array = ["Ice Cream", "Fudge", "Whipped Cream", "Nuts"];
          public var zoomTool:UIComponent;
          public function setup():void {

               zoomWidget.visible = true;

               // Remove the dragged rectangle.
```

```
                PopUpManager.removePopUp(zoomTool);
            }
     ]]>
     </fx:Script>

    <mx:HBox>
          <mx:HBox backgroundColor="0x00eeee" height="140" paddingTop="4" paddingRight="4">
               <mx:Label text="Drag Rectangle"/>
               <mx:UIComponent id="zoomWidget" width="17" height="17"/>
               <mx:Canvas id="zoom"
                    borderStyle="solid"
                    width="132"
                    height="132"
               >
                    <mx:UIComponent id="zoomed" width="128" height="128"/>
               </mx:Canvas>
          </mx:HBox>
          <mx:List dataProvider="{data1}"/>
     </mx:HBox>
</s:Application>
```

The following example main application loads the previous example application. It sets the value of the `trustContent` property to `false` to mimic the behavior of a remotely loaded untrusted sub-application. It also links the PopUpManager because the sub-application uses it.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- apploading/MainZoomerPattern4.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
     <fx:Script>
          <![CDATA[
               /* The PopUpManager must be linked in to all applications that are
                  at the same security sandbox root. Because the sub-application
                  in this example uses the PopUpManager, the main application must also
                  link it it. */
               import mx.managers.PopUpManager; PopUpManager;
          ]]>
     </fx:Script>
     <mx:Text text="Portal (untrusted versioning application):"/>

     <mx:SWFLoader id="swf1"
          loadForCompatibility="true"
          trustContent="false"
          source="ZoomerPattern4.swf"/>

</s:Application>
```

Accessing flashVars variables in sandboxed applications

You can access application parameters that were passed into the sub-application as `flashVars` variables. To do this, you access the Array of parameters on the application object by using the `getSandboxRoot()` method.

The following example gets a reference to the root application and accesses the parameters:

```
var app:DisplayObject = DisplayObject(
    SystemManager.getSandboxRoot()["application"]);
var parameters:Object = app["parameters"];
```

Developing multi-versioned applications

In most applications, even very large applications, the entire base of source code is compiled before release. This recompilation ensures that all pieces of the applications are using the same APIs. This model works well for desktop software and software whose releases are tightly controlled. But it does not always work well in the Internet model of application development, where applications are continually updated.

Internet applications are often developed and released gradually, with new pieces of functionality being added to the application all the time. To ease application development of this kind, Flex lets you create multi-versioned applications. A single application can load multiple sub-applications even if those sub-applications are compiled with different versions of the Flex framework. Sub-applications must, however, be compiled with the same or older version of the compiler that was used to compile the main application.

Using multi-versioned applications is common for sandboxed applications where more than one group of developers works on different pieces of functionality. It is also common on very large applications that are continually improved on and released.

When compiling multi-versioned applications, you should include the MarshallingSupport class into the main application and sub-applications. You do this with the `includes` compiler argument, as the following example shows:

```
-includes=mx.managers.systemClasses.MarshallingSupport
```

Using RPC and DataServices-related functionality in your multi-versioned applications has some limitations. These limitations depend on the type of remote data access you use: RPC classes with a proxy server, RPC classes without a proxy server, and DataServices and RemoteObject functionality. In many of these cases, you should develop sandboxed applications rather than multi-versioned applications. For more information, see “Using RPC and DataServices classes with multi-versioned applications” on page 214.

Flex supports multi-versioned applications that were compiled with version 3.2 of the Flex framework and later. For example, your main application can be a Flex 4.6 application, and the loaded applications can be compiled with the following versions of the framework:

- 3.2
- 3.4
- 3.6
- 4
- 4.5
- 4.6

If you try to load an sub-application that was compiled with a more recent version of the framework than the main application, you will get run time errors if the two applications use a shared resource whose API changed between versions of the Flex framework.

In general, a main application that is compiled for Flash Player 11 can load sub-applications that were compiled for Flash Player 11 or Flash Player 10. However, main applications that were compiled for Flash Player 10 cannot load sub-applications that were compiled for Flash Player 11.

Sub-applications that are compiled with an older version of the Flex framework can be loaded either locally (from the same domain or subdomain, in which case they are trusted) or cross-domain (from a different domain, in which case they are untrusted by default). A trusted multi-versioned application will have nearly the same level of interoperability with the main application as a single-versioned trusted application. Styles and resource bundles are not shared, but otherwise they have the same level of interoperability. An untrusted multi-versioned application has slightly more interoperability than a single-versioned untrusted application has when loaded. With untrusted multi-versioned applications, focus management and mouse events work with the main application.

When you load a multi-versioned application, you set the `loadForCompatibility` property of the SWFLoader control to `true`. Setting this property instructs the loader to load the application into a sibling application domain. Applications that are in sibling application domains each maintain their own class definitions. They communicate through event passing, if necessary. For example, if a sub-application must do something that only the top-level application's manager can do, then it communicates with the main application by dispatching an event.

The following sections describe how to develop multi-versioned applications. They assume that all applications are trusted (loaded into the same security domain), and loaded into sibling application domains of the main application. For information about building applications that are in separate security domains, see "Developing sandboxed applications" on page 205.

Using RPC and DataServices classes with multi-versioned applications

RPC and DataServices classes are a special case when used in multi-versioned sub-applications. All applications in the same security domain must share the same definitions of the RPC and DataServices classes for messaging to work. In addition, they might also need to share the same definitions for custom value object classes. This can be a problem because the only way to ensure that a main application and a sub-application use the same set of definitions is to load the sub-application into a child application domain of the main application, which would prevent multi-versioned applications from working. As a result, to use RPC classes in multi-versioned applications, you can do one of the following:

Load the applications as sandboxed applications If you do this, you must call the `Security.allowDomain()` method from the main application on the sub-application's domain in the SWFLoader control's `complete` event handler. You must also call the `Security.allowDomain()` method from the sub-application on the main application's domain. This provides the same level of application interoperability as multi-versioned applications. In the sub-application, you must call the `allowDomain()` method early on in the initialization cycle. Use the application's `preinitialize` event.

Use a bootstrap loader You define the messaging classes in a bootstrap loader. You then load the main application into the bootstrap loader. The main application and its sub-applications can then share those class definitions.

When you use RPC classes (such as WebService and HTTPService) without a proxy server, you do not need to load the sub-application as a sandboxed application or externalize the classes in a bootstrap class loader. Applications that use these classes without a proxy server should work as well as any multi-versioned application. Be sure to that either the URLs for the target services are on the same server as the main application, or that the target server has a crossdomain.xml file on it that allows access.

"Bootstrap loading" on page 219

Pop-up controls in multi-versioned applications

When a sub-application launches a pop-up control, it floats over the entire application, and can be dragged anywhere on the stage. Pop-up controls are created in the sub-application’s application domain and passed to the main application's PopUpManager. Pop-up controls cannot be strongly-typed as IUIComponent, so they are marshaled from the sub-application to the main application for display.

Pop-up windows behave as follows in a multi-versioned sub-application (these behaviors are the same for single-versioned sub-applications):

- Launching a modal dialog box dims the entire application, not just the sub-application that launched it
- Centering a pop-up centers it over the entire application, not just the sub-application
- Dragging pop-up controls works over the entire application, not just the sub-application
- Focus shifts to the pop-up when you first launch a pop-up from the sub-application

The PopUpManager must be linked in to all applications that are sandbox roots. When using the PopUpManager in a child application, there must also be an instance of the PopUpManager in the main application. To link the PopUpManager to a main application that doesn’t use it, you can add the following code:

```
import mx.managers.PopUpManager;
private var popupManager1:PopUpManager;
```

If you do not link a PopUpManager into an application, and a sub-application in its sandbox requests that it display a modal dialog box, you might get the following error:

```
No class registered for interface 'mx.managers::IPopUpManager'.
```

List controls require some additional code when used in sub-applications. If you have a List control in a sub-application’s pop-up and no List control in your main application, you must also link the List class into your main application. In addition, the List control must have a data provider. You can link an invisible List into your main application and set its data provider to an empty array, as the following example shows:

```
<mx:List visible="false" includeInLayout="false" dataProvider="[]"/>
```

Embedded fonts in multi-versioned applications

Applications that are in the same application domain are able to use the same embedded fonts by specifying the font name. However, if the sub-application is loaded into a different application domain (as is the case with multi-versioned applications), then the sub-application must embed the font to use it.

Styles and style modules in multi-versioned applications

Using styles and style modules in multi-versioned sub-applications is the same as using them in sandboxed sub-applications. For more information on using styles and style modules in sub-applications, see “Styles and style modules in sandboxed applications” on page 206.

Focus in multi-versioned applications

Using the FocusManager in multi-versioned sub-applications is the same as using the FocusManager in sandboxed sub-applications. (See “Focus in sandboxed applications” on page 207.)

Cursors in multi-versioned applications

The CursorManager class in the main application and sub-application communicate much like the PopupManager class. If the sub-application changes the cursor to a custom cursor, this custom cursor continues to appear when the cursor is moved outside the sub-application and over the main application. Calling a method or setting a property on the CursorManager in the sub-application bubbles up to the main application, and vice versa.

If a busy cursor is visible while the mouse is over the sub-application, and you move the cursor to the main application, the cursor remains as a busy cursor.

Localizing multi-versioned applications

Using resource bundles in multi-versioned sub-applications is the same as using them in sandboxed sub-applications. For more information on using resource bundles in sub-applications, see "Localizing sandboxed applications" on page 208.

ToolTip objects in multi-versioned applications

ToolTip objects are created in the sub-application's application domain and are passed to the main application's ToolTipManager. This is an example of marshaling a class across application boundaries.

This behavior applies to error tips and data tips on List objects in multi-versioned applications as well.

Layouts in multi-versioned applications

The main application dictates the area of the screen that is available to the sub-application for screen layout.

LayoutManagers in different applications run independent of one another. The applications are not clipped.

Deep linking in multi-versioned applications

You cannot access the main application's BrowserManager directly from a sub-application that is in a different application domain. The sub-application's BrowserManager is disabled. This is the same for sandboxed and multi-versioned sub-applications. For more information, see "Deep linking in sandboxed applications" on page 209.

Dragging and dropping in multi-versioned applications

When the sub-application is in the same security domain as the main application, but in a different application domain, you can drag list items from a sub-application to a list in the main application, and vice versa. For this to work across applications, the class that defines the drop target must be public.

The DragProxy maintains the item's appearance during the entire event, regardless of which application the mouse is over. Drag events are triggered for all source and destination controls, as if they are in the same application.

In the background, the DragManager generates the DragProxy in the sub-application's application domain then passes that DragProxy to the main application's DragManager during the drag operation.

Strongly-typed objects cannot be passed from the main application to the sub-application or vice versa. As a result, the DragManager accepts a DragProxy that is not strongly typed.

All properties and methods defined by the IDragManager interface are handled through delegation to the main application's DragManager.

If you drag a generic type object, the object will be of generic type Object in Flash Player's application domain. Flex marshals the properties so that the drag and drop operation works without having to write any custom code.

If you use a custom class as part of the drop data, that class cannot be shared as strongly-typed. In that case, override the drop events and add logic to marshall the data from the drag source to the drop target.

Listening for mouse events in multi-versioned applications

Mouse interaction between a main application and a sub-application can be confusing, especially when those events occur in different application domains. For example, when you click and drag an object in a sub-application, and then release the button over the main application, typical Flex mouse events such as `MOUSE_UP`, `MOUSE_DOWN_OUTSIDE`, or `MOUSE_LEAVE` are triggered but cannot be listened to directly in the sub-application.

To listen for mouse events across application domains, listen to all mouse activity in the security domain. To listen, get a reference to the sandbox root and register your event listeners with that SystemManager.

When loaded into a separate application domain, the `topLevelSystemManager` property refers to the sub-application's SystemManager because the main application's SystemManager is in another application domain. As a result, you do not use the `topLevelSystemManager` property to get a reference to the main application's SystemManager. Instead, you use the `systemManager.getSandboxRoot()` method to get a reference to the top-level SystemManager in the security domain. From this SystemManager, you can access all mouse activity in the current security domain.

The following example uses calls to the `getSandboxRoot()` method to get references to the top-level SystemManager in the security domain.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- apploading/ZoomerPattern3.mxml -->
<s:Application
    creationComplete="setup()"
    height="250"
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
     <fx:Script>
     <![CDATA[
          import mx.core.UIComponent;
          import mx.managers.PopUpManager;
          [Bindable]
          public var data1:Array = ["Ice Cream", "Fudge", "Whipped Cream", "Nuts"];
          public var zoomTool:UIComponent;
          public function setup():void {
               // Draw the zoom rectangle.
               zoomWidget.graphics.lineStyle(1);
               zoomWidget.graphics.beginFill(0, 0);
               zoomWidget.graphics.drawRect(0, 0, 17, 17);
               zoomWidget.graphics.endFill();

               // Listen for mouse down events.
               zoomWidget.addEventListener(MouseEvent.MOUSE_DOWN, zoom_mouseDownHandler);
          }
          private var lastX:int;
          private var lastY:int;
          private function zoom_mouseDownHandler(event:MouseEvent):void {
               // When the mouse is down, listen for the move and up events.
               // The getSandboxRoot() method lets you listen to all mouse activity in your
               // SecurityDomain.
               systemManager.getSandboxRoot().addEventListener(
                    MouseEvent.MOUSE_MOVE, zoom_mouseMoveHandler, true);
               systemManager.getSandboxRoot().addEventListener(
                    MouseEvent.MOUSE_UP, zoom_mouseUpHandler, true);
               // Update last position of the mouse.
               lastX = event.stageX;
               lastY = event.stageY;
              // Create and pop up the zoomTool. This is the rectangle that is dragged around.
               // It must be a popup so that it can float over other content.
               zoomTool = new UIComponent();
               PopUpManager.addPopUp(zoomTool, this);

               var pt:Point = new Point(zoomWidget.transform.pixelBounds.x,
                    zoomWidget.transform.pixelBounds.y);
               pt = zoomTool.parent.globalToLocal(pt);
               zoomTool.x = pt.x;
               zoomTool.y = pt.y;
               zoomTool.graphics.lineStyle(1);
               zoomTool.graphics.beginFill(0, 0);
               zoomTool.graphics.drawRect(0, 0, 17, 17);
               zoomTool.graphics.endFill();
               // Hide the rectangle that was the target.
               zoomWidget.visible = false;
          }
          private function zoom_mouseMoveHandler(event:MouseEvent):void {
               // Update the position of the dragged rectangle.
               zoomTool.x += event.stageX - lastX;
               zoomTool.y += event.stageY - lastY;
               lastX = event.stageX;
               lastY = event.stageY;
               var bm:BitmapData = new BitmapData(16, 16);
               // Capture the bits on the screen.
               // You must use the getSandboxRoot() method here, too, because it gets
               // the parent of all of the pixels you are allowed to access.
               bm.draw(DisplayObject(systemManager.getSandboxRoot()),
                    new Matrix(1, 0, 0, 1, -zoomTool.transform.pixelBounds.x - 2,
                    -zoomTool.transform.pixelBounds.y - 2));
               // Create a Bitmap to hold the bits.
               if (zoomed.numChildren == 0) {
                    var bmp:Bitmap = new Bitmap();
                    zoomed.addChild(bmp);
               } else
                    bmp = zoomed.getChildAt(0) as Bitmap;
               // Set the bits.
               bmp.bitmapData = bm;
               // Zoom in on the bits.
               bmp.scaleX = bmp.scaleY = 8;
          }
          private function zoom_mouseUpHandler(event:Event):void {
               // Remove the listeners.
               systemManager.getSandboxRoot().removeEventListener(
                    MouseEvent.MOUSE_MOVE, zoom_mouseMoveHandler, true);
               systemManager.getSandboxRoot().removeEventListener(
                    MouseEvent.MOUSE_UP, zoom_mouseUpHandler, true);
               // Replace the target rectangle.
               zoomWidget.visible = true;
               // Remove the dragged rectangle.
```

```
                PopUpManager.removePopUp(zoomTool);
            }
        ]]>
    </fx:Script>

    <mx:HBox>
        <mx:HBox backgroundColor="0x00eeee" height="140" paddingTop="4" paddingRight="4">
            <mx:Label text="Drag Rectangle"/>
            <mx:UIComponent id="zoomWidget" width="17" height="17"/>
            <mx:Canvas id="zoom"
                borderStyle="solid"
                width="132"
                height="132"
            >
                <mx:UIComponent id="zoomed" width="128" height="128"/>
            </mx:Canvas>
        </mx:HBox>
        <mx:List dataProvider="{data1}"/>
    </mx:HBox>
</s:Application>
```

The following example main application loads the previous example application. It sets the `loadForCompatibility` property to `true` so that the sub-application loads a multi-versioned application.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- apploading/MainZoomerPattern3.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <mx:Text text="Cross-Versioning (trusted versioning application):"/>
    <mx:SWFLoader id="swf1" loadForCompatibility="true" source="ZoomerPattern3.swf"/>

</s:Application>
```

Bootstrap loading

A bootstrap loader is a lightweight application that defines classes that you want to share among applications.

The bootstrap loader gets loaded first instead of the actual main application, and then loads the main application into a child application domain of itself. The main application then loads a sub-application into a sibling application domain. The two applications are both loaded into child application domains of the bootstrap loader's application domain. The result is that they share any classes that are defined in the bootstrap, but use their own class definitions for everything else.

You can typically only have one bootstrap loader in a security domain. Bootstrapped classes are not shared across security domains.

Furthermore, when using bootstrap loading to load sub-applications, the sub-applications must be compiled with the same or older version of the compiler that the main application is compiled with.

Changes to any class in a bootstrap loader can break other sub-applications. As a result, ensure that the classes you add to a bootstrap loader are not likely to change.

When you use RPC classes with a proxy server (such as Blaze DS or LCDS), you must externalize the RPC classes in a bootstrap loader for multi-versioned applications. The bootstrap loader should contain only the RPC classes. You typically do not add your custom value object classes to the bootstrap loader to get or put data on the server. You can add those classes if you want to reduce marshalling, but in that case they should be simple classes that do not link in Flex framework classes such as Array or ArrayCollection.

When you use DataServices or RemoteObject functionality, you typically use a bootstrap loader for loading multi-versioned applications. The bootstrap loader should contain the necessary RPC and DataServices-related classes. It must also contain any value object classes that are used to send data to or from the server. If you add custom value object classes to your bootstrap loader, they should be simple classes that do not link in Flex framework classes such as Array or ArrayCollection. Adding complex value object classes to the bootstrap loader is not supported.

The following is an example of the bootstrap loader for RPC classes. This kind of bootstrap loader is commonly used when a sub-application uses classes such as HTTPService and WebService with a proxy server.

Take note of the way that the MainApp.swf is loaded. The bootstrap loader uses a Loader class, and does not define the LoaderContext, which results in default behavior for the Loader. The defaults are to load a sub-application into a child application domain, and to assume the defaults for the security domain.

Notice, too, that for each import, a definition of the class immediately follows the class's import statement exists. The result is that the class definitions are linked into the bootstrap loader. The loaded application, and all subsequently loaded applications, then share those definitions.

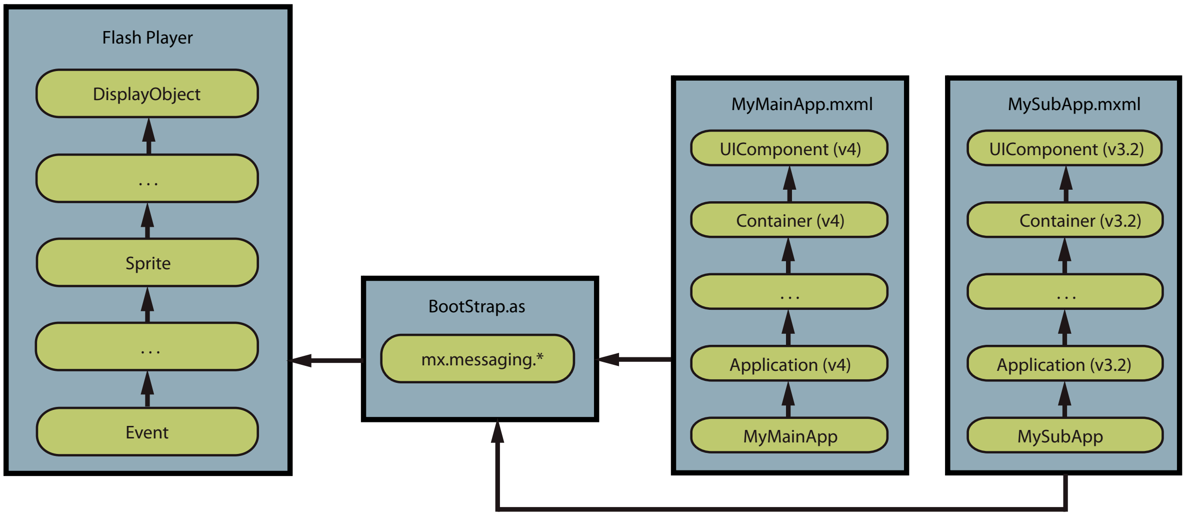
                super();
                if (ApplicationDomain.currentDomain.hasDefinition("mx.core::UIComponent"))
                       throw new Error("UIComponent should not be in the bootstrap loader.");
                stage.scaleMode = StageScaleMode.NO_SCALE;
                stage.align = StageAlign.TOP_LEFT;
                if (!stage)
                        isStageRoot = false;
                root.loaderInfo.addEventListener(Event.INIT, initHandler);
        }
        /**
         *  The Loader that loads the main application's SWF file.
         */
        private var loader:Loader;
        /**
         *  Whether the bootstrap loader is at the stage root or not.
         *  It is only the stage root if it was the root
         *  of the first SWF file that was loaded by Flash Player.
         *  Otherwise, it could be a top-level application but not stage root
         *  if it was loaded by some other non-Flex shell or is sandboxed.
         */
        private var isStageRoot:Boolean = true;
        /**
         *  Called when the bootstrap loader's SWF file has been loaded.
         *  Starts loading the application SWF specified by the applicationURL property.
         */
        private function initHandler(event:Event):void {
                loader = new Loader();
                addChild(loader);
                loader.load(new URLRequest(applicationURL));
                loader.addEventListener("mx.managers.SystemManager.isBootstrapRoot",
                        bootstrapRootHandler);
                loader.addEventListener("mx.managers.SystemManager.isStageRoot",
                        stageRootHandler);
                stage.addEventListener(Event.RESIZE, resizeHandler);
        }
        private function bootstrapRootHandler(event:Event):void {
                // Cancel event to indicate that the message was heard.
                event.preventDefault();
        }
        private function stageRootHandler(event:Event):void {
                // Cancel event to indicate that the message was heard.
                if (!isStageRoot)
                        event.preventDefault();
        }
        private function resizeHandler(event:Event):void {
                loader.width = stage.width;
                loader.height = stage.height;
                Object(loader.content).setActualSize(stage.stageWidth, stage.stageHeight);
        }
}
}
```

The following image shows where each domain gets it class definitions for a bootstrap loader that defines the mx.messaging.* classes.



Flex Ajax Bridge

The Adobe® Flex™ Ajax Bridge (FABridge) is a small, unobtrusive code library that you can insert into an Flex application, a Flex component, or an empty SWF file to expose it to scripting in the web browser.

About the Flex Ajax Bridge

The Flex Ajax Bridge (FABridge) is a small code library that you can insert into an Flex application, a Flex component, or an empty SWF file to expose it to scripting in the browser.

Rather than having to define new, simplified APIs to expose a graph of ActionScript objects to JavaScript, with FABridge you can make your ActionScript classes available to JavaScript without any additional coding. After you insert the library, essentially anything you can do with ActionScript, you can do with JavaScript.

Adobe Flash Player has the native ability, through the External API (the ExternalInterface class), to call JavaScript from ActionScript, and vice versa. But ExternalInterface has some limitations:

- The ExternalInterface class requires you, the developer, to write a library of extra code in both ActionScript and JavaScript, to expose the functionality of your Flex application to JavaScript, and vice versa.
- The ExternalInterface class also limits what you can pass across the gap – primitive types, arrays, and simple objects are legal, but user-defined classes, with associated properties and methods, are off-limits.
- The ExternalInterface class lets you define an interface so your JavaScript can call your ActionScript. FABridge lets you write JavaScript instead of ActionScript.

When to use the Flex Ajax Bridge

The FABridge library is useful in the following situations:

- You want to use a rich Flex component in an Ajax application but do not want to write a lot of Flex code. If you wrap the component in a FABridge-enabled stub application, you can script it entirely from JavaScript, including using JavaScript generated remotely by the server.

- You have only one or two people on your team who know Flex. The FABridge library lets everyone on your team use the work produced by one or two Flex specialists.
- You are building an integrated rich Internet application (RIA) with Flex and Ajax portions. Although you could build the integration yourself using ExternalInterface, you might find it faster to start with the FABridge.

Requirements for using the Ajax Bridge

To use the FABridge library and samples, you must have the following:

- Flex Ajax Bridge, which is included in the following directory of the Flex 3 SDK installation:

  installation_dir\frameworks\javascript\fabridge
- Adobe Flex SDK
- Adobe® Flash® Player 9 or later, or Adobe® AIR™ 1.5 or later
- Microsoft Internet Explorer, Mozilla Firefox, or Opera with JavaScript enabled
- Any HTTP server to run the samples

To run the samples:

1. Place the *installation_dir*\frameworks\javascript\fabridge\src and *installation_dir*\frameworks\javascript\fabridge\samples folders side by side on any HTTP server.
2. Open a web browser to http://*yourwebserver*/samples/FABridgeSample.html and samples/SimpleSample.html and follow the instructions there. Make sure you access the samples through http:// URLs and not file:// URLs. The Flash Player security sandbox prevents them from working correctly when they are accessed as local files.

Integrating with the Flex Ajax Bridge

To use the FABridge library in your own Flex and Ajax applications in Adobe® Flash® Builder™, right-click a project in the Flex Navigator and select Create Ajax Bridge. For more information, see Automatically generating Flex Ajax Bridge code.

Or, complete the following manual steps:

1. Add the *installation_dir*\frameworks\javascript\fabridge\src folder to the ActionScript classpath of your Flex application.
2. If you are compiling from the command line, add the *installation_dir*\frameworks\javascript\fabridge\src folder to your application by specifying the `--actionscript-classpath` compiler option.
3. Add the following tag to your application file:

   ```
   <s:Application …>
       <fab:FABridge xmlns:fab="bridge.*" />
   ...
   ```

Use the following code to access your application instance from JavaScript:

```
function useBridge() {
    var flexApp = FABridge.flash.root();
}
```

To get the value of a property, call it like a function, as the following example shows:

```
function getMaxPrice() {
    var flexApp = FABridge.flash.root();
    var appWidth = flexApp.getWidth();
    var maxPrice = flexApp.getMaxPriceSlider().getValue();
}
```

To set the value of a property from JavaScript, call the `setPropertyName()` function, as the following example shows:

```
function setMaxPrice(newMaxPrice) {
    var flexApp = FABridge.flash.root();
    flexApp.getMaxPriceSlider().setValue(newMaxPrice);
}
```

You call object methods directly, just as you would from ActionScript, as the following example shows:

```
function setMaxPrice(newMaxPrice) {
    var flexApp = FABridge.flash.root();
    flexApp.getShoppingCart().addItem("Antique Figurine", 12.99);
}
```

You also pass functions, such as event handlers, from JavaScript to ActionScript, as the following example shows:

```
function listenToMaxPrice() {
    var flexApp = FABridge.flash.root();
    var maxPriceCallback = function(event) {
        document.maxPrice = event.getNewValue();
        ocument.loadFilteredProducts(document.minPrice, document.maxPrice);
    }
    flexApp.getMaxPriceSlider().addEventListener("change", maxPriceCallback);
}
```

To run initialization code on a Flex file, you must wait for it to download and initialize first. Register a callback to be invoked when the movie is initialized, as the following example shows:

```
function initMaxPrice(maxPrice) {
    var initCallback = function() {
        var flexApp = FABridge.flash.root();
        flexApp.getMaxPriceSlider().setValue(maxPrice);
    }
    FABridge.addInitializationCallback("flash",initCallback);
}
```

To script multiple applications on the same page, give them unique bridge names through the flashvars mechanism. Use the bridge name to access them from the bridge, and to register for initialization callbacks, as the following example shows:

```
<object ...>
    <param name='flashvars' value='bridgeName=shoppingPanel'/>
    <param name='src' value='app.swf'/>
    <embed ... flashvars='bridgeName=shoppingPanel'/>
</object>
function initMaxPrice(maxPrice) {
    var initCallback = function() {
        var flexApp = FABridge.shoppingPanel.root();
        flexApp.getMaxPriceSlider().setValue(maxPrice);
    }
    FABridge.addInitializationCallback("shoppingPanel",initCallback);
}
```

Automatic memory management

The FABridge provides automatic memory management that uses a reference counting mechanism for all objects that are passed across the bridge. Objects created from the JavaScript side are kept in memory unless the memory is manually released. Events and other ActionScript-initiated objects are destroyed as soon as the corresponding JavaScript function that handles them directly completes its execution. You manually call the `addRef()` method for an object to have it remain available, or call the `release()` method to decrease its reference counter.

If you must break the function call chain by using the `setTimeout()` function in JavaScript, (for example to act on an event later on, as the following example shows), you must ensure that the event will still exist. Because the FABridge implements a reference counting mechanism to save memory, events thrown from ActionScript exist only for the duration of the dispatch function.

```
var flexApp = FABridge.flash.root();
flexApp.getMaxPriceSlider().addEventListener("change", maxPriceCallback );
function maxPriceCallback(event) {
    // When the doSomethingLater function is hit, the event is no longer available;
    // to make it work you would have to call FABridge.addRef(event); then, when you're
    // done with it, call FABridge.release(event).
    setTimeout(function() {doSomethingLater(event);},10);
}
```

Manually destroying objects

You can manually destroy a specific object that has been passed across the bridge, regardless of its reference count by invoking the `releaseNamedASObject(myObject)` method from JavaScript. This invalidates the object over the bridge and any future calls to it or one of its methods will throw an error.

Handling exceptions

Exceptions that take place in the ActionScript of the bridge as a direct consequence of some JavaScript action are now thrown over the bridge into JavaScript. The mechanism works as follows:

- When an exception is raised in the ActionScript section, it is caught in a try-catch block, serialized, and passed to JavaScript.
- When the JavaScript part receives an answer from ActionScript, it checks for the exception serialization and, if found, throws a JavaScript error with the message received from ActionScript.

***Note:** To catch and use the exception information, you must surround the code that calls into ActionScript with a `try-catch` block. You can handle the error in the `catch(e)` block.*

Limitations of the Flex Ajax Bridge

The FABridge library has been tested on Mozilla Firefox 2 (Windows and Linux), Microsoft Internet Explorer 6, Opera 9, and Apple Safari 2.0.4.

Exceptions thrown across the bridge into JavaScript depend on the user having installed Flash Debug Player to display the entire error description. Otherwise, only the error ID is thrown.

For performance reasons, when an anonymous object is sent from ActionScript to JavaScript, the bridge assumes it contains only primitives, arrays, and other anonymous objects, and no strongly typed objects or methods. Instances or methods sent as part of an anonymous object are not bridged correctly.

Communicating with the wrapper

You exchange data between an Adobe® Flex® application and the HTML page that embeds that application in several ways, depending on the type of integration that your application requires.

About exchanging data with applications

Applications built with Flex generally exist inside larger web applications that control everything from security to state management to the overall look and feel of the website. In this scenario it is important that the application is able to communicate with the surrounding environment, providing a deeper integration with the larger web application. Enabling the application to communicate with the environment provides a method of integration with other technologies such as Ajax.

Often, an application is loaded in a browser within a wrapper. This wrapper is often an HTML page that can include JavaScript or other client-side logic that the application can interact with.

There are several ways to communicate between the surrounding environment and the application; depending on the type of integration required, any combination of `flashVars` properties, query string parameters, the `navigateToURL()` method, and the ExternalInterface class can be employed. In addition, you can communicate between two applications on the same page by using SharedObjects.

To pass request data into your applications, you can define `flashVars` properties inside your HTML wrapper and access their values using the `FlexGlobals.topLevelApplication.parameters`. For more information, see "Passing request data with flashVars properties" on page 229. Using these techniques, you can personalize an application without requiring a recompilation.

Use the methods of the ExternalInterface API to call the methods of your applications and vice versa. The addCallback() method exposes methods of your application to the wrapper. The call() method invokes a method within the wrapper and returns any results. If the wrapper is HTML, the `addCallback()` and `call()` methods enable method invocation between your application and the hosted scripting language running within the browser. For more information, see "About the ExternalInterface API" on page 227.

In some situations, you want to open a new browser window or navigate to a new location. You can do this with the navigateToURL() global function. Although it is not part of the ExternalInterface API, this method is flexible enough to let you write JavaScript inside it, and invoke JavaScript functions on the resulting HTML page. The `navigateToURL()` method is a global function in the flash.net package.

"Creating a wrapper" on page 2552

Determining the application's URL

Flex provides some simple mechanisms for getting information about the browser and the environment in which the application runs. From within the application, you can get the URL to the SWF file by using the `FlexGlobals.topLevelApplication.url` property. To access properties of the FlexGlobals class, you must import mx.core.FlexGlobals.

The following example gets the SWF file's URL and extracts the host name from the URL:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- wrapper/GetURLInfo.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark" creationComplete="getHostName()">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <fx:Script>
    <![CDATA[
      import mx.core.FlexGlobals;
      [Bindable]
      public var g_HostString:String;
      [Bindable]
      public var g_ContextRoot:String;
      [Bindable]
      public var g_BaseURL:String;
      private function getHostName():void {
         g_BaseURL = FlexGlobals.topLevelApplication.url;
         var pattern1:RegExp = new RegExp("http://[^/]*/");
         if (pattern1.test(g_BaseURL) == true) {
            g_HostString = pattern1.exec(g_BaseURL).toString();
         } else{
            g_HostString = "http://localhost/"
         }
      }
      ]]>
    </fx:Script>

  <mx:Form>
     <mx:FormItem label="Base URL:">
        <mx:Label text="{g_BaseURL}"/>
     </mx:FormItem>
     <mx:FormItem label="Host Name:">
        <mx:Label text="{g_HostString}"/>
     </mx:FormItem>
  </mx:Form>
</s:Application>
```

You can also use the flash.system.Capabilities class to access information about the client, such as Operating System, Player version, and language. For more information, see Using the Capabilities class.

You can access more information about the browser and the application’s environment using the ExternalInterface. For more information, see “About the ExternalInterface API” on page 227.

About the ExternalInterface API

You use the ExternalInterface API to let your application call methods in the wrapper and to allow the wrapper to call functions in your application. The ExternalInterface API consists primarily of the call() and addCallback() methods in the flash.external package.

The following browsers support the ExternalInterface API:

- All versions of Internet Explorer for Windows (5.0 and later)
- Embedded custom ActiveX containers, such as a desktop application embedding the Adobe® Flash® Player ActiveX control

- Any browser that supports the NPRuntime interface (which currently includes the following browsers):
  - Firefox 1.0 and later
  - Mozilla 1.7.5 and later
  - Netscape 8.0 and later
  - Safari 1.3 and later

Before you execute code that uses the ExternalInterface API, you should check whether the browser supports it. You do this by using the `available` property of the ExternalInterface object in your application. The `available` property is a Boolean value that is `true` if the browser supports the ExternalInterface API and `false` if the browser does not. It is a read-only property.

The following example uses the `available` property to detect support for the ExternalInterface API before executing methods that use the class:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- wrapper/CheckExternalInterface.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="checkEI()">
     <s:layout>
        <s:BasicLayout/>
     </s:layout>

     <fx:Script>
        <![CDATA[
         [Bindable]
         public var eiStatus:String;
         private function checkEI():void {
               eiStatus = ExternalInterface.available.toString();
         }
         ]]>
     </fx:Script>

     <s:Label id="l1" text="External Interface supported? {eiStatus}"/>
</s:Application>
```

The `available` property determines only if the browser can support the ExternalInterface API, based on its version and manufacturer. If JavaScript is disabled in the browser, the `available` property still returns `true`.

For examples of using the ExternalInterface API with applications, see “Using the ExternalInterface API to access JavaScript” on page 235 and “Accessing Flex from JavaScript” on page 247.

In addition to requiring that browsers meet certain version requirements, the ExternalInterface API requires that JavaScript is enabled in the browser. You can use the `<noscript>` tag in the HTML page to handle a browser with disabled JavaScript. For more information, see “Handling browsers that disable JavaScript” on page 250.

The ExternalInterface API is restricted by the security sandbox in which the SWF file is running. Its use relies on the domain-based security restrictions that the `allowScriptAccess` and `allowNetworking` parameters define. You set the values of the `allowScriptAccess` and `allowNetworking` parameters in the SWF file’s wrapper.

Enabling Netscape connections

In some versions of Netscape browsers, you must set the value of the `swliveconnect` property to `true` in your HTML wrapper to enable the application to connect with the page's scripting language (usually JavaScript).

If you are using SWFObject 2 to embed your application, then set the value of the `swliveconnect` property on the params object to `true`, as the following example shows:

```
var params = {};
params.swfliveconnect = "true";
params.quality = "high";
params.bgcolor = "#ffffff";
params.allowscriptaccess = "sameDomain";
```

If your wrapper uses the `<object>` and `<embed>` syntax, include `swliveconnect=true` in the `<embed>` tag in your wrapper, as the following example shows:

```
<embed pluginspage='http://www.adobe.com/go/getflashplayer'
    width='300'
    height='100'
    flashvars=''
    src='TitleTest.mxml.swf'
    name='MyApp'
    swliveconnect='true'
/>
```

You are not required to set the value of `swliveconnect` to `true` in the `<object>` tag because the `<object>` tag is used by Microsoft Internet Explorer, and not by Netscape browsers.

Passing request data with flashVars properties

You pass request data to applications built with Flex by defining the `flashVars` properties in the wrapper. You can also access URL fragments by using the BrowserManager. For more information, see "Passing request data with URL fragments" on page 2031.

The `flashVars` properties and URL fragments are read in the application at run time. As a result, changing `flashVars` properties or URL fragments does not require you to recompile the application.

Passing request data with flashVars properties

If you are using the generated wrapper from Flash Builder, then you add `flashVars` variables by creating an object called flashvars, setting properties on that object, and then passing that object to the `swfobject.embedSWF()` method of SWFObject 2.

The following example sets the `firstname` and `lastname` properties of the flashvars object, and then passes that object to the `embedSWF()` method:

```
<script type="text/javascript">
    var swfVersionStr = "10.0.0";
    var xiSwfUrlStr = "playerProductInstall.swf";
    var flashvars = {};
    flashvars.firstname = "Nick";
    flashvars.lastname = "Danger";
    var params = {};
    params.quality = "high";
    params.bgcolor = "#ffffff";
    params.allowscriptaccess = "sameDomain";
    var attributes = {};
    attributes.id = "TestProject";
    attributes.name = "TestProject";
    attributes.align = "middle";
    swfobject.embedSWF(
        "FlashVarTest.swf", "flashContent", "100%", "100%", swfVersionStr,
        xiSwfUrlStr, flashvars, params, attributes);
    swfobject.createCSS("#flashContent", "display:block;text-align:left;");
</script>
```

If your wrapper uses the `<object>` and `<embed>` tags, you can pass variables to your applications by using the `flashVars` properties in the `<object>` and `<embed>` tags in your wrapper. You do this by adding ampersand-separated sets of name-value pairs to these properties.

The following example sets the values of the `firstname` and `lastname` in the `flashVars` properties inside the `<object>` and `<embed>` tags in a simple wrapper:

```
<html>
<head>
<title>code/wrapper/SimplestFlashVarTestWrapper.html</title>
<style>
    body {
        margin: 0px;
        overflow:hidden
    }
</style>
</head>
<body scroll='no'>
<table width='100%' height='100%' cellspacing='0' cellpadding='0'><tr><td valign='top'>
<h1>Simplest FlashVarTest Wrapper</h1>
    <object id='mySwf' classid='clsid:D27CDB6E-AE6D-11cf-96B8-444553540000' height='100%'
width='100%'>
        <param name='src' value='FlashVarTest.swf'/>
        <param name='flashVars' value='firstname=Nick&lastname=Danger'/>
        <embed name='mySwf' src='FlashVarTest.swf' height='100%' width='100%'
flashVars='firstname=Nick&lastname=Danger'/>
    </object>
</td></tr></table>
</body>
</html>
```

The value of the `flashVars` properties do not have to be static. If you use JSP to return the wrapper, for example, you can use any JSP expression for the value of the `flashVars` properties that can be evaluated to a String.

The following example uses the values stored in the HttpServletRequest object (in this case, you can use form or query string parameters):

```
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN"
"http://www.w3.org/TR/xhtml1/DTD/xhtml1-transitional.dtd">
<!-- saved from url=(0014)about:internet -->
<%
    String fName = (String) request.getParameter("firstname");
    String lName = (String) request.getParameter("lastname");
%>
<html xmlns="http://www.w3.org/1999/xhtml" lang="en" xml:lang="en">
    <head>
        <title>DynamicFlashVarTestWrapper.jsp</title>
        <script type="text/javascript" src="swfobject.js"></script>

        <script type="text/javascript">
            var swfVersionStr = "0";
            var xiSwfUrlStr = "";
            var flashvars = {};
            flashvars.firstname = "<%= fName %>";
            flashvars.lastname = "<%= lName %>";
            var params = {};
            params.quality = "high";
            params.bgcolor = "#ffffff";
            params.allowscriptaccess = "sameDomain";
            var attributes = {};
            attributes.id = "FlashVarTest";
            attributes.name = "FlashVarTest";
            attributes.align = "middle";
            swfobject.embedSWF(
                "FlashVarTest.swf", "flashContent",
                "100%", "100%",
                swfVersionStr, xiSwfUrlStr,
                flashvars, params, attributes);
        </script>
    </head>
    <body>
        <div id="flashContent"/>
   </body>
</html>
```

You can also PHP expressions to pass query string parameters in a wrapper, as the following example shows:

```
<!-- saved from url=(0014)about:internet -->
<html lang="en">
<head>
<?php
    @ $fName = $_GET['firstname'];
    @ $lName = $_GET['lastname'];
?>
<script type="text/javascript" src="swfobject.js"></script>
<script type="text/javascript">
    var swfVersionStr = "";
    var xiSwfUrlStr = "";
    var flashvars = {};
    flashvars.fName = "<?php echo $fName; ?>"
    flashvars.lName =  "<?php echo $lName; ?>"
    var params = {};
    params.quality = "high";
    params.bgcolor = "#ffffff";
    params.allowscriptaccess = "sameDomain";
    var attributes = {};
    attributes.id = "FlashVarTest";
    attributes.name = "FlashVarTest";
    attributes.align = "middle";
    swfobject.embedSWF(
        "FlashVarTest.swf", "flashContent",
        "100%", "100%",
        swfVersionStr, xiSwfUrlStr,
        flashvars, params, attributes);
    swfobject.createCSS("#flashContent", "display:block;text-align:left;");
</script>
</head>
<body >
    <div id="flashContent">
</body>
</html>
```

For more information about the HTML wrapper, see “Creating a wrapper” on page 2552.

If your user requests the SWF file directly in the browser, without a wrapper, you can access variables on the query string without providing additional code in the wrapper (because there is no wrapper). The following URL passes the name Nick and the hometown San Francisco to the application:

```
http://localhost:8100/flex/myApp.swf?myName=Nick&myHometown=San%20Francisco
```

About flashVars properties encoding

The values of the `flashVars` properties must be URL encoded. The format of the string is a set of name-value pairs separated by an ampersand (&). You can escape special and nonprintable characters with a percent symbol (%) followed by a two-digit hexadecimal value. You can represent a single blank space by using the plus sign (+).

The encoding for `flashVars` properties is the same as the page. Internet Explorer provides UTF-16-compliant strings on the Windows platform. Netscape sends a UTF-8-encoded string to Flash Player.

Most browsers support a `flashVars` string or query string up to 64 KB (65535 bytes) in length. They can include any number of name-value pairs.

Using the SWF file path to pass request data

You can append the values of properties to the application’s SWF file path in the wrapper. The `swfUrlStr` property identifies the location of the application’s SWF file. It is the first argument in the `swfobject.embedSWF()` method call.

The following example appends query string parameters to the `swfUrlStr` properties in the custom wrapper:

```
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN"
"http://www.w3.org/TR/xhtml1/DTD/xhtml1-transitional.dtd">
<!-- saved from url=(0014)about:internet -->
<html xmlns="http://www.w3.org/1999/xhtml" lang="en" xml:lang="en">
    <head>
        <title>wrapper/SwfObjectWithFlashVars.html</title>
        <script type="text/javascript" src="swfobject.js"></script>
        <script type="text/javascript">
            var swfVersionStr = "0";
            var xiSwfUrlStr = "";
            var flashvars = {};
            var params = {};
            params.quality = "high";
            params.bgcolor = "#ffffff";
            params.allowscriptaccess = "sameDomain";
            var attributes = {};
            attributes.id = "FlashVarTest";
            attributes.name = "FlashVarTest";
            attributes.align = "middle";
            swfobject.embedSWF(
                "FlashVarTest.swf?firstname=Nick&lastname=Danger",
                "flashContent", "100%", "100%",
                swfVersionStr, xiSwfUrlStr,
                flashvars, params, attributes);
        </script>
    </head>
    <body>
        <div id="flashContent"/>
   </body>
</html>
```

Variables you define in this manner are accessible in the same way as `flashVars` properties. For more information, see “Accessing the flashVars properties” on page 233.

Accessing the flashVars properties

To access the values of the `flashVars` properties, you use the FlexGlobals object’s `topLevelApplication.parameters` property. This property points to a dynamic object that stores the parameters as name-value pairs. You can access variables on the parameters object by specifying `parameters.`*`variable_name`*.

In your application, you typically assign the values of the run-time properties to local variables. You assign the values of these properties after the Application’s `creationComplete` event is dispatched. Otherwise, the run-time properties might not be available when you try to assign their values to local variables.

The following example defines the `myName` and `myHometown` variables and binds them to the text of Label controls in the `initVars()` method:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- wrapper/ApplicationParameters.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark" creationComplete="initVars()">
     <s:layout>
          <s:VerticalLayout/>
     </s:layout>

       <fx:Script><![CDATA[
          import mx.core.FlexGlobals;

          /* Declare bindable properties in Application scope. */
          [Bindable]
          public var myName:String;
          [Bindable]
          public var myHometown:String;

          /* Assign values to new properties. */
          private function initVars():void {
               myName = FlexGlobals.topLevelApplication.parameters.myName;
               myHometown = FlexGlobals.topLevelApplication.parameters.myHometown;
          }
     ]]></fx:Script>

     <s:HGroup>
          <s:Label text="Name: "/>
          <s:Label text="{myName}" fontWeight="bold"/>
     </s:HGroup>

     <s:HGroup>
           <s:Label text="Hometown: "/>
           <s:Label text="{myHometown}" fontWeight="bold"/>
     </s:HGroup>
</s:Application>
```

When a user requests this application with the `myName` and `myHometown` parameters defined as `flashVars` properties or as query string parameters, Flex displays their values in the Label controls.

To view all the `flashVars` properties, you can iterate over the `FlexGlobals.topLevelApplication.parameters` properties, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- wrapper/FlashVarTest.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="init()">

     <s:layout>
        <s:HorizontalLayout/>
     </s:layout>

     <fx:Script><![CDATA[
         import mx.core.FlexGlobals;
         private function init():void {
              for (var i:String in FlexGlobals.topLevelApplication.parameters) {
                 ta1.text += i + ":" + FlexGlobals.topLevelApplication.parameters[i] + "\n";
              }
          }
      ]]></fx:Script>

      <s:Label text="flashVars"/>
      <s:RichText id="ta1" width="300" height="200"/>
</s:Application>
```

Accessing JavaScript functions

You can call JavaScript functions in the enclosing HTML page from your application. By allowing Flex to communicate with the browser, you can change style settings, invoke remote processes, or perform any other action that you can normally do from within the page's scripts.

You can even pass data from the application to the enclosing HTML page, process it, and then pass it back to the application. You do this by using the ExternalInterface API or the navigateToURL() method. For more information, see "Using the ExternalInterface API to access JavaScript" on page 235 and "Using the navigateToURL() method in Flex" on page 241.

Whenever you communicate with the enclosing page, you must determine if the browser can handle the kinds of actions that you want to perform. Therefore, you should first determine if the browser supports the objects that you want to use. For some general guidelines for determining browser support, see "Using the ExternalInterface API to access JavaScript" on page 235.

Using the ExternalInterface API to access JavaScript

The easiest way to call JavaScript functions from your application is to use the ExternalInterface API. You can use this API to call any JavaScript method on the wrapper, pass parameters, and get a return value. If the method call fails, Flex returns an exception.

The ExternalInterface API encapsulates checks for browser support, so you are not required to do that when using its methods. However, you can check whether the browser supports the interface by using its `available` property. For more information, see "About the ExternalInterface API" on page 227.

The ExternalInterface API consists of a single class, flash.external.ExternalInterface. This class has the call() static method that you use to facilitate the JavaScript to Flash communication. You can also call methods in your application from the wrapper by using the ExternalInterface API's addCallback() method. For more information, see "About the addCallback() method" on page 253.

Calling JavaScript methods from applications

The ExternalInterface API makes it very simple to call methods in the enclosing wrapper. You use the static call() method, which has the following signature:

```
flash.external.ExternalInterface.call(function_name:String[, arg1, ...]):Object;
```

The *function_name* is the name of the function in the HTML page's JavaScript. The arguments are the arguments that you pass to the JavaScript function. You can pass one or more arguments in the traditional way of separating them with commas, or you can pass an object that is deserialized by the browser. The arguments are optional.

The following example `<fx:Script>` block calls the JavaScript `changeDocumentTitle()` function in the enclosing wrapper by using the `call()` method:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- wrapper/WrapperCaller.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
     <s:layout>
        <s:HorizontalLayout/>
     </s:layout>
  <fx:Script>
     import flash.external.*;

     public function callWrapper():void {
        var s:String;
        if (ExternalInterface.available) {
           var wrapperFunction:String = "changeDocumentTitle";
           s = ExternalInterface.call(wrapperFunction,ti1.text);
        } else {
           s = "Wrapper not available";
        }
        trace(s);
     }
  </fx:Script>

  <mx:Form>
     <mx:FormItem label="New Title:">
        <mx:TextInput id="ti1"/>
     </mx:FormItem>
  </mx:Form>

  <s:Button label="Change Document Title" click="callWrapper()"/>
</s:Application>
```

In your HTML wrapper, you define a function as you would any other JavaScript function. You can return a value, as the following example shows:

```
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN"
"http://www.w3.org/TR/xhtml1/DTD/xhtml1-transitional.dtd">
<!-- saved from url=(0014)about:internet -->
<html xmlns="http://www.w3.org/1999/xhtml" lang="en" xml:lang="en">
    <head>
        <title>Wrapper Being Called</title>
        <script type="text/javascript" src="swfobject.js"></script>
        <script type="text/javascript">
            var swfVersionStr = "0";
            var xiSwfUrlStr = "";
            var flashvars = {};
            var params = {};
            params.quality = "high";
            params.bgcolor = "#ffffff";
            params.allowscriptaccess = "sameDomain";
            var attributes = {};
            attributes.id = "WrapperCaller";
            attributes.name = "WrapperCaller";
            attributes.align = "middle";
            swfobject.embedSWF(
                "WrapperCaller.swf", "flashContent",
                "100%", "100%",
                swfVersionStr, xiSwfUrlStr,
                flashvars, params, attributes);
        </script>
    </head>
     <SCRIPT LANGUAGE="JavaScript">
         function changeDocumentTitle(a) {
             window.document.title=a;
             alert(a);
             return "successful";
         }
     </SCRIPT>
    <body>
        <div id="flashContent"/>
   </body>
</html>
```

Using the ExternalInterface's `call()` method requires that the embedded application have a name in the wrapper; you must set the `attributes.id` and `attributes.name` properties to the name of the SWF file. If you are using the `<object>` and `<embed>` tags in your wrapper, you must define an `id` attribute on the `<object>` tag and a `name` attribute on the `<embed>` tag. Without these, no call to or from your application will succeed. In addition, these properties cannot contain periods or other special characters.

The `call()` method accepts zero or more arguments, which can be ActionScript types. Flex serializes the ActionScript types as JavaScript numbers and strings. If you pass an object, you can access the properties of that deserialized object in the JavaScript, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- wrapper/DataTypeSender.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
     <s:layout>
        <s:HorizontalLayout/>
     </s:layout>
  <fx:Script><![CDATA[
     import flash.external.*;

     public function callWrapper():void {
        var s:String;
        if (ExternalInterface.available) {
           var o:Object = new Object();
           o.fname = "Nick";
           o.lname = "Danger";
           var wrapperFunction:String = "receiveComplexDataTypes";
           s = ExternalInterface.call(wrapperFunction, o);
        } else {
           s = "Wrapper not available";
        }
        trace(s);
     }
  ]]></fx:Script>

  <s:Button label="Send" click="callWrapper()"/>
</s:Application>
```

Flex only serializes public, nonstatic variables and read-write properties of ActionScript objects. You can pass numbers and strings as properties on objects, simple objects such as primitive types and arrays, or arrays of simple objects.

The JavaScript code can then access properties of the object, as the following example shows:

```
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN"
"http://www.w3.org/TR/xhtml1/DTD/xhtml1-transitional.dtd">
<!-- saved from url=(0014)about:internet -->
<html xmlns="http://www.w3.org/1999/xhtml" lang="en" xml:lang="en">
    <head>
        <title>Data Type Sender Test</title>
        <script type="text/javascript" src="swfobject.js"></script>
        <script type="text/javascript">
            var swfVersionStr = "0";
            var xiSwfUrlStr = "";
            var flashvars = {};
            var params = {};
            params.quality = "high";
            params.bgcolor = "#ffffff";
            params.allowscriptaccess = "sameDomain";
            var attributes = {};
            attributes.id = "DataTypeSender";
            attributes.name = "DataTypeSender";
            attributes.align = "middle";
            swfobject.embedSWF(
                "DataTypeSender.swf", "flashContent",
                "100%", "100%",
                swfVersionStr, xiSwfUrlStr,
                flashvars, params, attributes);
        </script>
    </head>
    <SCRIPT LANGUAGE="JavaScript">
        function receiveComplexDataTypes(o) {
            alert("Welcome " + o.fname + " " + o.lname + "!");
            return "successful";
        }
    </SCRIPT>
    <body>
        <div id="flashContent"/>
   </body>
</html>
```

You can also embed objects within objects, such as an Array within an Object, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- wrapper/ComplexDataTypeSender.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
     <s:layout>
      <s:HorizontalLayout/>
     </s:layout>
  <fx:Script><![CDATA[
     import flash.external.*;

     public function callWrapper():void {
        var s:String;
        if (ExternalInterface.available) {
           var o:Object = new Object();
           o.fname = "Nick";
           o.lname = "Danger";
           o.b = new Array("DdW","E&T","LotR:TS");
           var wrapperFunction:String = "receiveComplexDataTypes";
           s = ExternalInterface.call(wrapperFunction, o);
        } else {
           s = "Wrapper not available";
        }
        trace(s);
     }
  ]]></fx:Script>

  <s:Button label="Send" click="callWrapper()"/>
</s:Application>
```

The code triggers the `receiveComplexDataTypes()` JavaScript function in the following wrapper:

```
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN"
"http://www.w3.org/TR/xhtml1/DTD/xhtml1-transitional.dtd">
<!-- saved from url=(0014)about:internet -->
<html xmlns="http://www.w3.org/1999/xhtml" lang="en" xml:lang="en">
    <head>
        <title>Complex Data Type Sender Test</title>
        <script type="text/javascript" src="swfobject.js"></script>
        <script type="text/javascript">
            var swfVersionStr = "0";
            var xiSwfUrlStr = "";
            var flashvars = {};
            var params = {};
            params.quality = "high";
            params.bgcolor = "#ffffff";
            params.allowscriptaccess = "sameDomain";
            var attributes = {};
            attributes.id = "ComplexDataTypeSender";
            attributes.name = "ComplexDataTypeSender";
            attributes.align = "middle";
            swfobject.embedSWF(
                "ComplexDataTypeSender.swf", "flashContent",
                "100%", "100%",
                swfVersionStr, xiSwfUrlStr,
                flashvars, params, attributes);
        </script>
    </head>
    <SCRIPT LANGUAGE="JavaScript">
        function receiveComplexDataTypes(o) {
            // Get value of fname and lname properties.
            var s = ("Welcome " + o.fname + " " + o.lname + "!\n");
            // Iterate over embedded object's properties.
            for (i=0; i<o.b.length; i++) {
                s +=  i + ": " + o.b[i] + "\n";
            }
            alert(s);
        }
    </SCRIPT>
    <body>
        <div id="flashContent"/>
   </body>
</html>
```

Flex and Flash Player have strict security in place to prevent cross-site scripting. By default, you cannot call script on an HTML page if the HTML page is not in the same domain as the application. However, you can expand the sources from which scripts can be called. For more information, see “About ExternalInterface API security in Flex” on page 252.

You cannot pass objects or arrays that contain circular references. For example, you cannot pass the following object:

```
var obj = new Object();
obj.prop = obj; // Circular reference.
```

Circular references cause infinite loops in both ActionScript and JavaScript.

Using the navigateToURL() method in Flex

The navigateToURL() method loads a document from a specific URL into a window or passes variables to another application at a defined URL. You can use this method to call JavaScript functions in the HTML page that encloses an application.

You should not confuse the functionality of the `navigateToURL()` method with the `load()` method of the URLLoader class. The URLLoader class loads a specified URL into an object for manipulation with ActionScript. The `navigateToURL()` method navigates to the specified URL with a browser.

In most cases, you should use the ExternalInterface API to perform Flex-to-wrapper communication. However, the `navigateToURL()` method is not part of the ExternalInterface API and, therefore, does not have as stringent a set of requirements for which browsers support it. These requirements are described in “About the ExternalInterface API” on page 227.

The `navigateToURL()` method is restricted by the security sandbox in which the SWF file is running. Its use relies on the domain-based security restrictions that the `allowScriptAccess` and `allowNetworking` parameters define. You set the values of the `allowScriptAccess` and `allowNetworking` parameters in the SWF file’s wrapper.

For more information on these parameters, see “Creating a wrapper” on page 2552. For more information on security restrictions, see “Security” on page 117.

The navigateToURL() method syntax

The navigateToURL() method is in the flash.net package. It has the following signature:

```
navigateToURL(request:URLRequest, window:String):void
```

The *request* argument is a URLRequest object that specifies the destination. The *window* argument specifies whether to launch a new browser window or load the new URL into the current window. The following table describes the valid values for the *window* argument:

Value	Description
`_self`	Specifies the current frame in the current window.
`_blank`	Specifies a new window. This new window acts as a pop-up window in the client's browser, so you must be aware that a pop-up blocker could prevent it from loading.
`_parent`	Specifies the parent of the current frame.
`_top`	Specifies the top-level frame in the current window.

You pass a URLRequest object to the `navigateToURL()` method. This object defines the URL target, variables, method (POST or GET), window, and headers for the request. The following example defines a simple URL to navigate to:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- wrapper/SimplestNavigateToURL.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
     <s:layout>
      <s:HorizontalLayout/>
     </s:layout>
  <fx:Script><![CDATA[
     import flash.net.*;
     public function openNewWindow(event:MouseEvent):void {
        var u:URLRequest = new URLRequest("http://www.adobe.com/flex");
        navigateToURL(u,"_blank");
     }
  ]]></fx:Script>
  <s:Button label="Open New Window" click="openNewWindow(event)"/>
</s:Application>
```

The `navigateToURL()` method URL encodes the value of the `url` argument.

To send data with a URLRequest object, you can append variables to the request string. The following example launches a new window and passes a search term to the URL:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- wrapper/SimpleNavigateToURL.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:HorizontalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            import flash.net.*;
            public function executeSearch(event:MouseEvent):void {
                var u:URLRequest = new URLRequest("http://www.google.com/search?hl=en&q=" +
ta1.text);
                navigateToURL(u,"_blank");
            }
        ]]>
    </fx:Script>
    <s:TextArea id="ta1"/>
    <s:Button label="Search" click="executeSearch(event)"/>
</s:Application>
```

In addition to appending strings, you can also use the `data` property of the URLRequest to add URL variables to a GET or POST request. The query string parameters are of type URLVariables. Flex adds ampersand delimiters for you in the URL request string. The following example adds `name=fred` to the URLRequest:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- wrapper/NavigateWithGetMethod.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
     <s:layout>
      <s:HorizontalLayout/>
     </s:layout>
  <fx:Script><![CDATA[
     import flash.net.*;
     public function openNewWindow(event:MouseEvent):void {
        var url:URLRequest = new
URLRequest("http://aspexamples.adobe.com/chart_examples/stocks.aspx");
        var uv:URLVariables = new URLVariables();
        url.method = "GET";
        uv.tickerSymbol = ti1.text;
        url.data = uv;
        navigateToURL(url,"_blank");
     }
  ]]></fx:Script>
  <mx:TextInput id="ti1" text="STRK"/>

  <s:Button label="Open New Window" click="openNewWindow(event)"/>
</s:Application>
```

To use POST data with the URLRequest object, set the value of the URLRequest object’s `method` property to POST.

Opening multiple windows with the navigateToURL() method

You can open any number of new browser windows with calls to the `navigateToURL()` method. However, because ActionScript is asynchronous, if you tried a simple loop over the method, Flash Player would only open the browser window for the last call. To avoid this, you use the `callLater()` method. This method instructs Flash Player to open a new browser window on each new frame in your application. The following example uses the `callLater()` method to open multiple browser windows with the `navigateToURL()` method:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- wrapper/NavigateToMultipleURLs.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
     <s:layout>
      <s:HorizontalLayout/>
     </s:layout>
  <fx:Script><![CDATA[
     import flash.net.navigateToURL;
     private var listingData:Array=[
        "http://flex.org",
        "http://www.adobe.com",
        "http://aspexamples.adobe.com"
     ];
     private function openWindows(n: Number):void {
        if (n < listingData.length) {
           navigateToURL(new URLRequest(listingData[n]), '_blank');
           callLater(callLater, [openWindows, [n+1]]);
        }
     }
  ]]></fx:Script>
  <s:Button label="Click Me to Open Multiple Windows"
    click="openWindows(0)"/>
</s:Application>
```

Some browsers block popups. You might need to disable popup blocking to view this example. In some cases, you can also Control+click the button to avoid the popup blocker behavior.

Calling JavaScript functions with the URLRequest object

You can use theURLRequest to call a JavaScript function by embedding that function in the first parameter of the method, as the following example shows:

```
public var u:URLRequest = new URLRequest("javascript:window.close()");
```

The previous code does not work on all browsers. You should include code that detects the browser type, and closes the window based on the type of browser. Also, some browsers, such as Internet Explorer, behave in unexpected ways when you invoke a URLRequest that contains JavaScript. Here are some examples:

- Executes the JavaScript URLs asynchronously. This means that it is possible to have multiple calls to the navigateToURL() method that is trying to execute JavaScript methods, and have only the last one occur. Each one overwrites the next.
- Stops all other navigation, such as loading of images and IFRAMEs when you call a JavaScript URL.
- Displays a security warning dialog box if the URL contains ampersand (&) or question mark (?) characters.

Invoking JavaScript with the navigateToURL() method

You can use the `navigateToURL()` method to invoke JavaScript functions on the HTML page in which the application runs. However, when passing parameters by using the `navigateToURL()` method, you must enclose each parameter in quotation marks, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- wrapper/CallingJavaScriptWithNavigateToURL.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
     <s:layout>
      <s:HorizontalLayout/>
     </s:layout>
    <fx:Script><![CDATA[
        import flash.net.*;
        public function callWrapper(e:Event):void {
            var eType:String = String(e.type);
            var eName:String = String(e.currentTarget.id);
          var u:URLRequest = new URLRequest("javascript:catchClick('" + eName + "','" + eType
+ "')");
            navigateToURL(u,"_self");
        }
    ]]></fx:Script>
    <s:Button id="b1" click="callWrapper(event)" label="Call Wrapper"/>
</s:Application>
```

The enclosing HTML wrapper includes the JavaScript to process this call, as the following example shows:

```
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN"
"http://www.w3.org/TR/xhtml1/DTD/xhtml1-transitional.dtd">
<!-- saved from url=(0014)about:internet -->
<html xmlns="http://www.w3.org/1999/xhtml" lang="en" xml:lang="en">
    <head>
        <title>navigateToURL() Wrapper</title>
        <script type="text/javascript" src="swfobject.js"></script>
        <script type="text/javascript">
            var swfVersionStr = "0";
            var xiSwfUrlStr = "";
            var flashvars = {};
            var params = {};
            params.quality = "high";
            params.bgcolor = "#ffffff";
            params.allowscriptaccess = "sameDomain";
            var attributes = {};
            attributes.id = "CallingJavaScriptWithNavigateToURL";
            attributes.name = "CallingJavaScriptWithNavigateToURL";
            attributes.align = "middle";
            swfobject.embedSWF(
                "CallingJavaScriptWithNavigateToURL.swf", "flashContent",
                "100%", "100%",
                swfVersionStr, xiSwfUrlStr,
                flashvars, params, attributes);
        </script>
    </head>
    <SCRIPT LANGUAGE="JavaScript">
        function catchClick(name, type) {
            alert(name + " triggered the " + type + " event.");
        }
    </SCRIPT>
    <body>
        <div id="flashContent"/>
   </body>
</html>
```

You can also use the `navigateToURL()` method with basic JavaScript functions in the URLRequest itself. For example, you can launch the default e-mail client with a single line of code:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- wrapper/EmailWithNavigateToURL.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
     <s:layout>
        <s:HorizontalLayout/>
     </s:layout>
  <fx:Script>
     import flash.net.*;
     public function sendMail(e:Event):void {
        var u:URLRequest = new URLRequest("mailto:" + ti1.text);
        navigateToURL(u,"_self");
     }
  </fx:Script>
  <s:Button id="b1" click="sendMail(event)" label="Send Mail"/>
  <mx:Form>
     <mx:FormItem>
        <mx:Label text="Email Address: "/>
     </mx:FormItem>
     <mx:FormItem>
        <mx:TextInput id="ti1"/>
     </mx:FormItem>
  </mx:Form>
</s:Application>
```

Not all browsers support invoking the `javascript` protocol with the `navigateToURL()` method. If possible, you should use the call() method of the ExternalInterface API to invoke JavaScript methods in the enclosing HTML page. For more information, see "Using the ExternalInterface API to access JavaScript" on page 235.

Accessing Flex from JavaScript

You can call Flex methods from your enclosing wrapper by using the ExternalInterface API. You do this by adding a public method in your application to a list of callable methods. In your application, you add a local Flex function to the list by using the addCallback() method of the ExternalInterface API. This method registers an ActionScript method as callable from the JavaScript or VBScript in the wrapper.

Note: *This feature requires that the client is running certain browsers. For more information, see "About the ExternalInterface API" on page 227.*

The signature for the `addCallback()` method is as follows:

```
addCallback(function_name:String, closure:Function):void
```

The *function_name* parameter is the name by which you call the Flex function from your HTML page's scripts. The *closure* parameter is the local name of the function that you want to call. This parameter can be a method on the application or an object instance.

The following example declares the `myFunc()` function to be callable by the wrapper:

```
<?xml version="1.0"?>
<!-- wrapper/AddCallbackExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark" creationComplete="initApp()">
    <fx:Script>
        import flash.external.*;
         public function initApp():void {
            ExternalInterface.addCallback("myFlexFunction",myFunc);
         }
         public function myFunc(s:String):void {
            l1.text = s;
         }
    </fx:Script>
    <s:Label id="l1"/>

</s:Application>
```

To call the Flex method from the HTML wrapper, you get a reference to the movie object. The name of the movie is the same value as the `attributes.id` and `attributes.name` properties. In this case, it is AddCallbackExample, as the following example wrapper shows:

```
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN"
"http://www.w3.org/TR/xhtml1/DTD/xhtml1-transitional.dtd">
<!-- saved from url=(0014)about:internet -->
<html xmlns="http://www.w3.org/1999/xhtml" lang="en" xml:lang="en">
    <head>
        <title>addCallback() Wrapper</title>
        <script type="text/javascript" src="swfobject.js"></script>
        <script type="text/javascript">
            var swfVersionStr = "0";
            var xiSwfUrlStr = "";
            var flashvars = {};
            var params = {};
            params.quality = "high";
            params.bgcolor = "#ffffff";
            params.allowscriptaccess = "sameDomain";
            var attributes = {};
            attributes.id = "AddCallbackExample";
            attributes.name = "AddCallbackExample";
            attributes.align = "middle";
            swfobject.embedSWF(
                "AddCallbackExample.swf", "flashContent",
                "100%", "100%",
                swfVersionStr, xiSwfUrlStr,
                flashvars, params, attributes);
        </script>
    </head>
    <SCRIPT LANGUAGE="JavaScript">
        function callApp() {
            window.document.title = document.getElementById("newTitle").value;
            var AddCallbackExample = document.getElementById("AddCallbackExample");
            AddCallbackExample.myFlexFunction(window.document.title);
        }
    </SCRIPT>
    <body>
        <form id="f1">
            Enter a new title: <input type="text" size="30" id="newTitle"
onchange="callApp()">
        </form>
        <div id="flashContent"/>
   </body>
</html>
```

If your wrapper uses `<object>` and `<embed>` tags, the movie object is the same value as the `id` and `name` properties of the `<object>` and `<embed>` tags. You then call the method on that object, passing whatever parameters you want, as the following example shows:

```
<html>
<head>
<title>wrapper/AddCallbackWrapper.html</title>
</head>
<body scroll='no'>
<SCRIPT LANGUAGE="JavaScript">
    function callApp() {
        window.document.title = document.getElementById("newTitle").value;
        mySwf.myFlexFunction(window.document.title);
    }
</SCRIPT>
<h1>AddCallback Wrapper</h1>
<form id="f1">
    Enter a new title: <input type="text" size="30" id="newTitle" onchange="callApp()">
</form>
<table width='100%' height='100%' cellspacing='0' cellpadding='0'>
    <tr>
        <td valign='top'>
         <object id='mySwf' classid='clsid:D27CDB6E-AE6D-11cf-96B8-444553540000' height='200'
width='400'>
                <param name='src' value='AddCallbackExample.swf'/>
                <param name='flashVars' value=''/>
                <embed name='mySwf' src='AddCallbackExample.swf' height='100%' width='100%'
flashVars=''/>
            </object>
        </td>
    </tr>
</table>
</body></html>
```

If there is no method with the appropriate name in the application or that method hasn't been made callable, the browser throws a JavaScript error.

Getting a reference to the application object and other DOM objects is not the same in Internet Explorer as it is in Chrome or FireFox. If you do not know which browser your users will be using when they request your application, you should make your wrapper's script browser independent. For some ideas on detecting the browser type, you can look at the code in the swfobject.js file. To cover most cases, you typically use the `getElementById()` method.

Flash Player has strict security in place to prevent cross-site scripting. By default, Flex methods are not callable by HTML scripts. You must explicitly identify them as callable. You also cannot call a Flex method from an HTML page if the HTML page is not in the same domain as the application. However, it is possible to expand the sources from which Flex methods are called. For more information, see "About the addCallback() method" on page 253.

Handling browsers that disable JavaScript

In some cases, the client's browser either does not support JavaScript or the user has purposely disabled it. You can use the `<noscript>` tag in the wrapper to define what happens when this user tries to run your applications. Most commonly, you use the `<object>` and `<embed>` tags inside the wrapper's `<noscript>` block to embed the application. However, without scripting, deep linking and Express Install functionality is not available.

The following is an example of a `<noscript>` block that embeds an application built with Flex:

```
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN"
"http://www.w3.org/TR/xhtml1/DTD/xhtml1-transitional.dtd">
<!-- saved from url=(0014)about:internet -->
<html xmlns="http://www.w3.org/1999/xhtml" lang="en" xml:lang="en">
    <head>
        <title>wrapper/NoScriptWrapper.html</title>
        <meta http-equiv="Content-Type" content="text/html; charset=iso-8859-1" />
    </head>
    <body>
       <noscript>
            <object classid="clsid:D27CDB6E-AE6D-11cf-96B8-444553540000" width="100%"
height="100%" id="AddCallbackExample">
                <param name="movie" value="TestProject.swf" />
                <param name="quality" value="high" />
                <param name="bgcolor" value="#ffffff" />
                <param name="allowScriptAccess" value="sameDomain" />
                <!--[if !IE]>
            <object type="application/x-shockwave-flash" data="TestProject.swf" width="100%"
height="100%">
                    <param name="quality" value="high" />
                    <param name="bgcolor" value="#ffffff" />
                    <param name="allowScriptAccess" value="sameDomain" />
                <![endif]-->
                <!--[if gte IE 6]>
                <p>
                Either scripts and active content are not permitted to run or Adobe Flash 
Player version
                10.0.0 or greater is not installed.
                </p>
                <![endif]-->
                    <a href="http://www.adobe.com/go/getflashplayer">
                         <img 
src="http://www.adobe.com/images/shared/download_buttons/get_flash_player.gif" alt="Get Adobe 
Flash Player" />
                    </a>
                <!--[if !IE]>
                </object>
                <![endif]-->
            </object>
        </noscript>
   </body>
</html>
```

If your application *requires* functionality that is available only to scripting-enabled browsers (such as deep linking or access to the ExternalInterface API), then you can insert a message in the `<noscript>` block that warns the user against accessing your application while JavaScript is disabled. The following example warns users when someone with JavaScript disabled tries to run your application:

```
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN"
"http://www.w3.org/TR/xhtml1/DTD/xhtml1-transitional.dtd">
<!-- saved from url=(0014)about:internet -->
<html xmlns="http://www.w3.org/1999/xhtml" lang="en" xml:lang="en">
    <head>
        <title>wrapper/NoScriptWarning.html</title>
        <script type="text/javascript" src="swfobject.js"></script>
        <script type="text/javascript">
            var swfVersionStr = "0";
            var xiSwfUrlStr = "";
            var flashvars = {};
            var params = {};
            params.quality = "high";
            params.bgcolor = "#ffffff";
            params.allowscriptaccess = "sameDomain";
            var attributes = {};
            attributes.id = "TestProject";
            attributes.name = "TestProject";
            attributes.align = "middle";
            swfobject.embedSWF(
                "TestProject.swf",
                "flashContent", "100%", "100%",
                swfVersionStr, xiSwfUrlStr,
                flashvars, params, attributes);
        </script>
    </head>
    <body>
        <div id="flashContent"/>
       <noscript>
            <EM>Your browser either does not support JavaScript or has disabled it.
            Some features of this application require JavaScript.
            Please enable JavaScript and reload this page.</EM>
       </noscript>
   </body>
</html>
```

About ExternalInterface API security in Flex

Allowing applications built with Flex to call embedded scripts on HTML pages and vice versa is subject to stringent security constraints. By default, scripts on the HTML page can communicate only with ActionScript in an application if the page and the application are in the same domain. You can expand this restriction to include applications outside of the domain.

About the call() method

The success of the call() method depends on the HTML page's use of the `allowScriptAccess` parameter. This parameter is not an ActionScript mechanism; it is an HTML parameter. Its value determines whether your application can call JavaScript in the HTML page, and it applies to all functions on the page. The default value of `allowScriptAccess` only allows communication if the application and the HTML page are in the same domain.

In an HTML wrapper that uses SWFObject 2, you set the value of the `allowscriptaccess` property on the params object that is passed to the `swfobject.embedSWF()` method. The following example sets the value of the `allowScriptAccess` property to `sameDomain`:

```
var params = {};
params.quality = "high";
params.bgcolor = "#ffffff";
params.allowscriptaccess = "sameDomain";
```

The following table describes the valid values of the `allowScriptAccess` parameter:

Value	**Description**
`never`	The `call()` method fails.
`sameDomain`	The `call()` method succeeds if the calling application is from same domain as the HTML page that loaded the application. This is the default value.
`always`	The `call()` method succeeds, regardless of whether the calling application is in the same domain as the HTML page that loaded the application.

If your HTML wrapper uses the `<object>` and `<embed>` tags, you set the value of the `allowScriptAccess` property on the `<object>` tag as follows:

```
<object id='SendComplexDataTypes' classid='clsid:D27CDB6E-AE6D-11cf-96B8-444553540000'
allowScriptAccess='sameDomain' height='100%' width='100%'>
```

On the `<embed>` tag, set the property as follows:

```
<embed name='SendComplexDataTypes.mxml.swf' src='SendComplexDataTypes.mxml.swf'
allowScriptAccess='sameDomain' height='100%' width='100%' flashvars=''/>
```

About the addCallback() method

Flex prevents JavaScript methods from calling just any method in your application by requiring that you explicitly make the method callable. The default for all methods is to not be callable from JavaScript. The ExternalInterface API enables a SWF file to expose a specific interface that JavaScript can call.

By default, an HTML page can only communicate with the ActionScript in your application if it originates from the same domain. You allow HTML pages outside of the application's domain to call methods of your application using the allowDomain() method. For more information, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Runtime Shared Libraries

Introduction to RSLs

One way to reduce the size of your applications' SWF files is by externalizing shared assets into stand-alone files that can be separately downloaded and cached on the client. These shared assets can be loaded and used by any number of applications at run time, but are transferred only once to the client. These shared files are known as *Runtime Shared Libraries* or *RSLs*.

When multiple applications share a core set of components or classes, clients can download those assets only once as an RSL rather than once for each application. The RSLs are persisted on the client disk so that they do not need to be transferred across the network a second time. The resulting file size for the applications can be reduced. The benefits increase as the number of applications that use the RSL increases.

Applications built with Flex support the following types of RSLs:

- Framework RSLs — Libraries of components and framework classes that all applications can share. Framework RSLs are precompiled for you. Adobe provides hosted, signed framework RSLs that you can link to from any application that has internet access. For more information, see "Using the framework RSLs" on page 260.
- Standard RSLs — A library of custom classes created by you to use across applications that are in the same domain. Standard RSLs are stored in the browser's cache. For more information, see "About standard RSLs" on page 267.
- Cross-domain RSLs — A library of custom classes, like standard RSLs, with the difference being that they can be loaded by applications in different domains and sub-domains. Cross-domain RSLs are stored in the browser's cache. For more information, see "About cross-domain RSLs" on page 268.

You can create your own RSLs from custom libraries. You do this by using either the Adobe® Flex® Builder's™ Build Project option for your Flex Library Project or the compc command-line compiler.

About linking

Understanding library linking can help you understand how RSLs work and how you can most benefit from their use. The Flex compilers support static linking and dynamic linking for class libraries (including RSLs). Static linking is the most common type of linking when compiling an application. However, dynamic linking lets you take advantage of RSLs to achieve a reduction of the final SWF file size and, therefore, a reduction in the application download time.

When you use *static linking*, the compiler includes all referenced classes and their dependencies in the application SWF file. The end result is a larger file that takes longer to download than a dynamically-linked application, but loads and runs quickly because all the code is in the SWF file.

To statically link a library's definitions into your application, you use the `library-path` and `include-libraries` compiler options to specify locations of SWC files.

When you use the `library-path` option, the compiler includes only those classes required at compile time in the SWF file, so the entire contents of a library are not necessarily compiled into the SWF file. The `include-libraries` option includes the entire contents of the library, regardless of which classes are required. You can also use the `source-path` and `includes` options to embed individual classes in your SWF file.

In Flash Builder, you use the Project > Properties > Flex Build Path > Library Path dialog to add libraries to your project. To statically link a library at compile time, you select Merged Into Code for the library's Link Type. This includes only those classes that are used in the application, so it is the equivalent of the `library-path` compiler option.

If you statically link any part of a library into your application, you cannot use that library as an RSL.

Dynamic linking is when some classes used by an application are left in an external file that is loaded at run time. The result is a smaller SWF file size for the main application, but the application relies on external files that are loaded at run time. Dynamic linking is used by modules, runtime stylesheets, and RSLs.

When you want to use a dynamically-linked library, you instruct the compiler to exclude that library's contents from the application SWF file when you compile the application. You must provide link-checking at compile time even though the classes are not going to be included in the final SWF file. At run time, the application loads the entire library into the application SWF file, which can result in slower startup times and greater memory usage.

You can use the `runtime-shared-library-path` (Flex 4 and later) and `runtime-shared-libraries` (Flex 3) options to specify the location of dynamically-linked libraries.

You can also use the `external-library-path`, `externs`, or `load-externs` compiler options to specify the files to dynamically link into an application. These options instruct the compiler to exclude classes and libraries from the application, but to check links against them and prepare to load them at run time. The `external-library-path` option specifies SWC files or directories for dynamic linking. The `externs` option specifies individual classes or symbols for dynamic linking. The `load-externs` option specifies an XML file that describes what classes to use for dynamic linking. These options are most often used when externalizing assets from modules so that the module and the application do not contain overlapping class definitions. The `runtime-shared-library-path` option provides all the arguments to use external libraries as RSLs.

In Flash Builder, to use dynamically-linked libraries, you specify either RSL or External as the Link Type in the Library Path dialog for the library.

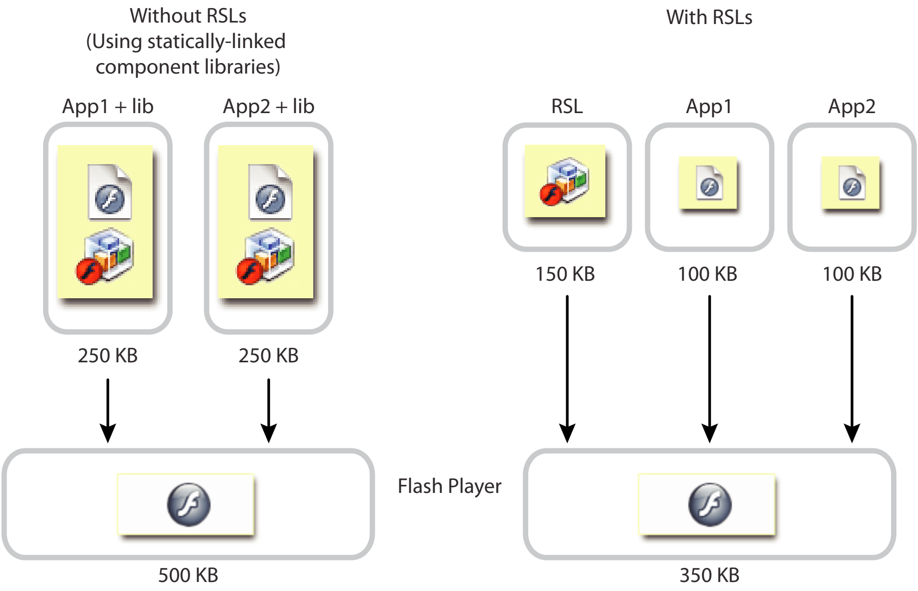
You can view the linking information for your application by using the `link-report` compiler option. This generates a report that has the same syntax as the file that you load with the `load-externs` option, so you can use it as an argument to that option without changing it. For more information about this report, see “Examining linker dependencies” on page 2308.

For more general information about the command-line compiler options, see “Flex compilers” on page 2164.

RSL benefits

The following example shows the possible benefit of separating shared components into an RSL. In this example, the library’s size is 150 KB (kilobytes) and the compiled application’s size is 100 KB. Without RSLs, you merge the library into both applications for an aggregate download size of 500 KB. If you add a third or fourth application, the aggregate download size increases by 250 KB for each additional application.

With RSLs, the RSL needs to be downloaded once only. For two applications that use the same RSL, the result is an aggregate download size of 350 KB, or a 30% reduction. If you add a third or fourth application, the aggregate download size increases by 100 KB instead of 250KB for each additional application. In this example, the benefits of using an RSL increase with each new application.



In this example, the applications with statically-linked libraries run only after Adobe® Flash® Player loads the 250 KB for each application. With dynamically linked RSLs, however, only the first application must load the entire 250 KB (the combined size of the application and the RSL). The second application runs when just 100 KB loads because the RSL is cached.

The illustrated scenario shows one possible outcome. If your applications do not use all of the components in the RSL, the size difference (and, as a result, the savings in download time) might not be as great. Suppose that each application only uses half of the components in the RSL. If you statically link the library, only those classes that are used are included; the output, as a result, is 100 KB + 75 KB for the first application and the library and 100 KB + 75 KB for the second application and the library, or an aggregate download size of 350 KB. When you use a library as an RSL, its entire SWF file must be transferred across the network and loaded by the application at run time, regardless of how much of that library is actually used. In this second case, the combined download size when using RSLs and when not using RSLs is the same.

In general, the more applications that use a common RSL, the greater the benefit.

RSL considerations

RSLs are not necessarily beneficial for all applications. You should try to test both the download time and startup time of your application with and without RSLs.

Standard RSLs can not be shared across domains. If a client runs an application in domain1.com and uses an RSL, and then launches an application in domain2.com that uses the same RSL, the client downloads the RSL twice even though the RSL is the same. You can overcome this limitation of standard RSLs by using cross-domain RSLs.

Cross-domain RSLs can be loaded by any application, even if that application is not in the same domain. They do, however, require that you create and check a digest when the RSL is loaded. This can increase startup time of the application by a small amount.

Framework RSLs can also be loaded by any application. To take advantage of the fact that framework RSLs can be cached in the Player cache, the client must be running a recent version of Flash Player. Not all clients necessarily have the latest Player, so loading a framework RSL might fail. In these cases, you can specify a failover RSL.

An RSL usually increases the startup time of an application. This is because the entire library is loaded into an application regardless of how much of the RSL is actually used. For this reason, make your RSLs as small as possible. This contrasts with how statically-linked libraries are used. When you compile an application, the compiler extracts just the components it needs from those component libraries.

If you have several applications that share several libraries, it might be tempting to merge the libraries into a single library that you use as an RSL. However, if the individual applications generally do not use more than one or two libraries each, the penalty for having to load a single, large RSL might be higher than it would be to have the applications load multiple smaller RSLs.

In this case, test your application with both a single large RSL and multiple smaller RSLs, because the gains are largely application specific. It might be better to build one RSL that has some extra classes than to build two RSLs, if most users will load both of them anyway.

If you have overlapping classes in multiple RSLs, be sure to synchronize the versions so that the wrong class is never loaded.

You cannot use RSLs in ActionScript-only projects if the base class is Sprite or MovieClip. RSLs require that the application's base class, such as Application or SimpleApplication, understand RSL loading.

In general, you should disable RSLs when compiling modules, CSS SWF files, and applications that will be loaded as child SWFs in a parent application. The parent application will likely use RSLs and dynamically link the required classes.

About caching

RSLs are cached when they are first used. When they are needed by another application, they can be loaded from the cache rather than across the network. Caching is one of the benefits of RSLs, because disk access is much faster than network access.

The type of caching used by an RSL is based on the type of RSL. Standard or cross-domain RSLs are stored in the browser's cache. If the user clears their cache, the RSLs are removed and must be downloaded again the next time they are needed. Unsigned framework RSLs are also stored in the browser's cache.

Signed framework RSLs are stored in the Player cache. This is a special cache that is maintained by Flash Player. To clear this cache, clients must invoke the Settings Manager. RSLs stored in this cache are signed and therefore can be used by any application without the need for a cross-domain policy file.

For more information about the framework cache, see "About the Player cache" on page 263.

Common RSL tasks

The techniques in this section apply to framework and custom RSLs.

Removing unused RSLs

By default, the compiler removes unused RSLs when an application is compiled. This prevents an application from having to download RSLs that it does not use. You can override this behavior by preventing the compiler from removing unused RSLs.

To prevent unused RSLs from being removed, set the `remove-unused-rsls` compiler option to `false`. The default value is `true`.

You can configure the `remove-unused-rsls` compiler option in the flex-config.xml file, as the following example shows:

```
<remove-unused-rsls>true</remove-unused-rsls>
```

In Flash Builder, to toggle the `remove-unused-rsls` option:

1 Select Project > Properties.

2 Select Flex Build Path. The Flex Build Path dialog appears.

3 Select the Library Path panel.

4 Select or deselect the "Remove unused RSLs" checkbox.

5 Click OK to save your changes.

Forcing RSLs to load

You can force the compiler to load particular RSLs when compiling your application. You do this with the `force-rsls` compiler option.

Forcing RSLs to load can be useful if you use classes that are only referenced indirectly (sometimes referred to as "soft references"), so the compiler might not know they are needed.

When forcing RSLs to load, you must configure them in the `runtime-shared-library-path` option in addition to specifying them with the `force-rsls` option.

The following example forces the osmf.swc and rpc.swc RSLs to be loaded:

```
mxmlc -force-rsls=libs/osmf.swc,libs/rpc.swc MyApp.mxml
```

You can configure the `force-rsls` compiler option in the flex-config.xml file, as the following example shows:

```
<runtime-shared-library-settings>
    <force-rsls>
        <path-element>libs/osmf.swc</path-element>
        <path-element>libs/rpc.swc</path-element>
    </force-rsls>
</runtime-shared-library-settings>
```

In Flash Builder, to force an RSL to load:

1. Select Project > Properties.
2. Select Flex Build Path. The Flex Build Path dialog appears.
3. Select the Library Path panel.
4. Select the RSL from the “Build path libraries” list and click Edit. The Library Path Item Options dialog box appears.
5. Select the “Force load RSL” checkbox.
6. Click OK to save your changes.

Viewing required RSLs

By default the compiler outputs a list of RSLs that an application uses. This is viewable in the command line compiler’s output.

The following is an example of the output from an application that loads the framework, textLayout, spark, sparkskins, and osmf RSLs:

```
Required RSLs:
    http://fpdownload.adobe.com/pub/swz/flex/4.6.0/framework_4.6.0.swf with 1 failover.
    http://fpdownload.adobe.com/pub/swz/flex/4.6.0/textLayout_2.0.0.139.swf with 1 failover.
    http://fpdownload.adobe.com/pub/swz/flex/4.6.0/spark_4.6.0.swf with 1 failover.
    http://fpdownload.adobe.com/pub/swz/flex/4.6.0/osmf_1.0.0.16316.swf with 1 failover.
```

The list of required RSLs displays the expected location of the RSLs at runtime. In this case, the expected location is the signed SWFs available on Adobe’s website. The output also notes that there is a failover location in case the Adobe RSLs are unavailable. You can see this location in the flex-config.xml file.

Note that if `static-link-runtime-shared-libraries` option is set to `true`, then no RSLs are listed because they are not used. Static linking is used instead.

Disabling RSLs

You can disable RSLs when you compile your application by setting the `static-link-runtime-shared-libraries` compiler option to `true`.

In general, disabling RSLs is useful only when compiling style SWF files, resource bundles, or other non-application assets.

Using RSLs with modules and sub-applications

RSLs are designed to work efficiently with modules and sub-applications. When using RSLs with modules and sub-applications, note that:

- Main applications only load RSLs that are needed, but create placeholders for the remaining framework RSLs. This lets the module or sub-application load other framework RSLs into the main application when they need it.
- Sub-applications and modules share framework RSLs by default.
- Sub-applications and modules can share custom RSLs if you configure the application domain that the RSLs are loaded into.

Using placeholder RSLs

When you compile an application with Flex, the default behavior is to compile the application against the framework (or default) RSLs. When the application runs, it loads only the framework RSLs that it actually uses, and creates placeholders for the remaining framework RSLs. When the application loads a module or sub-application that requires one of the framework RSLs for which there is a placeholder, the module or sub-application then loads that RSL into the main application.

If a module or sub-application requires a framework RSL that is already loaded, it will not load the RSL again. It will instead use the existing RSL.

To ensure that placeholders for framework RSLs are used, set the `remove-unused-rsls` compiler argument is `true` when compiling the main application, sub-applications, and modules. This is the default.

By default, framework RSLs are loaded into the top-most application domain that contains a placeholder for that RSL. As a result, modules or sub-applications can share RSLs that were loaded by other modules or sub-applications, as long as you do not restrict the domain into which the RSL was loaded.

Specifying domains for RSLs (advanced)

When loading custom or framework RSLs into a sub-application or module, you can specify the application domain into which the RSL is loaded. You do this with the `application-domain` compiler argument. This lets you restrict RSLs from being shared, or ensure that they are shared, among modules and sub-applications.

The `application-domain` compiler argument has the following syntax:

```
runtime-shared-library-settings.application-domain=
    path-element,application-domain-target
```

The `path-element` option specifies the location of the RSL’s SWC library file. This RSL must also be defined by the `runtime-shared-library-path` option.

The `application-domain-target` option takes one the following values:

- `default` — Loads the RSL into the top-most application domain with a placeholder. If no placeholder is found, then the RSL is loaded into the current application domain.
- `current` — Loads the RSL into the module or sub-application’s current application domain. Modules and sub-applications will not be able to share this RSL with anything other than child modules or sub-applications.
- `top-level` — Loads the RSL into the application domain of the top-level SystemManager. This is the main or root application. In this case, all modules and sub-applications will be able to share this RSL.
- `parent` — Loads the RSL into the application domain of the parent application or module.

The following example snippet from the flex-config.xml file defines a custom RSL, MyLibrary, and instructs it to be loaded into the top-level application domain:

```
<runtime-shared-library-path>
    <path-element>libs/MyLibrary.swc</path-element>
    <rsl-url>bin/MyLibrary.swf</rsl-url>
    <policy-file-url></policy-file-url>
</runtime-shared-library-path>
<runtime-shared-library-settings>
    <application-domain>
        <path-element>libs/MyLibrary.swc</path-element>
        <application-domain-target>top-level</application-domain-target>
    </application-domain>
</runtime-shared-library-settings>
```

Note that RSLs can only be shared between sub-applications and modules that have a common parent. A sub-application or module cannot share RSLs with a sub-application that is untrusted (sandboxed) or loaded for version compatibility (multi-versioned).

Changing RSL application domains in Flash Builder

To change the application domain of an RSL in Flash Builder:

1. Select Project > Properties.
2. Select Flex Build Path. The Flex Build Path dialog appears.
3. Select the Library Path panel.
4. Select the RSL from the "Build path libraries" list and click Edit. The Library Path Item Options dialog appears.
5. Select the appropriate application domain from the Application Domain drop-down box.
6. Click OK to save your settings.

Preventing framework RSLs from being shared among modules and sub-applications

For framework RSLs, the default is to load an RSL into the highest application domain that has a placeholder for the RSL (typically the main application). The result is that once a module or sub-application loads an RSL, all subsequent modules or sub-applications that need this RSL will not have to load it. The downside to this is that when the module or sub-application is unloaded, the RSL is not unloaded.

To prevent a framework RSL from being loaded into the main application, you can specify `"current"` for the application domain. This loads the RSL into the module or sub-application's application domain. When the module or sub-application is unloaded, so is the RSL. Other modules or sub-applications will not have access to it. You should not specify `"current"` for the application domain when loading the OSMF or MX RSLs. These RSLs are always loaded into the root application.

Sharing custom RSLs among modules and sub-applications

For custom RSLs, the default is to load the RSL into the module or sub-application's current application domain. The result is that the module or sub-application does not share the RSL with sibling modules or sub-applications, but only with child sub-applications or modules that it loads.

To load a custom RSL into an application domain so that it can then be shared with other modules and sub-applications, you specify `"top-level"` for the application domain. This loads the custom RSL into the main application. All modules and sub-applications will then be able to access that RSL.

You should ensure that applications or modules do not statically link classes in a custom RSL. If those classes are loaded before the RSL is loaded, then class conflicts can occur when the RSL is loaded. One technique to use when doing this is to ensure that all modules, sub-applications, and the main application share the same RSL definitions. If this is the case, classes will not be statically linked when they exist in an RSL.

Using the framework RSLs

Every application built with Flex uses some aspects of the Flex framework, which is a relatively large set of classes that define the infrastructure of an application. If a client uses two different applications, the applications will likely load overlapping class definitions. The result is that applications are larger and load slower than they should. This can be a problem for users who are on dialup or slow network connections. It also leads to the perception that applications load more slowly than other web-based applications.

To overcome these limitations, Flex provides framework RSLs. These libraries are comprised of the Flex class libraries and can be used with any application built with Flex. The framework RSLs are precompiled libraries of framework classes and components.

Framework RSLs come in two versions: signed and unsigned.

- *Signed framework RSLs* are cached in a special Player cache and in the browser cache. They can be accessed by any application regardless of that application's originating domain. They only need to be downloaded to the client once. When the browser's cache is cleared, signed framework RSLs persist in the special Player cache.
- *Unsigned framework RSLs* are cached in the browser cache and can only be used by applications that have access to the RSL's source domain. When the browser's cache is cleared, unsigned framework RSLs are removed just like any other file in the cache.

By default, framework RSLs are dynamically linked into your applications. When an application loads on the client, the client attempts to load the framework RSLs if they are not already in the client's cache. Typically, they attempt to load the signed framework RSL that is hosted by Adobe first. The location and order of RSLs loaded is defined in the flex-config.xml file. You can override these values on the command line or by using the Library Path panel of the Flex Build Path properties panel in Flash Builder.

Flash Player 9.0.115 and later support loading signed framework RSLs. These RSLs can be loaded by applications in different domains. The framework RSLs are signed and have the extension SWZ.

Only Adobe can create signed RSLs, and only signed RSLs can be stored in the Player cache. If you create an RSL that contains a custom library, it will be unsigned. You cannot sign it. If a Player with a version earlier than 9.0.115 attempts to load a framework RSL, then Flash Player skips it and loads a failover RSL, if one was specified when the application was compiled. (Flex 4 applications require Player 10.0 or later, so this might not be an issue for you.)

Only applications compiled with the Flex 3 and later compilers can use signed framework RSLs. Applications compiled with earlier versions of the compilers cannot use signed framework RSLs.

Included framework RSLs

If your application uses framework RSLs, the client attempts to load them from Adobe first. If the Adobe site is unavailable, or the client's network access is restricted, you can instruct the client to use the included framework RSLs instead.

The framework RSLs that are included in the SDK installation are located in the *flex_sdk_dir*/frameworks/rsls directory. The naming convention includes the version number of Flex, plus the build number of the compiler that you currently use. The following framework RSLs are included:

File Name	Description
advancedgrids_*version.build*.swf advancedgrids_*version.build*.swz	Signed and unsigned RSLs containing AdvancedDataGrid and OLAPDataGrid classes. Flash Builder only.
charts_*version.build*.swf charts_*version.build*.swz	Signed and unsigned RSLs containing charting classes.
framework_*version.build*.swf framework_*version.build*.swz	Signed and unsigned RSLs containing framework classes.
mx_*version.build*.swf mx_*version.build*.swz	Signed and unsigned RSLs containing MX components and supporting classes.

File Name	Description
osmf_*version.build*.swf osmf_*version.build*.swz	Signed and unsigned RSLs containing OSMF-related classes.
rpc_*version.build*.swf rpc_*version.build*.swz	Signed and unsigned RSLs containing data services classes.
spark_*version.build*.swf spark_*version.build*.swz	Signed and unsigned RSLs containing Spark components and supporting classes.
spark_dmv_*version.build*.swf spark_dmv_*version.build*.swz	Signed and unsigned RSLs containing Spark classes used by the AdvancedDataGrid and OLAPDataGrid classes.
sparkskins_*version.build*.swf sparkskins_*version.build*.swz	Signed and unsigned RSLs containing Spark skins classes for MX components.
textLayout_*version.build*.swf textLayout_*version.build*.swz	Signed and unsigned RSLs containing TLF-related classes.

The SWZ and SWF files are files that you deploy. The SWC files in the framework/libs directory are the files that you compile your application against.

The signed framework RSLs are optimized, as described in "Optimizing RSL SWF files" on page 273. This means that they do not include debugging information. Flash Builder automatically uses unoptimized debug RSLs when you launch the debugger. If you compile on the command line, however, and use the command line debugger, you must either disable RSLs or specify non-optimized RSLs to use. Otherwise, you will not be able to set break points or take advantage of other debugging functionality.

Configuring framework RSLs

The Flex compilers compile against the framework RSLs by default. This means that all classes in the Flex framework are dynamically linked into your application SWF file, which should result in a smaller SWF file than if you statically linked in the library. In most cases, you do not have to specify which RSLs to use, or what order to use them in. The Flex compiler handles this for you.

You can view the order of preference for the location of these RSLs and their failovers in the flex-config.xml file. The preference is to use hosted, signed RSLs first, with local signed RSLs second.

The following example shows an entry in the configuration file that loads one of the framework RSLs:

```
<runtime-shared-library-path>
    <path-element>libs/framework.swc</path-element>
    <rsl-url>${hosted.rsl.url}/flex/${build.number}/framework_${build.number}.swz</rsl-url>
    <policy-file-url>${hosted.rsl.url}/crossdomain.xml</policy-file-url>
    <rsl-url>framework_${build.number}.swz</rsl-url>
    <policy-file-url></policy-file-url>
</runtime-shared-library-path>
```

The configuration file uses a `{hosted.rsl.url}` token in the first `<rsl-url>` element. The compiler replaces this with the location of the signed framework RSLs on the Adobe web site. If the client does not have network access, Flash Player then attempts to load the RSL that is specified by the next `<rsl-url>` element in the list. In this case, it is the SWZ file in the same directory as the application.

The configuration file also uses a `{build.number}` token in the name of the RSLs. The compiler replaces this with a build number during compilation. The name of the framework RSL depends on the build number of Flex that you are using.

You can also manually specify framework RSLs for your applications. You do this by compiling against the SWC files in your /frameworks/libs directory with the `runtime-shared-library-path` option on the command line. You can optionally add a policy file URL if necessary, plus one or more failover RSLs and their policy file URLs.

The following example compiles SimpleApp with the framework RSL:

```
mxmlc -runtime-shared-library-path=libs/framework.swc,
    framework_4.6.0.swz,,framework_4.6.0.swf
    SimpleApp.mxml
```

This example sets the signed framework RSL (*.swz) as the primary RSL, and then the unsigned framework RSL (*.swf) as the secondary RSL. This example does not specify a location for the policy file, so it is assumed that either the RSLs and the application are in the same domain or the policy file is at the root of the target server.

You can also specify the unsigned framework RSL as the primary RSL. This is common if you want to include debug information in the RSL, such as when you are using the command line to compile your SWF file and the command line debugger to debug it. Flash Builder automatically uses debug RSLs when you debug with it so you do not have to change any compiler options.

You can specify a signed SWZ file as the framework RSL and not specify an unsigned SWF file as a failover RSL. In this case, the application will not work in any Flash Player of version earlier than 9.0.115. In the HTML wrapper, you can detect and upgrade users to the newest Player by using the Express Install feature. For more information, see “Using Express Install in the wrapper” on page 2558. (Flex 4 applications require Player 10.0 or later, so this might not be an issue for you.)

If you use locally-hosted signed framework RSLs when you deploy your application, you must deploy the SWZ file to the location that you specified on the command line. You must also be sure that the crossdomain.xml file is in place at the RSL’s domain. To ensure that your application can support older versions of Flash Player, you should also deploy the unsigned framework RSL SWF file (in addition to the signed SWZ file), and specify that file as a failover RSL.

Disabling framework RSLs

The use of framework RSLs is enabled by default. You can disable RSLs when you compile your application by setting the `static-link-runtime-shared-libraries` compiler option to `true`, as the following example shows:

```
mxmlc -static-link-runtime-shared-libraries=true MyApp.mxml
```

Framework RSL digests

After the framework RSLs are transferred across the network, Flash Player generates a digest of the framework RSL and compares that digest to the digest that was stored in the application when it was compiled. If the digests match, then the RSL is loaded. If not, then Flash Player throws an error and attempts to load a failover RSL.

About the Player cache

The Player cache stores signed RSLs, such as the framework RSLs. You can manage the settings of the Player cache with the Settings Manager. The use of the RSLs in the Player cache is secure; no third party can inject code that will be executed. Only Adobe can sign RSLs; therefore, only Adobe RSLs can be stored in the Player cache.

The default size of the framework cache is 20MB. When the aggregate size of the cached RSLs in this directory meets or exceeds 20MB, Flash Player purges the cache. Files are purged on a least-recently-used basis. Less-used files are purged before files that have been used more recently. Purging continues until the cache size is below 60% of the maximum size. By default, this is 12MB.

The Global Storage Settings panel in the Settings Manager lets the user turn off the caching feature and increase or decrease its size. The Settings Manager is a special control panel that runs on your local computer but is displayed within and accessed from the Adobe website. If the user disables the Player cache, then Flash Player will not load SWZ files. Flash Player will load failover RSLs instead.

The following table shows the locations of the Player cache on various platforms:

Platform	Location
Windows 95/98/ME/2000/XP	C:\Documents and Settings*user_name*\Application Data\Adobe\Flash Player\AssetCache\
Windows Vista	C:\Users\user_name\AppData\Roaming\Adobe\Flash Player\AssetCache\
Linux	/home/*user_name*/.adobe/Flash_Player/AssetCache/
Mac OSX	/Users/*user_name*/Library/Cache/Adobe/Flash Player/AssetCache/

Using the framework RSLs in Flash Builder

Framework RSLs are enabled by default in Flash Builder. You can use the information in this section if you want to specify that only some of them are used, reorder the failover options, or customize some other aspect of the framework RSLs.

You can use Flash Builder to organize your RSLs and decide which SWC files to use as RSLs and which to use as statically-linked libraries. You can also use Flash Builder to configure the deployment locations, digests, and other properties of RSLs. The signed and unsigned framework RSLs have already been created for you and optimized. By default, the Flex compiler dynamically links against these RSLs. For locally-hosted RSLs, you must also deploy them to the location that you specified at compile time.

You can set each SWC file that your project uses to use one of the following linkage types:

- Merged Into Code —Indicates that classes and their dependencies from this library are added to the SWF file at compile time. They are not loaded at run time. The result is a larger SWF file, but one with no external dependencies.
- RSL — Indicates that this library will be used as an RSL. When you compile your application, the classes and their dependencies in this library are externalized, but you compile against them. You must then make them available as an RSL at run time.
- External — Indicates that this library will be externalized from the application, but it will not be used as an RSL. This excludes all the definitions in a library from an application but provides compile time link checking. Typically, only playerglobal.swc has this setting in an application project, but you might also use it to externalize assets that are used as modules or dynamically-loaded SWF files.

By default, all SWC files in the library path use the same linkage as the framework.

Use the framework SWC files as RSLs in Flash Builder

1. Open your Flex project in Flash Builder.
2. Select the project in the Navigator and select Project > Properties.
3. Select the Flex Build Path option in the resource list at the left. The Flex Build Path dialog box appears.
4. Select the Library Path tab.
5. Select Runtime Shared Library (RSL) from the Framework Linkage drop-down list. This instructs the application compiler to use the framework SWC files as RSLs.
6. Click OK to save your changes.

In the release output directory, Flash Builder includes the framework's SWF and SWZ files for you to deploy if your users require locally-hosted RSLs.

You can view the settings of the SWC files that are included with Flex but whose classes are not included in the framework RSLs by expanding the list of libraries used by Flex in the Library Path tab. This list includes the automation.swc and qtp.swc files. You might want to compile your application against these SWC files as RSLs if your application will benefit from doing so. These SWC files are not optimized, so if you use them as RSLs, you should optimize them as described in "Optimizing RSL SWF files" on page 273.

Use other Adobe SWC files as RSLs in Flash Builder

1 On the Library Path tab, click the + next to Flex 4.x to expand the list of SWC files.

2 Select the SWC file that you want to use as an RSL and click the + to show its properties. For example, click the + next to the automation.swc file.

3 Click the Link Type property and click the Edit button. The default link type is "Merged into code", which means that the library is statically linked to your application by default.

4 If you are already using the framework.swc file as an RSL, you can select the Use Same Linkage As Framework option. This option lets you toggle the RSL's status on and off by changing only the framework.swc file's linkage status. Otherwise, select Runtime Shared Library (RSL) from the Link Type drop-down list.

   The RSL Options field is enabled.

5 Select the Verification type and the deployment locations of the RSL as described in "Compiling applications with standard and cross-domain RSLs" on page 270.

6 Click OK to save your changes.

In some cases, you might not want to deploy the framework RSLs in the same directory as your main application. You might have a central server where these RSLs are stored, and need to share them across multiple applications.

Customize the deployment location of the framework RSLs

1 Edit the framework.swc file's Link Type settings in the Library Path Item Options dialog box.

2 Select the Digests radio button, if it is not already selected.

   Notice the two default entries in the Deployment paths field: an SWZ file and an SWF file. The SWZ file is the signed RSL that can be stored in the framework cache. The SWF file is an unsigned SWF file that is a failover if the SWZ file cannot be loaded.

3 To change the deployment location of the framework RSLs, click the SWZ file and then click the Edit button. The Edit RSL Deployment Path dialog box appears.

   In the Deployment Path/URL field, enter the location of the SWZ file. For example, "http://www.remoteserver.com/rsls/framework_4.0.0.5902.swc". The application tries to load the RSL from this location at run time.

   The location can be relative to the application's SWF file, or a full URL to a remote server. If the RSL is on a remote server, you might also be required to point to the policy file.

   In the Policy file URL field, enter the location of the crossdomain.xml file. You do not need to enter anything in this field if the application's SWF file and the RSLs are served from the same domain, or if the crossdomain.xml file is at the target server's root.

4 Click OK to save your changes in the Edit RSL Deployment Path dialog box.

5 Repeat the previous two steps for the SWF file, if you are also deploying the unsigned framework RSL with your application. If you do not deploy the failover SWF file, then users with Flash Player versions earlier than 9.0.115 will not be able to use your application. (Flex 4 applications require Player 10.0 or later, so this might not be an issue for you.)

6 Click OK to save your changes to the Library Path Item Options dialog box.

7 Ensure that the Verify RSL Digests option on the Library Path tab is selected.

8 Click OK to save your changes to the Flex Build Path settings.

When you deploy your application, you must manually copy the framework RSLs to the path that you specified on the remote server.

Example of using the framework RSLs on the command line

Framework RSLs are enabled by default for the command-line compiler. You can use the information in this section if you want to specify that only some of them are used, reorder the failover options, or customize some other aspect of the framework RSLs.

Create an application with a single Button control. After you create the application, determine the size of the application's compiled SWF file before you use the framework RSL. This will give you an idea of how much memory you are saving by using the framework RSL.

Compile the application as you normally would, with one exception. Add the `static-link-runtime-shared-libraries=true` option; this ensures that you are not using the framework RSL when compiling the application, regardless of the settings in your configuration files. Instead, you are compiling the framework classes into your application's SWF file.

With the mxmlc command-line compiler, use the following command to compile the application:

```
mxmlc -static-link-runtime-shared-libraries=true bin/SimpleApp.mxml
```

Examine the output size of the SWF file. Even though the application contains only a Button control, the size of the SWF file should be over 100KB. That is because it not only includes component and application framework classes, but it also includes all classes that those classes inherit from plus other framework dependencies. For visual controls such as a Button, the list of dependencies can be lengthy. If you added several more controls to the application, you will notice that the application does not get much larger. That is because there is a great deal of overlap among all the visual controls.

Run the application in a browser either from the file system or from a server. You can also run the application in the standalone player.

Next, compile the application again, but this time add the signed framework RSL as an RSL and the unsigned framework RSL as a failover RSL. For example:

```
mxmlc -runtime-shared-library-path=c:/p4/flex/flex/sdk/frameworks/libs/framework.swc,
    framework_4.0.0.5902.swz,,framework_4.0.0.5902.swf rsls/SimpleApp.mxml
```

The result is a SWF file that should be smaller than the previous SWF file.

This command includes a blank entry for the policy file URL. In this example, the crossdomain.xml file is not needed because you will deploy the RSLs and the application to the same domain, into the same directory.

In addition, the `runtime-shared-library-path` option includes an unsigned failover RSL as its final parameter. This is a standard framework RSL SWF file that is provided to support older versions of Flash Player that do not support signed RSLs. It is not cross domain, and if used by the client, it is stored in the browser's cache, not the framework cache.

Deploy the application and the framework RSLs to a server. You cannot request the SimpleApp.swf file from the file system because it loads network resources (the framework RSLs). This causes a security sandbox violation unless the application is loaded from a server. Deploy the SimpleApp.swf, framework_4.0.0.5902.swz, and framework_4.0.0.5902.swf files to the same directory on your web server.

Note: *You can point to the SWZ files that are hosted on the Adobe web site, rather than deploy your own SWZ files as RSLs. In this case, view the default entries for the RSLs in the flex-config.xml file to see how to link to them.*

Request the application in the browser or create a wrapper for the application and request that file.

To verify that the signed framework RSL was loaded by your application, you can look for an SWZ file in your framework cache. For more information, see "About the Player cache" on page 263.

After the client downloads the signed framework RSL, they will not have to download that RSL again for any application that uses signed framework RSLs, unless a new version of the framework is released or the RSL's SWZ file is purged from the Player cache.

Using standard and cross-domain RSLs

Standard and cross-domain RSLs are RSLs that you create from your custom component libraries. These RSLs are different from signed framework RSLs in that they are unsigned and can only be stored in the browser's cache. They are never stored in the Player cache.

To use standard or cross-domain RSLs, you perform the following tasks:

Create a library An RSL is created from a library of custom classes and other assets. You can create a library with either the Flash Builder Library Project or the compc command-line compiler. You can output the library as a SWC file or an open directory. The library includes a library.swf file and a catalog.xml file; the library.swf file is deployed as the RSL. For more information, see "Creating libraries" on page 276.

Compile your application against the library When you compile your application, you externalize assets from your application that are defined in the RSL. They can then be linked at run time rather than at compile time. You do this when you compile the application by passing the compile-time location of the library SWC file as well as the run-time location of the library's SWF file. For more information, see "Compiling applications with standard and cross-domain RSLs" on page 270.

Optimize the RSL After you generate a library and compile your application against it, you should run the optimizer against the library's SWF file. The optimizer reduces the SWF file by removing debugging code and unneeded metadata from it. While this step is optional, it is best practice to optimize a library SWF file before deploying it. For more information, see "Optimizing RSL SWF files" on page 273.

Deploy the RSL After you have compiled and optionally optimized your RSL, you deploy the library.swf file with your application so that it is accessible at run time. If the RSL is a cross-domain RSL, then you might also be required to deploy a crossdomain.xml file.

About standard RSLs

Standard RSLs can only be used by applications that are in the same domain as the RSL. You can benefit from using standard RSLs if you meet all of the following conditions:

- You host multiple applications in the same domain.
- You have custom component libraries.
- More than one application uses those custom component libraries.

Not all applications can benefit from standard RSLs. Applications that are in different domains or that do not use component libraries will not benefit from standard RSLs.

Standard RSLs can benefit from digests. While they do not require digests, you can use them to ensure that your application loads the latest RSL. For more information, see “About RSL digests” on page 269.

The following is a list of typical applications that can benefit from standard RSLs:

- Large applications that load multiple smaller applications that use a common component library. The top-level application and all the subordinate applications can share components that are stored in a common RSL.
- A family of applications on a server built with a common component library. When the user accesses the first application, they download an application SWF file and the RSL. When they access the second application, they download only the application SWF file (the client has already downloaded the RSL, and the components in the RSL are used by the two applications).
- A single monolithic application that changes frequently, but has a large set of components that rarely change. In this case, the components are downloaded once, while the application itself might be downloaded many times. This might be the case with charting components, where you might have an application that uses you change frequently, but the charting components themselves remain fairly static.

About cross-domain RSLs

Cross-domain RSLs can be used by applications in any domain or sub-domain. The benefits of cross-domain RSLs are the same as standard RSLs, but they are not restricted to being in the same domain as the application that loads them. This lets you use the same RSL in multiple applications that are in different domains.

To use a cross-domain RSL that is located on a remote server, the remote server must have a crossdomain.xml file that allows access from the application’s domain. The easiest way to do this is to add a crossdomain.xml file to the server’s root. To ensure that applications from any domain can access the RSL SWF file, you can use an open crossdomain.xml file such as the following:

```
<cross-domain-policy>
    <site-control permitted-cross-domain-policies="all"/>
    <allow-access-from domain="*" to-ports="*"/>
</cross-domain-policy>
```

This is not a best practice, however, because it allows requests from any domain to load the RSL, and other assets, from your server. You should instead restrict requests to only those domains that you trust by narrowing the entries in the `domain` attribute. You should also consider using a more restrictive meta-policy with the `permitted-cross-domain-policies` attribute. For more information, see “Using cross-domain policy files” on page 125.

You can store the crossdomain.xml file anywhere on the target server. When you compile a cross-domain RSL, you can specify the location of the crossdomain.xml file, and the application will look to that location to get permission to load the RSL. If you do not specify the location of the crossdomain.xml file when you compile your application, the application looks in the server’s root directory by default.

Cross-domain RSLs can fail to load into an application under the following conditions:

- The server on which the RSL is located fails
- The network fails, so remote files cannot be loaded
- The digest of the RSL when the application was compiled does not match the digest of the RSL when it is loaded
- The policy file is absent from the RSL’s server, or that server has a restrictive meta-policy

Cross-domain RSLs support a backup mechanism where a failover RSL can be loaded in the case of a server failure. If the server on which the main RSL fails, Flash Player will try to load a failover RSL whose location you specify when you compile the application.

About RSL digests

To ensure that the cross-domain RSL is coming from the trusted party, Flash Player reads the bytes of the incoming RSL and computes a one-way hash, or *digest*. The digest must match the digest that was stored in the application at compile time when the application was linked to the cross-domain RSL. If the RSL's digest matches the known digest, then Flash Player loads the cross-domain RSL. If the digests do not match, Flash Player displays an error message and does not load the RSL.

You can also use digests for standard RSLs. This is useful if you update your RSLs frequently, and want to ensure that the application loads the latest RSL.

To create a digest while compiling a library, you set the `compute-digest` compiler option to `true`. You can set this value in the flex-config.xml file, as the following example shows:

```
<compute-digest>true</compute-digest>
```

The default value of the `compute-digest` option is `true`.

In Flash Builder, to disable digests, you must add the following to the Additional Compiler Arguments field in the Flex Library Compiler dialog box:

```
-compute-digest=false
```

The compiler writes the digest inside the `swc/libraries/library/digests` element of the RSL's catalog.xml file. The following example shows the structure of `digest` elements, which are optional children of the `digests` element in the catalog.xml file:

```
<digests>
    <digest type="SHA-256" signed="true"
        value="d604d909d8d6d358097cf2f4ebf4707faf330469ed6b41dcdc5aaf6f4dd3bea9"/>
    <digest type="SHA-256" signed="false"
        value="d604d909d8d6d358097cf2f4ebf4707faf330469ed6b41dcdc5aaf6f4dd3bea9"/>
</digests>
```

The following table describes the tag and its attributes:

Option	Description
`digest`	Optional child of `digests` element.
`signed`	Whether the library is signed or not. This value is `true` if the digest is of a signed library and `false` otherwise. Only Adobe can create signed libraries. This attribute is required.
`type`	The kind of hash used to create the digest. The only currently-supported value is "SHA-256". This attribute is required.
`value`	The hash of the specified type. This is the digest of the RSL associated with the catalog.xml. This attribute is required.

When you compile your production application with an RSL that uses a digest for verification, set the `verify-digests` compiler option to `true` to indicate that the application must check the digest before using the RSL. The default value of this option is `true`.

If you have multiple RSLs, such as a main RSL plus a failover RSL, the compiler stores multiple digests inside the application.

The Flex compiler uses the SHA-256 digest algorithm from the java.security libraries to generate the digest.

About failover

The failover feature is used for two reasons:

- If the Flash Player is not at least version 9.0.115 and it tries to load a signed RSL, it will attempt to load the failover RSL. (Flex 4 applications require Player 10.0 or later, so this might not be an issue for you.)
- If a network or server failure occurs while loading the main RSL, Flash Player will attempt to load the failover RSL.

For framework RSLs, you typically specify a signed RSL as the main RSL, and an unsigned RSL as the failover RSL. When loading an application that uses signed framework RSLs, older versions of Flash Player skip the signed RSL and attempt to load the failover RSL, which is typically an unsigned RSL.

For all RSLs, the failover RSL provides a mechanism to load an RSL if the primary server is unavailable.

You can specify the location of the RSL and a failover RSL in your flex-config.xml file or on the command line as parameters to the `runtime-shared-library-path` option. The default failover RSL is framework_4.0.${build.number}.swf. In Flash Builder, you can add failover RSLs by adding them to the Deployment Paths in the Library Path Item Options dialog box.

Compiling applications with standard and cross-domain RSLs

Compiling your application with standard or cross-domain RSLs is easier to do in Flash Builder than it is on the command line. Flash Builder can automatically extract the RSL SWF file for you during the compilation process, and use that SWF to compile your application against. If you use the command-line compiler, then you must extract this file from the SWC file yourself prior to deployment. In either case, when you deploy the RSL SWF file, you should optimize it as described in “Optimizing RSL SWF files” on page 273.

Compile with standard or cross-domain RSLs in Flash Builder

1. Open your application’s project.
2. Select Project > Properties.
3. Select Flex Build Path in the option list. The Flex Build Path settings appear.
4. Select the Library Path tab.
5. Click the Add SWC button. The Add SWC dialog box appears.
6. Enter the path to the SWC file or click the Browse button to find the SWC file.
7. Click OK to add the SWC file to your project’s library path. Flash Builder adds the new SWC file to the list of SWC files in the Library Path tree.
8. Expand the SWC file in the Build Path Libraries tree by clicking the + next to it.
9. Change the Link Type to “Runtime shared library (RSL)”. You do this by selecting the Link Type and clicking the Edit button. When you change the Link Type to an RSL, Flash Builder displays additional options in the Library Path Item Options dialog box.
10. For Verification, select Digests if you are using a cross-domain RSL or if you are using a standard RSL that you want to verify at run time with a digest.

    Click the Add button to add the deployment path of the RSL SWF file. The Edit RSL Deployment Path dialog box appears.

    In the Deployment Path/URL field, enter the location that you will deploy the RSL’s SWF file to. This path is relative to the main application’s SWF file. The default is to deploy the RSL in the same directory as the main application.

    (Cross-domain RSLs only) Add a policy file URL if the application and the RSL will be on separate domains, and the crossdomain.xml file is not at the root of the RSL’s server.

You can have Flash Builder extract the RSL's SWF file from the SWC file automatically or you can do it manually. Deselect the Auto Extract swf to Deployment Path option if you want to extract the RSL's SWF file from the SWC file manually. Otherwise, Flash Builder will extract the SWF file for you. In general, you should manually extract the SWF file and optimize it before deploying it. Otherwise, the library.swf file will be larger than necessary. For more information on optimizing the RSL, see "Optimizing RSL SWF files" on page 273.

Click OK to save your changes.

11 Select None for Verification if you are using a standard RSL that does not use a digest. In this case, the RSL is assumed to not be cross-domain, and you therefore cannot specify a policy file URL. This is because standard RSLs must be deployed in the same domain as the main application, so policy files are not necessary. The deployment path of the RSL can also only be a local path that is relative to the location of the main application's SWF file.

12 Click OK to save your Library Path Item Options.

13 If the RSL is a cross-domain RSL, ensure that the Verify RSL Digests option is selected in the Library Path tab. If the RSL is standard and you do not want to use a digest, deselect this option. This option is overridden by the Verification setting in the Library Path Item Options dialog box.

14 Click OK to save your changes to the Flex Build Path settings.

Compile with standard or cross-domain RSLs on the command line

To use standard or cross-domain RSLs in your application on the command line, you use the `runtime-shared-library-path` application compiler option. This option has the following syntax:

```
-runtime-shared-library-path=path-element,rsl-url[,policy-file-url,failover-url,...]
```

The following table describes the `runtime-shared-library-path` arguments:

Argument	Description
`path-element`	Specifies the location of the SWC file or open directory to compile against. For example, c:\flexsdk\frameworks\libs\framework.swc. The compiler provides compile-time link checking by using the library specified by this option. This argument is required.
`rsl-url`	Specifies the location of the RSL SWF file that will be loaded by the application at run time. The compiler does not verify the existence of the SWF file at this location at compile time. It does store this string in the application, however, and uses it at run time. As a result, the SWF file must be available at run time but not necessarily at compile time. You specify the location of the SWF file relative to the deployment location of the application. For example, if you store the library.swf file in the *web_root*/libraries directory on the web server, and the application in the web root, you specify libraries/library.swf for the RSL SWF file. This argument is required. You must know the deployment location of the RSL SWF file relative to the application when you compile it. You do not have to know the deployment structure when you create the library SWC file, though, because components and classes are compiled into a SWC file and can be used by any application at compile time. The value of the `rsl-url` argument can be a relative URL, such as "../libraries/library.swf", or an absolute URL, such as "http://www.mydomain.com/libraries/library.swf". If it is on a different server, it must be a cross-domain or framework RSL. Standard RSLs can only be loaded from the same domain as the application. The default name of the RSL SWF file is library.swf, but you can change it to any name you want after you extract it from the SWC file. If you change it, then you must change the name you specify in the `rsl-url` option.
`policy-file-url`	Specifies the location of the policy file (crossdomain.xml) that gives permission to load the RSL from the server. For example, http://www.mydomain.com/rsls/crossdomain.xml. This is only necessary if the RSL and the application that uses it are on different domains. If you are serving the application and the RSL SWF file from the same domain, then you do not need to specify a policy file URL. This argument is optional. If you do not provide a value, then Flash Player looks at the root of the target web server for the crossdomain.xml file. For more information on using RSLs in different domains, see "About cross-domain RSLs" on page 268.
`failover-url`	Specifies the location of a secondary RSL if the first RSL cannot be loaded. This is most commonly used to ensure that an unsigned framework RSL will be used if the signed framework RSL fails to load. If the version of Flash Player is earlier than 9.0.115, it cannot load signed RSLs, so it must load an unsigned RSL. (Flex 4 applications require Player 10.0 or later, so this might not be an issue for you.) While this argument is used primarily to ensure that the framework RSL is loaded, it can also be used by cross-domain RSLs to ensure that a secondary RSL is available in case of network or server failure. This argument is optional. If you specify a second `policy-file-url`, then Flash Player will look to that location for the crossdomain.xml file for the failover RSL.

The following example shows how to use the `runtime-shared-library-path` option when compiling your application on the command line:

```
mxmlc -runtime-shared-library-path=../lib/mylib.swc,../bin/library.swf Main.mxml
```

Do not include spaces between the comma-separated arguments of the `runtime-shared-library-path` option on the command line.

Your application can use any number of RSLs. In Flash Builder, you add a list of RSLs on the Library Path tab. When using the command line, you add additional `runtime-shared-library-path` options. In both cases, the order of the RSLs is significant because base classes must be loaded before the classes that use them.

You can also use a configuration file to use RSLs, as the following example shows:

```
<runtime-shared-library-path>
    <path-element>../lib/mylib.swc</path-element>
    <rsl-url>../bin/library.swf</rsl-url>
</runtime-shared-library-path>
```

In the previous example, the file structure at compile time looks like this:

```
c:/Main.mxml
c:/lib/CustomDataGrid.swc
```

The deployed files are structured like this:

```
web_root/Main.swf
web_root/bin/library.swf
```

If you are using a cross-domain RSL, you can also specify the location of the crossdomain.xml file, and the location of one or more RSLs to be used as a failover RSL. The following example specifies a full URL for the location of the RSL, and the locations of a crossdomain.xml file and failover RSL on the command line:

```
mxmlc -runtime-shared-library-path=
    ../lib/mylib.swc,
    http://www.my-domain.com/rsls/library.swf,
    http://www.my-domain.com/rsls/crossdomain.xml,
    http://www.my-other-domain.com/rsls/library.swf,
    http://www.my-other-domain.com/rsls/crossdomain.xml
    Main.mxml
```

In the configuration file, this would be represented as follows:

```
<runtime-shared-library-path>
    <path-element>../lib/mylib.swc</path-element>
    <rsl-url>http://www.my-domain.com/rsls/library.swf</rsl-url>
    <policy-file-url>http://www.my-domain.com/rsls/crossdomain.xml</rsl-url>
    <rsl-url>http://www.my-other-domain.com/rsls/library.swf</rsl-url>
    <policy-file-url>http://www.my-other-domain.com/rsls/crossdomain.xml</rsl-url>
</runtime-shared-library-path>
```

Toggling RSLs on the command line

When compiling an application that uses RSLs, the command-line compiler options can be unwieldy and difficult to read. It is generally easier to define RSLs in your configuration files. However, when you do that, it is not very easy to enable or disable them as you develop your application because you have to edit the configuration file any time you want to change the way the RSLs are compiled.

To enable the use of RSLs without editing the configuration file, set the value of `static-link-runtime-shared-libraries` to `false`. By doing this, you can toggle the use of RSLs from the command line without having to edit the configuration file or enter long sets of command-line options. The default value of this option is `true`.

While you typically set the value of the `static-link-runtime-shared-libraries` option on the command line, you can also set it in the configuration file. If you set any RSL values on the command line, then the value of the `static-link-runtime-shared-libraries` option in the configuration file is ignored.

Optimizing RSL SWF files

The default SWF file in your SWC files includes debugging code and metadata that increase the file size. The debugging code is necessary for the compiler to run, but is not necessary at run time unless you want to debug the RSL. You can remove the debug code and unnecessary metadata by using the optimizer tool. This should result in a smaller RSL.

If you use the optimizer tool, you must keep track of two separate library files: one for compiling (the larger, pre-optimized one) and one for deploying (the smaller, optimized one). You compile your main application against the non-optimized library but then deploy the optimized library so that it can be loaded at run time.

The optimizer tool is in the bin directory. For Unix and Mac OS, it is a shell script called optimizer. For Windows, it is optimizer.exe. You invoke it only from the command line. The Java settings are managed by the jvm.config file in the bin directory.

The syntax for the optimizer tool is as follows:

```
optimizer -keep-as3-metadata Bindable Managed ChangeEvent NonCommittingChangeEvent Transient
-input input_swf -output output_swf
```

You must specify the `keep-as3-metadata` option and pass it the required metadata. At a minimum, you should specify the Bindable, Managed, ChangeEvent, NonCommittingChangeEvent, and Transient metadata names. You can also specify custom metadata that you want to remain in the optimized SWF file.

You can specify the configuration file that the optimizer tool uses by using the `load-config` option.

To get help while using the optimizer tool, enter the `-help list advanced` option:

```
optimizer -help list advanced
```

By default, the optimizer tool saves an optimized version of the SWF file in the current directory, with the name output.swf. This file should be smaller than the library.swf because it does not contain the debugging code.

Use optimized RSLs

1 Create an RSL by compiling a library project in Flash Builder or building a SWC file with the compc command line tool.

2 Compile your main application and reference the RSL.

3 Extract the library.swf file from your RSL’s SWC file, if you haven’t done so already.

4 Run the optimizer against the library.swf file, for example:

```
optimizer -keep-as3-metadata Bindable Managed ChangeEvent NonCommittingChangeEvent
Transient -input c:\rsls\library.swf -output c:\rsls\output\output.swf
```

5 Run the digest tool against the optimized library.swf file; for example:

```
digest -digest.rsl-file c:\rsls\output\output.swf -digest.swc-path c:\rsls\output\
```

6 Deploy the optimized library (in this case, output.swf) with the application so that the application uses it at run time.

Example of creating and using a standard and cross-domain RSL

This example walks you through the process of creating a library and then using that library as a standard and a cross-domain RSL with an application. It uses the command-line compilers, but you can apply the same process to create and use RSLs with a Flash Builder project. This example first shows you how to use a standard RSL, and then how to use that same RSL as a cross-domain RSL.

Keep in mind that a SWC file is a library that contains a SWF file that contains run-time definitions and additional metadata that is used by the compiler for dependency tracking, among other things. You can open SWC files with any archive tool, such as WinZip, and examine the contents.

Before you use an RSL, first learn how to statically link a SWC file. To do this, you build a SWC file and then set up your application to use that SWC file.

In this example you have an application named app.mxml that uses the ProductConfigurator.as and ProductView.as classes. The structure of this example includes the following files and directories:

```
project/src/app.mxml
project/libsrc/ProductConfigurator.as
project/libsrc/ProductView.as
project/lib/
project/bin/
```

To compile this application without using libraries, you can link the classes in the /libsrc directory using the `source-path` option, as the following example shows:

```
cd project/src
mxmlc -o=../bin/app.swf -source-path+=../libsrc app.mxml
```

This command adds the ProductConfigurator and ProductView classes to the SWF file.

To use a library rather than standalone classes, you first create a library from the classes. You use the compc compiler to create a SWC file that contains the ProductConfigurator and ProductView classes, as the following command shows:

```
cd project
compc -source-path+=libsrc -debug=false -o=lib/mylib.swc ProductConfigurator ProductView
```

This compiles the mylib.swc file in the lib directory. This SWC file contains the implementations of the ProductConfigurator and ProductView classes.

To recompile your application with the new library, you add the library with the `library-path` option, as the following example shows:

```
cd project/src
mxmlc -o=../bin/app.swf -library-path+=../lib/mylib.swc app.mxml
```

This links the library at compile time, which does not result in any benefits of externalization. The library is not yet being used as an RSL. If you use the new library as an RSL, the resulting SWF file will be smaller, and the library can be shared across multiple applications.

Now you can recompile the application to use the library as an external RSL rather than as a library linked at compile time.

The first step is to compile your application with the `runtime-shared-library-path` option. This option instructs the compiler to specifically exclude the classes in your library from being compiled into your application, and provides a run time location of the RSL SWF file.

```
cd project/src
mxmlc -o=../bin/app.swf -runtime-shared-library-path=../lib/mylib.swc,myrsl.swf app.mxml
```

The next step is to prepare the RSL so that it can be found at run time. To do this, you extract the library.swf file from the SWC file with any archive tool, such as WinZip or jar.

The following example extracts the SWF file by using the unzip utility on the command line:

```
cd project/lib
unzip mylib.swc library.swf
mv library.swf ../bin/myrsl.swf
```

This example renames the library.swf file to myrsl.swf and moves it to the same directory as the application SWF file.

The next step is to optimize the library.swf file so that it does not contain any debug code or unnecessary metadata. The following example optimizes the SWF file by using the optimizer tool:

```
optimimzer -keep-as3-metadata Bindable Managed ChangeEvent NonCommittingChangeEvent Transient
    -input bin/myrsl.swf -output bin/myrsl.swf
```

You now deploy the main application and the RSL. In this example, they must be in the same directory. If you want to deploy the myrsl.swf file to a different directory, you specify a different path in the `runtime-shared-library-path` option.

You can optionally run the optimizer tool on the myrsl.swf file to make it smaller before deploying it. For more information, see "Optimizing RSL SWF files" on page 273.

To use the RSL as a cross-domain RSL, you add a crossdomain.xml file, a failover RSL, and its crossdomain.xml file to the option, as the following example shows:

```
cd project/src
    mxmlc -o=../bin/app.swf -runtime-shared-library-path=../lib/mylib.swc,
    http://www.my-remote-domain.com/rsls/myrsl.swf,
    http://www.my-remote-domain.com/rsls/crossdomain.xml,
    http://www.my-other-remote-domain.com/rsls/myrsl.swf,
    http://www.my-other-remote-domain.com/rsls/crossdomain.xml,
    Main.mxml
```

Next, you create a crossdomain.xml file. If the domain that are you running the application on is my-local-domain.com, then you can create a crossdomain.xml file that looks like the following:

```
<cross-domain-policy>
    <site-control permitted-cross-domain-policies="all"/>
    <allow-access-from domain="*.my-local-domain.com" to-ports="*"/>
</cross-domain-policy>
```

You now deploy the main application and the RSL. This time, however, the RSL is deployed on a remote server in the /rsls directory. You must also ensure that the crossdomain.xml file is in that directory. Finally, you must ensure that the failover RSL and its crossdomain.xm l file are deployed to the other remote domain.

Creating libraries

To use standard or cross-domain RSLs, you must first create the library that will be used as an RSL. If you want to use framework RSLs, the libraries are already created for you. In that case, all you need to do is compile against them and then deploy the SWZ or SWF file with your application.

A standard or cross-domain RSL is a library of custom components, classes, and other assets that you create. You can create a library using either Flash Builder or the compc command-line compiler. A library is a SWC file or open directory that contains a library.swf file and a catalog.xml file, as well as properties files and other embedded assets. You can use any library as an RSL, but libraries do not need to be used as RSLs.

Creating libraries in Flash Builder

In Flash Builder, you create a new library by selecting File > New > Flex Library Project. You add resources to a library by using the Flex Library Build Path dialog box. When you select Build Library or Build All, Flash Builder creates a SWC file. This SWC file contains the library.swf file.

Creating libraries on the command line

On the command line, you create a library by using the compc compiler. You add files to a library by using the `include-classes` and `include-namespaces` options when you compile the SWC file.

The following example creates a library called CustomCellRenderer.swc with the compc compiler:

```
compc -source-path ../mycomponents/components/local
    -include-classes CustomCellRendererComponent
    -directory=true
    -debug=false
    -output ../libraries/CustomCellRenderer
```

The options on the command line can also be represented by settings in the flex-config.xml file, as the following example shows:

```
<?xml version="1.0">
<flex-config>
    <compiler>
        <source-path>
            <path-element>../mycomponents/components/local</path-element>
        </source-path>
    </compiler>
    <output>../libraries/CustomCellRenderer</output>
    <directory>true</directory>
    <debug>false</false>
    <include-classes>
        <class>CustomCellRendererComponent</class>
    </include-classes>
</flex-config>
```

All classes and components must be statically linked into the resulting library. When you use the compc compiler to create the library, do not use the `include-file` option to add files to the library, because this option does not statically link files into the library.

Optimizing libraries

Optimizing libraries means to remove debugging and other code from the library prior to deployment. For normal libraries that you are not using as RSLs, you do not need to optimize. This is because you will likely want to debug against the library during development, so you will need the debug code inside the library. And, when you compile the release version of your application, the compiler will exclude debug information as it links the classes from the library.

When you compile a library for production use as an RSL, however, you can set the `debug` compiler option to `false`. The default value is `true` for compc, which means that the compiler, by default, includes extra information in the SWC file to make it debuggable. You should avoid creating a debuggable library that you intend to use in production so that the RSL's files are as small as possible. If you set the value of the `debug` option to `false`, however, you will not be able to debug against the RSL for testing.

If you do include debugging information, you can still optimize the RSL after compiling it, which removes the debugging information as well as unnecessary metadata. For more information, see "Optimizing RSL SWF files" on page 273.

Before you deploy an RSL, you extract the SWF file that is inside the library SWC file and optimize it. The default name of this SWF file is library.swf. After you extract it from the SWC file, you can rename it to anything you want. When you deploy the RSL, you deploy the SWF file so that the application can load it at run time.

On the command line, you typically specify that the output of compiling a library be an open directory rather than a SWC file by using the `directory` option and the `output` option. The output is an open directory that contains the following files:

- catalog.xml
- library.swf

In addition, the library contains properties files and any images or other embedded assets that are used by the library.

If you do not specify that the output be an open directory, you must manually extract the library.swf file from the SWC file with a compression utility, such as PKZip.

In Flash Builder, you can instruct the compiler to automatically extract the SWF file for you when you add the RSL SWC file to the project. Doing this does not optimize the SWF file, so the library will be bigger than if you extract it yourself and optimize it.

To manually extract an RSL SWF file from its SWC file in Flash Builder, add the `output` and `directory` options to the Additional Compiler Arguments field in the Flex Compiler dialog box. In both cases, you specify the deployment location of the SWF file when you add the SWC file to your project as an RSL.

When creating a library, you need to know if you will be using the library as a standard RSL or as a cross-domain RSL. If you are using it as a cross-domain RSL, you must include the digest information in the library. For more information, see “About cross-domain RSLs” on page 268.

After you create the library, you then compile your application against the SWC file and specify the library’s SWF file’s location for use at run time. For more information, see “Compiling applications with standard and cross-domain RSLs” on page 270.

For more information on using the compc compiler options, see “Flex compilers” on page 2164.

Troubleshooting RSLs

RSLs can be complicated to create, use, and deploy. The following table describes common errors and techniques to resolve them:

Error	**Resolution**
`#1001 Digest mismatch with RSL`	This error indicates that the digest of a library does not match the RSL SWF file. When you compile an application that uses an RSL, you specify the library SWC file that the application uses for link checking at compile time and an RSL SWF file that the application loads at run time. The digest in the library’s catalog.xml file must match the digest of the RSL SWF file or you will get this error. If this error persists, recompile the application against the library SWC file again and redeploy the application’s SWF file. If you are using framework RSLs, then the SWZ file is a different version than what the application was compiled against. Check whether this is the case by adding a failover RSL SWF file and recompiling. If the error does not recur, then the SWZ file is out of sync. If you are creating an optimized RSL, be sure to run the digest tool against the library.swf file after you optimized the library.swf file.
`#2032` Stream Error	This error indicates that the SWZ or SWF file is not being found. The frequently occurs if the client is not able to download the signed framework RSL from the Adobe web site, and you have not deployed a local signed framework RSL. If the client has limited or not internet connectivity, be sure to deploy the local framework RSL to a location that is accessible to the client. For more information, see “Using the framework RSLs” on page 260. It can also occur if Flash Player tries to load a custom RSL that is not available. For example, if you specified only “mylib.swf” as the value of the `rsl-url` parameter to the `runtime-shared-library-path` option, but the SWF file is actually in a sub-directory such as /rsls, then you must either recompile your application and update the value of the `rsl-url` parameter to “rsls/mylib.swf”, or move mylib.swf to the same directory as the application’s SWF file.
`#2046`	This error indicates that the loaded RSL was not signed properly. In the case of framework RSLs, the framework’s SWZ file that the application attempted to load at run time was not a properly signed SWZ file. You must ensure that you deploy an Adobe-signed RSL, or be sure to use the signed framework RSLs that are deployed on the Adobe web site.

Error	**Resolution**

`#2048`	The cause of this error is that you do not have a crossdomain.xml file on the server that is returning the RSL. You should add a file to that server. For more information, see “Using cross-domain policy files” on page 125.
	If you are loading signed framework RSLs from the Adobe web site, you should not get this error.
	If you put the crossdomain.xml file at the server’s root, you do not have to recompile your application. This is because the application will look for that file at the server’s root by default, so there is no need to explicitly define its location.
	If you cannot store a crossdomain.xml file at the remote server’s root, but can put it in another location on that server, you must specify the file’s location when you compile the application. On the command line, you do this by setting the value of the `policy-file-url` argument of the `runtime-shared-library-path` option.
	In the following example, the RSL SWF file is located in the /rsls directory on www.domain.com. The crossdomain.xml file is located in the same directory, which is not the server’s root, so it must therefore be explicitly specified:
	`mxmlc -runtime-shared-library-path=   ../lib/mylib.swc,`
	`http://www.mydomain.com/rsls/myrsl.swf,`
	`http://www.mydomain.com/rsls/crossdomain.xml   Main.mxml`

`#2148`	This error occurs when you try to open an application that uses RSLs in the standalone player or in the browser by using the file system and not a server. It means that you are violating the security sandbox of Flash Player by trying to load file resources. You must deploy your application and RSLs to a network location, and request the application with a network request so that Flash Player will load the RSL. If you are testing the application locally, you can add the directory to your Player trust file to avoid this error.
`Requested resource not found`	You might find this error in your web server logs. If you deploy the RSL SWF file to a location other than that specified when you compiled the application, then you will get an error similar to this when the application tries to run. The solution is to either recompile your application and correct the deployment location of the RSL SWF file or to move the RSL SWF file to the location that the application expects.

Chapter 4: Building the user interface

Visual components

You use visual components to build Adobe® Flex® applications. Visual components have a flexible set of characteristics that let you control and configure them as necessary to meet your application's requirements.

About visual components

Flex includes a component-based development model that you use to develop your application and its user interface. You can use the prebuilt visual components included with Flex, extend components to add new properties and methods, and create components as required by your application.

Visual components are extremely flexible and provide you with a great deal of control over the component's appearance, how the component responds to user interactions, the font and size of any text included in the component, the size of the component in the application, and many other characteristics.

The characteristics of visual components include the following:

Size Height and width of a component. All visual components have a default size. You can use the default size, specify your own size, or let Flex resize a component as part of laying out your application.

Events Application or user actions that require a component response. Events include component creation, mouse actions such as moving the mouse over a component, and button clicks.

Styles Characteristics such as font, font size, and text alignment. These are the same styles that you define and use with Cascading Style Sheets (CSS).

Effects Visible or audible changes to the component triggered by an application or user action. Examples of effects are moving or resizing a component based on a mouse click.

Skins Classes that control a visual component's appearance.

Spark and MX components

Flex defines two sets of components: Spark and MX. The Spark components are new for Flex 4 and are defined in the spark.* packages. The MX components shipped in previous releases of Flex and are defined in the mx.* packages.

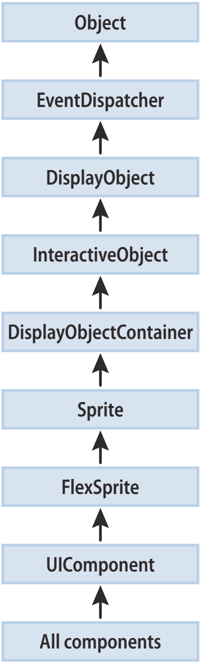
The main differences between Spark and MX components are how you use CSS styles with the components and how you skin them. For the container components, there are additional differences about how the containers perform layout.

Spark and MX define some of the same components. For example, Spark defines a button control in the spark.components package, and MX defines a button control in the mx.controls package. When a component is available in both Spark and MX, Adobe recommends that you use the Spark component.

Spark and MX also define components that are unique. For example, Spark defines components to perform three dimensional effects. MX defines data visualization components, such as the DataGrid and AdvancedDataGrid controls, not included in Spark. Your applications often contains a mixture of Spark and MX components.

Class hierarchy for visual components

Flex visual components are implemented as a class hierarchy in ActionScript. Therefore, each visual component in your application is an instance of an ActionScript class. The following image shows this hierarchy in detail up to the Object class:



All visual components are derived from the UIComponent class and its superclasses, the Flex Sprite through Object classes, and inherit the properties and methods of their superclasses. In addition, visual components inherit other characteristics of the superclasses, including event, style, and effect definitions.

Using the UIComponent class

The UIComponent class is the base class for all Flex visual components. For detailed documentation, see UIComponent in the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Commonly used UIComponent properties

The following table lists only the most commonly used properties of components that extend the UIComponent class:

Property	**Type**	**Description**
`doubleClickEnabled`	Boolean	Setting to `true` lets the component dispatch a `doubleClickEvent` when a user presses and releases the mouse button twice in rapid succession over the component.
`enabled`	Boolean	Setting to `true` lets the component accept keyboard focus and mouse input. The default value is `true`. If you set `enabled` to `false` for a container, Flex dims the color of the container and all of its children, and blocks user input to the container and to all its children.
`height`	Number	The height of the component, in pixels. In MXML tags, but not in ActionScript, you can set this property as a percentage of available space by specifying a value such as 70%; in ActionScript, you must use the `percentHeight` property. The property always returns a number of pixels. In ActionScript, you use the `perCent`
`id`	String	Specifies the component identifier. This value identifies the specific instance of the object and should not contain any white space or special characters. Each component in a Flex document must have a unique `id` value. For example, if you have two custom components, each component can include one, and only one Button control with the id "okButton".
`percentHeight`	Number	The height of the component as a percentage of its parent container, or for the Application container, the full height of the browser. Returns `NaN` if a percent-based width has never been set or if a `height` property was set after the `percentHeight` was set.
`percentWidth`	Number	The width of the component as a percentage of its parent container, or for the Application container, the full span of the browser. Returns `NaN` if a percent-based width has never been set or if a `width` property was set after the `percentWidth` was set.
`styleName`	String	Specifies the style class selector to apply to the component.
`toolTip`	String	Specifies the text string displayed when the mouse pointer hovers over that component.
`visible`	Boolean	Specifies whether the container is visible or invisible. The default value is `true`, which specifies that the container is visible.
`width`	Number	The width of the component, in pixels. In MXML tags, but not in ActionScript, you can set this property as a percentage of available space by specifying a value such as 70%; in ActionScript, you must use the `percentWidth` property. The property always returns a number of pixels.
`x`	Number	The component's ***x*** position within its parent container. Setting this property directly has an effect only if the parent container uses absolute positioning.
`y`	Number	The component's ***y*** position within its parent container. Setting this property directly has an effect only if the parent container uses absolute positioning.

Using components in MXML and ActionScript

Every Flex component has an MXML API and an ActionScript API. A component's MXML tag attributes are equivalent to its ActionScript properties, styles, effects, and events. You can use both MXML and ActionScript when working with components.

Configure a component

1. Set the value of a component property, event, style, or effect declaratively in an MXML tag, or at run time in ActionScript code.
2. Call a component's methods at run time in ActionScript code. The methods of an ActionScript class are not exposed in the MXML API.

The following example creates a Spark Button control in MXML. When the user clicks the Button control, it updates the text of a Spark TextArea control by using an ActionScript function.

```
<?xml version="1.0"?>
<!-- components\ButtonApp.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            public function handleClick():void {
                text1.text="Thanks for the click!";
            }
        ]]>
    </fx:Script>
    <s:Button id="button1"
        label="Click here!"
        width="100"
        fontSize="12"
        click="handleClick();"/>
    <s:TextArea id="text1"/>
</s:Application>
```

This example has the following elements:

- The `id` property is inherited by the Button control from the UIComponent class. You use it to specify an identifier for the component. This property is optional, but you must specify it if you want to access the component in ActionScript.
- The `label` property is defined by the Button control. It specifies the text that appears in the button.
- The `width` property is inherited from the UIComponent class. It optionally specifies the width of the button, in pixels.
- The Button control dispatches a `click` event when a user presses and releases the main mouse button. The MXML `click` attribute specifies the ActionScript code to execute in response to the event.
- The `fontSize` style is inherited from the UIComponent class. It specifies the font size of the label text, in pixels.

Note: *The numeric values specified for font size in Flex are actual character sizes in pixels. These values are not equivalent to the relative font size specified in HTML by using the `<font>` tag.*

The `click` event attribute can also take ActionScript code directly as its value, without your having to specify it in a function. Therefore, you can rewrite this example as the following code shows:

```
<?xml version="1.0"?>
<!-- components\ButtonAppAS.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:Button id="button1"
        label="Click here!"
        width="100"
        fontSize="12"
        click="text1.text='Thanks for the click!';"/>
    <s:TextArea id="text1"/>
</s:Application>
```

***Note:** Although you can specify multiple lines of ActionScript code (separated by semicolons) as the value of the `click` event attribute, for readability you should limit the `click` event to only one or two lines of code.*

Initializing components at run time

Flex uses MXML property attributes to initialize your components. However, you might want to use some logic to determine initial values at run time. For example, you might want to initialize a component with the current date or time. Flex must calculate this type of information when the application executes.

Every component dispatches several events during its life cycle. In particular, all components dispatch the following events that let you specify ActionScript to initialize a component:

preInitialize Dispatched when a component has been created in a rough state, and no children have been created.

initialize Dispatched when a component and all its children have been created, but before the component size has been determined.

creationComplete Dispatched when the component has been laid out and the component is visible (if appropriate).

You can use the `initialize` event to configure most component characteristics; in particular, use it to configure any value that affects the component's size. Use the `creationComplete` event if your initialization code must get information about the component layout.

The following example configures Flex to call the `initDate()` function when it initializes the Label control. When Flex finishes initializing the Label control, and before the application appears, Flex calls the `initDate()` function.

```
<?xml version="1.0"?>
<!-- components\LabelInit.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
            private function initDate():void {
                label1.text += new Date();
            }
        ]]>
    </fx:Script>
    <s:VGroup>
        <s:Label id="label1"
            text="Today's Date: "
            initialize="initDate();"/>
    </s:VGroup>
</s:Application>
```

You can also express the previous example without a function call by adding the ActionScript code in the component's definition. The following example does the same thing, but without an explicit function call:

```
<?xml version="1.0"?>
<!-- components\LabelInitAS.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:VGroup>
        <s:Label id="label1"
            text="Today's Date:"
            initialize="label1.text += new Date();"/>
    </s:VGroup>
</s:Application>
```

As with other calls that are embedded within component definitions, you can add multiple ActionScript statements to the `initialize` MXML attribute by separating each function or method call with a semicolon. The following example calls the `initDate()` function and writes a message in the flexlog.txt file when the `label1` component is instantiated:

```
<?xml version="1.0"?>
<!-- components\LabelInitASAndEvent.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
            private function initDate():void {
                label1.text += new Date();
            }
        ]]>
    </fx:Script>
    <s:VGroup>
        <s:Label id="label1"
            text="Today's Date:"
            initialize="initDate(); trace('The label is initialized!');"/>
    </s:VGroup>
</s:Application>
```

By default, on Microsoft Windows, the flexlog.txt file is written to C:\Documents and Settings\USERNAME\Application Data\Macromedia\Flash Player\Logs. For the location of this file on other operating systems, see “Editing the mm.cfg file” on page 2224.

Configuring components: syntax summary

The following table summarizes the MXML and ActionScript component APIs that you use to configure components:

	MXML example	**ActionScript example**

Read-write property	`<s:Panel id="p1" title="My Title"`
	`visible="true"/>`
		`p1.title="My Title";`
		`tile1.visible=true;`

Read-only property	You cannot use a read-only property as an attribute in MXML.	To get the value of a read-only property: `var theClass:String=mp1.className;`
Method	Methods are not available in MXML.	`myList.sortItemsBy("data", "DESC");`

Event	`<mx:Accordion id="myAcc"`
	`change="changeHandler (event);"/>`
	You must also define a `changeHandler()` function as shown in the ActionScript example.
		`private function changeHandler(event:MouseEvent):void`
		`{...}`
		`myButton.addEventListener("click", changeHandler);`

Style	`<s:Panel id="p1"`
	`borderAlpha="0.5"`
	`borderColor="blue"/>`
		To set the style:
		`p1.setStyle("borderAlpha", 0.5);`
		`p1.setStyle("borderColor", 'blue');`
		To get the style:
		`var currentBorderAlpha:Number =`
		`p1.getStyle("borderAlpha");.`

Effect	`<s:Panel id="p1"`
	`show="scale.end();scale.play();"/>`
		Call the effect’s `end()` and `play()` methods in an event handler:.

Sizing visual components

The Flex sizing and layout mechanisms provide several ways for you to control the size of visual components:

Default sizing Automatically determines the sizes of controls and containers. To use default sizing, you do not specify the component’s dimensions or layout constraints.

Explicit sizing You set the `height` and `width` properties to pixel values. When you do this, you set the component dimension to absolute sizes, and Flex does not override these values. The following `<s:Application>` tag, for example, sets explicit Application dimensions:

```
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    height="300"
    width="600">
```

Percentage-based sizing You specify the component size as a percentage of its container size. To do this, you specify the `percentHeight` and `percentWidth` properties, or, in an MXML tag, set the `height` and `width` properties to percentage values such as 100%. The following code, for example, sets percentage-based dimensions for an HGroup container:

```
<s:HGroup id="hGroup1"
    height="30%" width="90%"/>
```

The following ActionScript line resets the HGroup width to a different percentage value:

```
hGroup1.percentWidth=40;
```

Constraint-based layout You can control size *and* position by anchoring components sides, centers, or baselines to locations in their container by specifying the `top`, `bottom`, `left`, `right`, `baseline`, `horizontalCenter`, and `verticalCenter` styles. You can use constraint-based layout only for the children of a container that uses absolute layout. That includes all Spark containers and the MX Application, Panel, and Canvas containers. The following example uses constraint-based layout to position an HGroup horizontally, and explicit sizing and positioning to determine the vertical width and position:

```
<s:HGroup id="hGroup2"
    left="30"right="30"
    y="150"
    height="100"/>
```

You can mix sizing techniques; however, you must ensure that the mix is appropriate. Do not specify more than one type of sizing for a component dimension; for example, do not specify a `height` and a `percentHeight` for a component. Also, ensure that the resulting sizes are appropriate; for example, if you do not want scroll bars or clipped components, ensure that the sizes of a container's children do not exceed the container size.

For detailed information on how Flex sizes components, and how you can specify sizing, see "Laying out components" on page 359.

Examples of component sizing

The following example shows sizing within an explicitly sized container when some of the container's child controls are specified with explicit widths and some with percentage-based widths. It shows the flexibility and the complexities involved in determining component sizes. The application logs the component sizes to flashlog.txt, so you can confirm the sizing effect.

```
<?xml version="1.0"?>
<!-- components\CompSizing.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    creationComplete="logSizes();">
    <fx:Script>
        <![CDATA[
            private function logSizes():void {
                trace("HGroup: "+ hb1.width);
                trace("Label: "+ lb1.width);
                trace("Image: "+ img1.width);
                trace("Button: "+ b1.width);
            }
        ]]>
    </fx:Script>
    <s:HGroup id="hb1" width="250">
        <s:Label id="lb1"
            text="Hello"
            width="50"/>
        <mx:Image id="img1"
            source="@Embed(source='assets/flexlogo.jpg')"
            width="75%"/>
        <s:Button id="b1"
            label="Button"
            width="25%"/>
    </s:HGroup>
</s:Application>
```

The application consists of a 250-pixel-wide HGroup container that contains a 50-pixel-wide label, an image that requests 75% of the container width, and a button that requests 25% of the container width. The component sizes are determined as follows:

1 Flex reserves 50 pixels for the explicitly sized Label control.

2 Flex puts an 6-pixel gap between components in an HGroup container by default, so it reserves 12 pixels for the gaps; this leaves 188 pixels available for the two percentage-based components.

3 The minimum width of the Button component, if you do not specify an explicit width, fits the label text plus padding around it. In this case, the minimum size is 70 pixels. However, since you specified the width as 25%, Flex reserves 25% of the available 188 pixels, or 47 pixels, for the Button control.

4 The percentage-based image requests 75% of 188 pixels, or 141 pixels.

If you change the button and image `size` properties to 50%, each get 50% of the available space, or 94 pixels.

The following example uses explicit sizing for the Image control and default sizing for the Button control:

```
<?xml version="1.0"?>
<!-- components\CompSizingExplicit.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    creationComplete="logSizes();">
    <fx:Script>
        <![CDATA[
            private function logSizes():void {
                trace("HGroup: "+ hb1.width);
                trace("Label: "+ lb1.width);
                trace("Image: "+ img1.width);
                trace("Button: "+ b1.width);
            }
        ]]>
    </fx:Script>
    <s:HGroup id="hb1" width="250">
        <s:Label id="lb1"
            text="Hello"
            width="50"/>
        <mx:Image id="img1"
            source="@Embed(source='assets/flexlogo.jpg')"
            width="119" />
        <s:Button id="b1"
            label="Button"/>
    </s:HGroup>
</s:Application>
```

Percentage-based sizing removes the need to explicitly consider the gaps and margins of a container in sizing calculations, but its greatest benefit applies when containers resize. Then, the percentage-based children resize automatically based on the available container size. In the following example, the series of controls on the left resize as you resize your browser, but the corresponding controls on the right remain a fixed size because their container is fixed. Click the first Button control to log the component sizes to flashlog.txt.

```
<?xml version="1.0"?>
<!-- components\CompSizingPercent.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
            private function logSizes():void {
                trace("HGroup: "+ hb1.width);
                trace("Label: "+ lb1.width);
                trace("Image: "+ img1.width);
                trace("Button: "+ b1.width);
            }
        ]]>
    </fx:Script>
    <s:HGroup width="100%">
        <s:HGroup id="hb1" width="40%">
            <s:Label id="lb1"
                text="Hello"
                width="50"/>
            <mx:Image id="img1"
                source="@Embed(source='assets/flexlogo.jpg')"
                width="60%"/>
            <s:Button id="b1"
                label="Button"
                width="40%"
                click="logSizes();"/>
        </s:HGroup>

        <s:HGroup width="260">
            <s:Label
                text="Hello"
                width="50"/>
            <mx:Image
                source="@Embed(source='assets/flexlogo.jpg')"
                width="119" />
            <s:Button
                label="Button"/>
        </s:HGroup>
    </s:HGroup>
</s:Application>
```

For more information about sizing considerations, see “Sizing components” on page 365.

Handling events

Flex applications are event driven. *Events* let a programmer know when the user has interacted with an interface component, and also when important changes have happened in the appearance or life cycle of a component, such as the creation or destruction of a component or its resizing.

When an instance of a component dispatches an event, objects that have registered as *listeners* for that event are notified. You define event listeners, also called event *handlers*, in ActionScript to process events. You register event listeners for events either in the MXML declaration for the component or in ActionScript. For additional examples of the event handling, see “Using components in MXML and ActionScript” on page 282.

The following example registers an event listener in MXML that is processed when you change views in an Accordion container.

```
<?xml version="1.0"?>
<!-- components\CompIntroEvent.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    width="300"
    height="280">
    <fx:Script>
        <![CDATA[
            import mx.controls.Alert;
            private function handleAccChange():void {
                Alert.show("You just changed views.");
            }
        ]]>
    </fx:Script>
    <!-- The Accordion container dispatches a change event when the
            selected child container changes. -->
    <mx:Accordion id="myAcc"
        height="60"
        width="200"
        change="handleAccChange();">
        <s:NavigatorContent label="Box 1">
            <s:Label text="This is one view."/>
        </s:NavigatorContent>
        <s:NavigatorContent label="Box 2">
            <s:Label text="This is another view."/>
        </s:NavigatorContent>
    </mx:Accordion>
</s:Application>
```

You can pass an event object, which contains information about the event, from the component to the event listener.

For the Accordion container, the event object passed to the event listener for the `change` event is of class IndexChangedEvent. You can write your event listener to access the event object, as the following example shows:

```
<?xml version="1.0"?>
<!-- components\CompIntroEventAcc.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    width="300"
    height="280">
    <fx:Script>
        <![CDATA[
            // Import the class that defines the event object.
            import mx.events.IndexChangedEvent;
            import mx.controls.Alert;

            private function handleChange(event:IndexChangedEvent):void {
                var currentIndex:int=event.newIndex;
                Alert.show("You just changed views.\nThe new index is "
                    + event.newIndex + ".");
            }
        ]]>
    </fx:Script>
    <!-- The Accordion control dispatches a change event when the
            selected child container changes. -->
    <mx:Accordion id="myAcc"
        height="60"
        width="200"
        change="handleChange(event);">
        <s:NavigatorContent label="Box 1">
            <s:Label text="This is one view."/>
        </s:NavigatorContent>
        <s:NavigatorContent label="Box 2">
            <s:Label text="This is another view."/>
        </s:NavigatorContent>
    </mx:Accordion>
</s:Application>
```

In this example, you access the `newIndex` property of the IndexChangedEvent object to determine the index of the new child of the Accordion container. For more information on events, see “Events” on page 54.

About the component instantiation life cycle

The component instantiation life cycle describes the sequence of steps that occur when you create a component object from a component class. As part of that life cycle, Flex automatically calls component methods, dispatches events, and makes the component visible.

The following example creates a Button control in ActionScript and adds it to a Group container:

```
// Create a Group container.
var groupContainer:Group = new Group();
// Configure the Group container.
groupContainer.x = 10;
groupContainer.y = 10;

// Create a Button control.
var b:Button = new Button()
// Configure the button control.
b.label = "Submit";
...
// Add the Button control to the Box container.
groupContainer.addElement(b);
```

The following steps show what occurs when you execute the code to create the Button control, and add the control to the container:

1 You call the component's constructor, as the following code shows:

   ```
   // Create a Button control.
   var b:Button = new Button()
   ```

2 You configure the component by setting its properties, as the following code shows:

   ```
   // Configure the button control.
   b.label = "Submit";
   ```

3 You call the `addElement()` method to add the component to its parent, as the following code shows:

   ```
   // Add the Button control to the Box container.
   groupContainer.addElement(b);
   ```

   Flex then performs the following actions:

4 Sets the `parent` property for the component to reference its parent container.

5 Computes the style settings for the component.

6 Dispatches the `preinitialize` event on the component. The component is in a very raw state when this event is dispatched. Many components, such as the Button control, create internal child components to implement functionality. When Flex dispatches the `preinitialize` event, the children (including the internal children, of a component) have not yet been created.

7 Dispatches the `initialize` event on the component. At this time, all of the component's children are initialized, but the component has not been sized or processed for layout. You can use this event to perform additional processing of the component before it is laid out.

   Because the `initialize` event is dispatched early in the component's startup sequence, make sure that none of your processing causes the component to invalidate itself. You typically perform any final processing during the `creationComplete` event.

8 Dispatches the `childAdd` event on the parent container.

9 Dispatches the `initialize` event on the parent container.

10 To display the application, a `render` event gets triggered, and Flex does the following:

   a Flex completes all processing required to display the component, including laying out the component.

   b Makes the component visible by setting the `visible` property to `true`.

   c Dispatches the `creationComplete` event on the component. The component is sized and processed for layout. This event is only dispatched once when the component is created.

d Dispatches the `updateComplete` event on the component. Flex dispatches additional `updateComplete` events whenever the layout, position, size, or other visual characteristic of the component changes and the component is updated for display.

You can later remove a component from a container by using the `removeElement()` method. The removed child's `parent` property is set to `null`. If you add the removed child to another container, it retains its last known state. If there are no references to the component, it is eventually deleted from memory by the garbage collection mechanism of Adobe® Flash® Player.

Given this sequence of actions, you should use the events as follows:

- The `preinitialize` event occurs too early in the component life cycle for most initialization activities. It is useful, however, in the rare situations where you must set the properties on a parent before the children are created.
- To configure a component before Flex has determined its visual appearance, use the `initialize` event. For example, use this for setting properties that affect its appearance, height, or width.
- Use the `creationComplete` event for actions that rely on accurate values for the component's size or position when the component is created. If you use this event to perform an action that changes the visual appearance of the component, Flex must recalculate its layout, which adds unnecessary processing overhead to your application.
- Use the `updateComplete` event for actions that must be performed each time a component's characteristics change, not just when the component is created.

Applying styles

Flex defines styles for setting some of the characteristics of components, such as fonts, padding, and alignment. These are the same styles as those defined and used with Cascading Style Sheets (CSS). Each visual component inherits many of the styles of its superclasses, and can define its own styles. Some styles in a superclass might not be used in a subclass. To determine the styles that a visual component supports, see the styles section of the page for the component in the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

You can set all styles in MXML as tag attributes. Therefore, you can set the styles of a BorderContainer container and its contents by using the `borderStyle` and `borderColor` properties, as the following example shows:

```
<?xml version="1.0"?>
<!-- components\MXMLStyles.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:BorderContainer id="myBC1"
        borderStyle="solid">
        <s:Button label="Submit"/>
    </s:BorderContainer>
    <s:BorderContainer id="myBC2"
        borderStyle="solid"
        borderColor="red">
        <s:Button label="Submit"/>
    </s:BorderContainer>
</s:Application>
```

You can also configure styles in ActionScript by using the `setStyle()` method, or in MXML by using the `<fx:Style>` tag. The `setStyle()` method takes two arguments: the style name and the value. The following example is functionally identical to the previous example:

```
<?xml version="1.0"?>
<!-- components\ComponentsASStyles.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            private function initBC():void {
                myBC2.setStyle("borderColor", "red");
            }
        ]]>
    </fx:Script>
    <s:BorderContainer id="myBC1"
        borderStyle="solid">
        <mx:Button label="Submit"/>
    </s:BorderContainer>
    <s:BorderContainer id="myBC2"
        borderStyle="solid"
        initialize="initBC();">
        <mx:Button label="Submit"/>
    </s:BorderContainer>
</s:Application>
```

When you use the `<fx:Style>` tag, you set the styles by using CSS syntax or a reference to an external file that contains style declarations, as the following example shows:

```
<?xml version="1.0"?>
<!-- components\TagStyles.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Style>
        .myStyle {borderColor: red;}
    </fx:Style>
    <s:BorderContainer id="myBC1"
        borderStyle="solid">
        <mx:Button label="Submit"/>
    </s:BorderContainer>
    <s:BorderContainer id="myBC2"
        borderStyle="solid"
        styleName="myStyle">
        <mx:Button label="Submit"/>
    </s:BorderContainer>
</s:Application>
```

A *class selector* in a style definition, defined as a label preceded by a period, defines a new named style, such as `myStyle` in the preceding example. After you define it, you can apply the style to any component by using the `styleName` property. In the preceding example, you apply the style to the second BorderContainer container.

A *type selector* applies a style to all instances of a particular component type. The following example defines the top and bottom margins for all BorderContainer containers:

```
<?xml version="1.0"?>
<!-- components\TypeSelStyles.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Style>
        @namespace s "library://ns.adobe.com/flex/spark";
        s|BorderContainer {borderColor: red;}
    </fx:Style>
    <s:BorderContainer id="myBC1"
        borderStyle="solid">
        <mx:Button label="Submit"/>
    </s:BorderContainer>
    <s:BorderContainer id="myBC2"
        borderStyle="solid">
        <mx:Button label="Submit"/>
    </s:BorderContainer>
</s:Application>
```

In Flex, some, but not all, styles are inherited from parent containers to their children and across style types and classes. Because the `borderStyle` style is not inherited, this example yields results that are identical to the previous examples.

Some Spark and MX components share the same local name. For example, there is a Spark Button component (in the spark.components.* package) and a MX Button component (in the mx.controls.* package). To distinguish between different components that share the same name, you specify namespaces in your CSS that apply to types. The preceding example defines the MX s namespace and uses "`s`" as an identifier:

For more information on styles, see "Styles and themes" on page 1492.

Applying effects

An *effect* is a visible or audible change to the component that occurs over a period of time, measured in milliseconds. Examples of effects are fading, resizing, or moving a component.

Effects let you add animation, motion, and sound to your application in response to some user or programmatic action. For example, you can use effects to cause a dialog box to bounce slightly when it receives focus, or to play a sound when the user enters an invalid value.

To create the effect, you define a specific effect with a unique ID in an `<fx:Declarations>` tag. The following example uses two Resize effects for a Button control. One Resize effect expands the size of the button by 10 pixels when the user clicks down on the button, and the second resizes it back to its original size when the user releases the mouse button.

```
<?xml version="1.0"?>
<!-- components\CompIntroBehaviors.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Declarations>
        <s:Resize id="myResizeEffectUp"
            target="{myImage}"
            widthBy="10" heightBy="10"/>
        <s:Resize id="myResizeEffectDown"
            target="{myImage}"
            widthBy="-10" heightBy="-10"/>
    </fx:Declarations>
    <mx:Image id="myImage"
        source="@Embed(source='assets/flexlogo.jpg')"/>
    <s:Button label="Resize Me Up"
        click="myResizeEffectUp.end();myResizeEffectUp.play();"/>
    <s:Button label="Resize Me Down"
        click="myResizeEffectDown.end();myResizeEffectDown.play();"/>
</s:Application>
```

For detailed information on using effects, see “Introduction to effects” on page 1784.

Applying skins

Skins are classes that a component uses to control its appearance. These classes are typically written in MXML and are applied to a component by using the skinClass style property. Skin classes can include embedded images or other media, FXG, ActionScript, and any visual component in them.

When creating custom skins, you can use the component’s default skin as a basis for writing your new skin, or the provided Wireframe skins that are simpler.

Skin classes have a contract with a component that enforces certain rules that the skin class and its host component must follow. For example, if a component uses states (such as “mouseOver” or “mouseDown”), the skin class must define the appearance of these states. If a component uses subcomponents (such as a down or up arrow on a slider), the skin class must define these as skin parts.

Typically, a skin class will define a `hostComponent` property so that is can get a reference to the component that uses it. This is not required by the skinning contract but is recommended. Skin classes can also share data with their host component by using data binding.

All components that are subclasses of SkinnableComponent class can have a skin class. Many containers cannot be skinned, however. Only containers that are subclasses of SkinnableContainer can be skinned.

Spark skins can be loaded and unloaded at run time, and their properties can be bound to the style properties of the host component.

For more information on skinning, see “Skinning MX components” on page 1655.

Changing the appearance of a component at run time

You can modify the look, size, or position of a component at run time by using several component properties, styles, or ActionScript methods, including the following:

- `x` and `y`
- `width` and `height`
- styles, by using `setStyle(stylename,value)`

You can set the `x` and `y` properties of a component only when the component is in a container that uses absolute positioning; that is, in a Canvas container, or in an Application or Panel container that has the `layout` property set to `absolute`. All other containers perform automatic layout to set the `x` and `y` properties of their children by using layout rules.

For example, you could use the `x` and `y` properties to reposition a Button control 15 pixels to the right and 15 pixels down in response to a Button control click, as the following example shows:

```
<?xml version="1.0"?>
<!-- components\ButtonMove.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    width="150"
    height="120">
    <fx:Script>
        <![CDATA[
            public function moveButton():void {
                myButton.x += 15;
                myButton.y += 15;
            }
        ]]>
    </fx:Script>
    <s:Button id="myButton"
        x="15"
        y="15"
        label="Move"
        click="moveButton();"/>
</s:Application>
```

In this application, you can move the Button control without concern for other components. However, moving a component in an application that contains multiple components, or modifying one child of a container that contains multiple children, can cause one component to overlap another, or in some other way affect the layout of the application. Therefore, you should be careful when you perform run-time modifications to container layout.

You can set the `width` and `height` properties for a component in any type of container. The following example increases the `width` and `height` of a Button control by 15 pixels each time the user selects it:

```
<?xml version="1.0"?>
<!-- components\ButtonSize.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    width="150"
    height="150">
    <fx:Script>
        <![CDATA[
            public function resizeButton():void {
                myButton.height = myButton.height + 15;
                myButton.width = myButton.width + 15;
            }
        ]]>
    </fx:Script>
    <s:BorderContainer
        height="80"
        width="100">
        <s:Button id="myButton"
            label="Resize"
            click="resizeButton();"/>
    </s:BorderContainer>
</s:Application>
```

If the container that holds the Button does not use absolute positioning, it repositions its children based on the new size of the Button control.

***Note:** The stored values of `width` and `height` are always in pixels regardless of whether the values were originally set as fixed values, as percentages, or not set at all.*

Extending components

Flex provides several ways for you to extend existing components or to create components. By extending a component, you can add new properties or methods to it.

For example, the following MXML component, defined in the file MyComboBox.mxml, extends the standard Spark ComboBox control to initialize it with the postal abbreviations of the states in New England:

```
<?xml version="1.0"?>
<!-- components\myComponents\MyComboBox.mxml -->
<s:ComboBox xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:dataProvider>
        <mx:ArrayList>
            <fx:String>CT</fx:String>
            <fx:String>MA</fx:String>
            <fx:String>ME</fx:String>
            <fx:String>NH</fx:String>
            <fx:String>RI</fx:String>
            <fx:String>VT</fx:String>
        </mx:ArrayList>
    </s:dataProvider>
</s:ComboBox>
```

After you create it, you can use your new component anywhere in your application by specifying its filename as its MXML tag name, as the following example shows:

```
<?xml version="1.0"?>
<!-- components\MainMyComboBox.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComps="myComponents.*"
    width="150"
    height="150">
    <MyComps:MyComboBox id="stateNames"/>
</s:Application>
```

In this example, the new component is in the myComponents subdirectory. The myComponents.* namespace is mapped to the MyComps identifier.

Flex lets you create custom components by using either of the following methods. The method you choose depends on your application and the requirements of your component:

- Create components as MXML files and use them as custom tags in other MXML files. MXML components provide an easy way to extend an existing component, particularly to modify the behavior of an existing component or add a basic feature to an existing component.
- Create components as ActionScript files by subclassing the UIComponent class or any of its subclasses, and use the resulting classes as custom tags. ActionScript components provide a powerful tool for creating new visual or nonvisual components.

For detailed information on creating custom components, see *"Custom Flex components" on page 2356* .

Data binding

Data binding lets you pass data between client-side objects in an Adobe® Flex™ application. Binding automatically copies the value of a property of a source object to a property of a destination object when the source property changes.

About data binding

Data binding is the process of tying the data in one object to another object. It provides a convenient way to pass data between the different layers of the application. Data binding requires a source property, a destination property, and a triggering event that indicates when to copy the data from the source to the destination. An object dispatches the triggering event when the source property changes.

Adobe Flex provides three ways to specify data binding: the curly braces ({}) syntax in MXML, the <fx:Binding> tag in MXML, and the BindingUtils methods in ActionScript. The following example uses the curly braces ({}) syntax to show a Label control that gets its data from a TextInput control's `text` property:

```
<?xml version="1.0"?>
<!-- binding/BasicBinding.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:TextInput id="myTI" text="Enter text here"/>
    <s:Label id="myText" text="{myTI.text}"/>
</s:Application>
```

The property name inside the curly braces is the source property of the binding expression. When the value of the source property changes, Flex copies the current value of the source property, `myTI.text`, to the destination property, the Label control's `text` property.

You can include ActionScript code and E4X expressions as part of the data binding expressions, as the following example shows:

```
<?xml version="1.0"?>
<!-- binding/BasicBindingWithAS.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:TextInput id="myTI"/>
    <s:Label id="myText" text="{myTI.text.toUpperCase()}"/>
</s:Application>
```

In this example, you use the ActionScript method `String.toUpperCase()` to convert the text in the source property to upper case when Flex copies it to the destination property. For more information, see "Using ActionScript in data binding expressions" on page 313 and "Using an E4X expression in a data binding expression" on page 316.

You can use the <fx:Binding> tag as an alternative to the curly braces syntax. When you use the `<fx:Binding>` tag, you provide a source property in the `<fx:Binding>` tag's `source` property and a destination property in its `destination` property. The following example uses the `<fx:Binding>` tag to define a data binding from a TextInput control to a Label control:

```
<?xml version="1.0"?>
<!-- binding/BasicBindingMXML.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Binding source="myTI.text" destination="myText.text"/>
    <s:TextInput id="myTI"/>
    <s:Label id="myText"/>
</s:Application>
```

In contrast to the curly braces syntax, you can use the `<fx:Binding>` tag to completely separate the view (user interface) from the model. The `<fx:Binding>` tag also lets you bind multiple source properties to the same destination property because you can specify multiple `<fx:Binding>` tags with the same destination. For an example, see "Binding more than one source property to a destination property" on page 305.

The curly braces syntax and the `<fx:Binding>` tag both define a data binding at compile time. You can also use ActionScript code to define a data binding at run time, as the following example shows:

```
<?xml version="1.0"?>
<!-- binding/BasicBindingAS.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
      <![CDATA[
        import mx.binding.utils.*;
        // Define data binding.
        public function initBindingHandler():void {
            BindingUtils.bindProperty(myText, "text", myTI, "text");
        }
      ]]>
    </fx:Script>
    <s:TextInput id="myTI"/>
    <s:Label id="myText" preinitialize="initBindingHandler();"/>
</s:Application>
```

In this example, you use the static `BindingUtils.bindProperty()` method to define the binding. You can also use the `BindingUtils.bindSetter()` method to define a binding to a function. For more information, see “Defining data bindings in ActionScript” on page 318.

Notice in this example that you use the `preinitialize` event to define the data binding. This is necessary because Flex triggers all data bindings at application startup when the source object dispatches the `initialize` event. For more information, see “When data binding occurs” on page 301.

When data binding occurs

Binding occurs under the following circumstances:

1 The binding source dispatches an event because the source has been modified.

   This event can occur at any time during application execution. The event triggers Flex to copy the value of the source property to the destination property.

2 At application startup when the source object dispatches the `initialize` event.

   All data bindings are triggered once at application startup to initialize the destination property.

To monitor data binding, you can define a binding watcher that triggers an event handler when a data binding occurs. For more information, see “Defining binding watchers” on page 320.

The `executeBindings()` method of the UIComponent class executes all the bindings for which a UIComponent object is the destination. All containers and controls, as well as the Repeater component, extend the UIComponent class. The `executeChildBindings()` method of the Container and Repeater classes executes all of the bindings for which the child UIComponent components of a Container or Repeater class are destinations. All containers extend the Container class.

These methods give you a way to execute bindings that do not occur as expected. By adding one line of code, such as a call to the `executeChildBindings()` method, you can update the user interface after making a change that does not cause bindings to execute. However, you should only use the `executeBindings()` method when you are sure that bindings do not execute automatically.

Properties that support data binding

You can use all properties of an object as the destination of a data binding expression. However, to use a property as the source of a data binding expression, the source object must be implemented to support data binding, which means that the object dispatches an event when the value of the property changes to trigger the binding. In this topic, a property that can be used as the source of a data-binding expression is referred to as a *bindable* property.

In the *ActionScript 3.0 Reference for the Adobe Flash Platform*, a property that can be used as the source of a data binding expression includes the following statement in its description:

“This property can be used as the source for data binding.”

Using read-only properties as the source for data binding

You can use a read-only property defined by a getter method, which means no setter method, as the source for a data-binding expression. Flex performs the data binding once when the application starts.

Using static properties as the source for data binding

You can automatically use a static constant as the source for a data-binding expression. Flex performs the data binding once when the application starts.

You can use a static variable as the source for a data-binding expression. Flex performs the data binding once when the application starts.

Creating properties to use as the source for data binding

When you create a property that you want to use as the source of a data binding expression, Flex can automatically copy the value of the source property to any destination property when the source property changes. To signal to Flex to perform the copy, you must use the `[Bindable]` data tag to register the property with Flex.

The `[Bindable]` metadata tag has the following syntax:

```
[Bindable]
[Bindable(event="eventname")]
```

You can optionally omit the `event` keyword, and specify the tag as shown below:

```
[Bindable("eventname")]
```

If you omit the event name, Flex automatically creates an event named `propertyChange`, and Flex dispatches that event when the property changes to trigger any data bindings that use the property as a data-binding source. If you specify the event name, it is your responsibility to dispatch the event when the source property changes. For more information and examples of using the `[Bindable]` metadata tag, see “Using the Bindable metadata tag” on page 320.

The following example makes the `maxFontSize` and `minFontSize` properties that you defined as variables usable as the sources for data bindings expressions:

```
<?xml version="1.0"?>
<!-- binding/FontPropertyBinding.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            // Define public vars for tracking font size.
            [Bindable]
            public var maxFontSize:Number = 15;
            [Bindable]
            public var minFontSize:Number = 5;
        ]]>
    </fx:Script>

    <s:Label text="{maxFontSize}"/>
    <s:Label text="{minFontSize}"/>
    <s:Button click="maxFontSize=20; minFontSize=10;"/>
</s:Application>
```

When you click the Button control, you update the values of the `maxFontSize` and `minFontSize` properties, and trigger a data binding update to the Label controls.

***Note:** If you omit the `[Bindable]` metadata tag, the compiler issues a warning stating that the data binding mechanism cannot detect changes to the property. For more information, see "Using the Bindable metadata tag" on page 320.*

Data binding uses

Common uses of data binding include the following:

- To bind properties of user interface controls to other user interface controls.
- To bind properties of user interface controls to a middle-tier data model, and to bind that data model's fields bound to a data service request (a three-tier system).
- To bind properties of user interface controls to data service requests.
- To bind data service results to properties of user interface controls.
- To bind data service results to a middle-tier data model, and to bind that data model's fields to user interface controls. For more information about data models, see "Storing data" on page 889.
- To bind an ArrayCollection or XMLListCollection object to the `dataProvider` property of a List-based control.
- To bind individual parts of complex properties to properties of user interface controls. An example would be a master-detail scenario in which clicking an item in a List control displays data in several other controls.
- To bind XML data to user interface controls by using ECMAScript for XML (E4X) expressions in binding expressions.

Although binding is a powerful mechanism, it is not appropriate for all situations. For example, for a complex user interface in which individual pieces must be updated based on strict timing, it would be preferable to use a method that assigns properties in order. Also, binding executes every time a property changes, so it is not the best solution when you want changes to be noticed only some of the time.

Data binding examples

Using data binding with data models

In the following example, a set of UI control properties act as the binding source for a data model. For more information about data models, see “Storing data” on page 889.

```
<?xml version="1.0"?>
<!-- binding/BindingBraces.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Declarations>
        <!-- Data model stores registration data that user enters. -->
        <fx:Model id="reg">
            <registration>
                <name>{fullname.text}</name>
                <email>{email.text}</email>
                <phone>{phone.text}</phone>
                <zip>{zip.text}</zip>
                <ssn>{ssn.text}</ssn>
            </registration>
        </fx:Model>
    </fx:Declarations>
    <!-- Form contains user input controls. -->
    <s:Form>
        <s:FormItem label="Name" required="true">
            <s:TextInput id="fullname" width="200"/>
        </s:FormItem>
        <s:FormItem label="Email" required="true">
            <s:TextInput id="email" width="200"/>
        </s:FormItem>
        <s:FormItem label="Phone" required="true">
            <s:TextInput id="phone" width="200"/>
        </s:FormItem>
        <s:FormItem label="Zip" required="true">
            <s:TextInput id="zip" width="60"/>
        </s:FormItem>
        <s:FormItem label="Social Security" required="true">
            <s:TextInput id="ssn" width="200"/>
        </s:FormItem>
    </s:Form>
</s:Application>
```

Binding a source property to more than one destination property

You can bind a single source property to more than one destination property by using the curly braces ({}) syntax, the <fx:Binding> tag, or the `BindingUtils`methods in ActionScript. In the following example, a TextInput control’s `text` property is bound to properties of two data models, and the data model properties are bound to the `text` properties of two Label controls.

```
<?xml version="1.0"?>
<!-- binding/BindMultDestinations.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Declarations>
        <fx:Model id="mod1">
            <data>
                <part>{input1.text}</part>
            </data>
        </fx:Model>
        <fx:Model id="mod2">
            <data>
                <part>{input1.text}</part>
            </data>
        </fx:Model>
    </fx:Declarations>
    <s:TextInput id="input1" text="Hello" />
    <s:Label text="{mod1.part}"/>
    <s:Label text="{mod2.part}"/>
</s:Application>
```

Binding more than one source property to a destination property

You can bind more than one source property to the same destination property. You can set up one of these bindings by using curly braces, but you must set up the others by using the `<fx:Binding>` tag, or by using calls to the `BindingUtils.bindProperty()` method or to the `BindingUtils.bindSetter()` method.

In the following example, the TextArea control is the binding destination, and both `input1.text` and `input2.text` are its binding sources:

```
<?xml version="1.0"?>
<!-- binding/BindMultSources.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Binding source="input2.text" destination="myTA.text"/>
    <s:TextInput id="input1"/>
    <s:TextInput id="input2"/>

    <s:TextArea id="myTA" text="{input1.text}"/>
</s:Application>
```

If `input1.text` or `input2.text` is updated, the TextArea control contains the updated value.

Defining bidirectional bindings

Bidirectional, or two-way, data binding occurs when two objects act as the source and the destination for each other. When you modify the source property of either object, the destination property of the other object is updated.

Define a bidirectional data binding using one of the following methods:

1 Define two objects that specify as the source a property of the other object. In the following example, input1 specifies input2.text as the source property, and input2 specifies input1.text as the source property. Any change to input1.text updates input2.text, and any change to input2.text updates input1.text:

```
<!-- Specify data binding for both controls. -->
<s:TextInput id="input1" text="{input2.text}"/>
<s:TextInput id="input2" text="{input1.text}"/>
```

2 Use the `@{bindable_property}` syntax for one source property, as the following example shows:

```
<!-- Specify data binding for both controls. -->
<s:TextInput id="input1" text="@{input2.text}"/>
<s:TextInput id="input2"/>
```

***Note:** The property definition that includes the `@{bindable_property}` syntax is called the primary property. If the primary property has not had a value assigned to it, the binding to it occurs first, before a binding to the other property.*

3 Use the `twoWay` property of the `<fx:Binding>` tag, as the following example shows:

```
<fx:Binding source="input1.text" destination="input2.text" twoWay="true"/>
```

Because both the source and the destination properties must resolve to a bindable property or property chain at compile time, neither property value can include a binding expression.

The following example shows these three techniques:

```
<?xml version="1.0"?>
<!-- binding/BindBiDirection.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout paddingTop="10"/>
    </s:layout>
    <s:Label text="Specify data binding for both controls."/>
    <s:TextInput id="input1" text="{input2.text}"/>
    <s:TextInput id="input2" text="{input1.text}"/>
    <s:Label text="Use the bidirectional data binding syntax."/>
    <s:TextInput id="input3" text="@{input4.text}"/>
    <s:TextInput id="input4"/>

    <s:Label text="Use the Binding tag."/>
    <s:TextInput id="input5"/>
    <s:TextInput id="input6"/>
    <fx:Binding source="input5.text" destination="input6.text" twoWay="true"/>
</s:Application>
```

In this example, the TextInput controls are the source of a data binding expression, and both are a destination. For example, when you modify input1, its value is copied to input2, and when you modify input2, its value is copied to input1.

Flex ensures that bidirectional data bindings do not result in an infinite loop; that is, Flex ensures that a bidirectional data binding is triggered only once when either source property is modified.

Restrictions on where you can use bidirectional data binding

Bidirectional data bindable is supported in most places in an application. However, the following table shows where bidirectional data binding is not supported:

Expression	Bidirectional Binding Supported
Style properties	No
Effect properties	No
The `request` property of the HttpService, RemoteObject, and WebService classes.	No
The `arguments` property of the RemoteObject class.	No

Binding compatibility with Flex 3

In Flex 3, the following binding expression was interpreted as a one-way binding:

```
<mx:String id="str">test</mx:String>
<mx:Text text="@{str}"/>
```

Flex 3 set the Text component’s `text` property to “test”, but the value of the String component did not change if the Text component’s `text` property changed.

In Flex 4 and later, this code is interpreted as a bidirectional data binding expression. A change in the String component updates the `text` property of the Text component, and a change in the `text` property of the Text component updates the String component. You can prevent the compiler from enforcing the bidirectional binding by setting the value of the `compatibility-version` compiler option to `3.0.0`, as the following example shows:

```
mxmlc ... -compatibility-version=3.0.0 ...
```

For more information, see “Backward compatibility” on page 2239.

Binding to functions, Objects, and Arrays

Using functions as the source for a data binding

You can use a function as part of the source of a data binding expression. Two common techniques with functions are to use bindable properties as arguments to the function to trigger the function, or to trigger the function in response to a binding event.

Using functions that take bindable properties as arguments

You can use ActionScript functions as the source of data binding expressions when using a bindable property as an argument of the function. When the bindable property changes, the function executes, and the result is written to the destination property, as the following example shows:

```
<?xml version="1.0"?>
<!-- binding/ASInBraces.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Declarations>
        <s:CurrencyFormatter id="usdFormatter" useCurrencySymbol="true"/>
    </fx:Declarations>
    <s:TextInput id="myTI" text="Enter number here"/>
    <s:TextArea text="{usdFormatter.format(myTI.text)}"/>
</s:Application>
```

In this example, Flex calls the `CurrencyFormatter.format()` method to update the TextArea control every time the `text` property of the TextInput control is modified.

If the function is not passed an argument that can be used as the source of a data binding expression, the function only gets called once when the applications starts.

Binding to functions in response to a data-binding event

You can specify a function that takes no bindable arguments as the source of a data binding expression. However, you then need a way to invoke the function to update the destination of the data binding.

In the following example, you use the `[Bindable]` metadata tag to specify to Flex to invoke the `isEnabled()` function in response to the event `myFlagChanged`. When the myFlag setter gets called, it dispatches the `myFlagChanged` event to trigger any data bindings that use the `isEnabled()` function as the source:

```
<?xml version="1.0"?>
<!-- binding/ASFunction.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import flash.events.Event;

            // Define a function that gets invoked
            // in response to the myFlagChanged event.
            [Bindable(event="myFlagChanged")]
            private function isEnabled():String {
                if (myFlag)
                    return 'true';
                else
                    return 'false';
            }
            private var _myFlag:Boolean = false;
            // Define a setter method that dispatches the
            // myFlagChanged event to trigger the data binding.
            public function set myFlag(value:Boolean):void {
                _myFlag = value;
                dispatchEvent(new Event("myFlagChanged"));
            }
            public function get myFlag():Boolean {
                return _myFlag;
            }
        ]]>
    </fx:Script>
    <!-- Use the function as the source of a data binding expression. -->
    <s:TextArea id="myTA" text="{isEnabled()}"/>
    <!-- Modify the property, causing the setter method to
        dispatch the myFlagChanged event to trigger data binding. -->
    <s:Button label="Clear MyFlag" click="myFlag=false;"/>
    <s:Button label="Set MyFlag" click="myFlag=true;"/>
</s:Application>
```

For more information on the `[Bindable]` metadata tag, see “Using the Bindable metadata tag” on page 320.

Using data binding with Objects

When working with Objects, you have to consider when you define a binding to the Object, or when you define a binding to a property of the Object.

Binding to Objects

When you make an Object the source of a data binding expression, the data binding occurs when the Object is updated, or when a reference to the Object is updated, but not when an individual field of the Object is updated.

In the following example, you create subclass of Object that defines two properties, `stringProp` and `intProp`, but does not make the properties bindable:

```
package myComponents
{
    // binding/myComponents/NonBindableObject.as
    // Make no class properties bindable.
    public class NonBindableObject extends Object {

        public function NonBindableObject() {
            super();
        }

        public var stringProp:String = "String property";
        public var intProp:int = 52;
    }
}
```

Since the properties of the class are not bindable, Flex will not dispatch an event when they are updated to trigger data binding. You then use this class in a Flex application, as the following example shows:

```
<?xml version="1.0"?>
<!-- binding/WholeObjectBinding.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    creationComplete="initObj();">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            import myComponents.NonBindableObject;
            [Bindable]
            public var myObj:NonBindableObject = new NonBindableObject();
            [Bindable]
            public var anotherObj:NonBindableObject =
                new NonBindableObject();
            public function initObj():void {
                anotherObj.stringProp = 'anotherObject';
                anotherObj.intProp = 8;
            }
        ]]>
    </fx:Script>
    <!-- Data binding updated at application startup. -->
    <s:Label id="text1" text="{myObj.stringProp}"/>
    <!-- Data binding updated at application startup. -->
    <s:Label id="text2" text="{myObj.intProp}"/>
    <!-- Data bindings to stringProp not updated. -->
    <s:Button label="Change myObj.stringProp"
        click="myObj.stringProp = 'new string';"/>

    <!-- Data bindings to intProp not updated. -->
    <s:Button label="Change myObj.intProp"
        click="myObj.intProp = 10;"/>

    <!-- Data bindings to myObj and to myObj properties updated. -->
    <s:Button label="Change myObj"
        click="myObj = anotherObj;"/>
</s:Application>
```

Because you did not make the individual fields of the NonBindableObject class bindable, the data bindings for the two Text controls are updated at application start up, and when myObj is updated, but not when the individual properties of myObj are updated.

When you compile the application, the compiler outputs warning messages stating that the data binding mechanism will not be able to detect changes to stringProp and intProp.

Binding to properties of Objects

To make properties of an Object bindable, you create a new class definition for the Object, as the following example shows:

```
package myComponents
{
    // binding/myComponents/BindableObject.as
    // Make all class properties bindable.
    [Bindable]
    public class BindableObject extends Object {

        public function BindableObject() {
            super();
        }

        public var stringProp:String = "String property";
        public var intProp:int = 52;
    }
}
```

By placing the `[Bindable]` metadata tag before the class definition, you make bindable all public properties defined as variables, and all public properties defined by using both a setter and a getter method. You can then use the stringProp and intProp properties as the source for a data binding, as the following example shows:

```
<?xml version="1.0"?>
<!-- binding/SimpleObjectBinding.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    creationComplete="initObj();">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            import myComponents.BindableObject;
            [Bindable]
            public var myObj:BindableObject = new BindableObject();
            [Bindable]
            public var anotherObj:BindableObject =
                new BindableObject();
            public function initObj():void {
                anotherObj.stringProp = 'anotherObject';
                anotherObj.intProp = 8;
            }
        ]]>
    </fx:Script>
    <!-- Data binding updated at application startup. -->
    <s:Label id="text1" text="{myObj.stringProp}"/>
    <!-- Data binding updated at application startup. -->
    <s:Label id="text2" text="{myObj.intProp}"/>
    <!-- Data bindings to stringProp updated. -->
    <s:Button label="Change myObj.stringProp"
        click="myObj.stringProp = 'new string';"/>

    <!-- Data bindings to intProp updated. -->
    <s:Button label="Change myObj.intProp"
        click="myObj.intProp = 10;"/>

    <!-- Data bindings to myObj and to myObj properties updated. -->
    <s:Button label="Change myObj"
        click="myObj = anotherObj;"/>
</s:Application>
```

Binding with arrays

When working with arrays, such as Array or ArrayCollection objects, you can define the array as the source or destination of a data binding expression.

***Note:** When defining a data binding expression that uses an array as the source of a data binding expression, the array should be of type ArrayCollection because the ArrayCollection class dispatches an event when the array or the array elements change to trigger data binding. For example, a call to `ArrayCollection.addItem()`, `ArrayCollection.addItemAt()`, `ArrayCollection.removeItem()`, and `ArrayCollection.removeItemAt()` all trigger data binding.*

Binding to arrays

You often bind arrays to the `dataProvider` property of Flex controls, as the following example shows for the List control:

```
<?xml version="1.0"?>
<!-- binding/ArrayBindingDP.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;
            [Bindable]
            public var myAC:ArrayCollection = new ArrayCollection([
                "One", "Two", "Three", "Four"]);

            [Bindable]
            public var myAC2:ArrayCollection = new ArrayCollection([
                "Uno", "Dos", "Tres", "Quatro"]);
        ]]>
    </fx:Script>

    <!-- Data binding updated at application startup,
        when myAC is modified, and when an element of
        myAC is modifed. -->
    <s:List width="150"
        dataProvider="{myAC}"/>
    <!-- Data bindings to myAC updated. -->
    <s:Button
        label="Change Element"
        click="myAC[0]='mod One'"/>

    <!-- Data bindings to myAC updated. -->
    <s:Button
        label="Add Element"
        click="myAC.addItem('new element');"/>

    <!-- Data bindings to myAC updated. -->
    <s:Button
        label="Remove Element 0"
        click="myAC.removeItemAt(0);"/>

    <!-- Data bindings to myAC updated. -->
    <s:Button
        label="Change ArrayCollection"
        click="myAC=myAC2"/>
</s:Application>
```

This example defines an ArrayCollection object, and then uses data binding to set the data provider of the List control to the ArrayCollection. When you modify an element of the ArrayCollection object, or when you modify a reference to the ArrayCollection object, you trigger a data binding.

Binding to array elements

You can use individual ArrayCollection elements as the source or a binding expression, as the following example shows:

```
<?xml version="1.0"?>
<!-- binding/ArrayBinding.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;
            [Bindable]
            public var myAC:ArrayCollection = new ArrayCollection([
                "One", "Two", "Three", "Four"]);

            [Bindable]
            public var myAC2:ArrayCollection = new ArrayCollection([
                "Uno", "Dos", "Tres", "Quatro"]);
        ]]>
    </fx:Script>
    <!-- Data binding updated at application startup
        and when myAC modified. -->
    <s:Label id="text1" text="{myAC[0]}"/>
    <!-- Data binding updated at application startup,
        when myAC modified, and when myAC[0] modified. -->
    <s:Label id="text2" text="{myAC.getItemAt(0)}"/>

    <s:Button id="button1"
        label="Change Element"
        click="myAC[0]='new One'"/>
    <s:Button id="button2"
        label="Change ArrayCollection"
        click="myAC=myAC2"/>
</s:Application>
```

If you specify an array element as the source of a data binding expression by using the square bracket syntax, [], data binding is only triggered when the application starts and when the array or a reference to the array is updated; data binding is not triggered when the individual array element is updated. The compiler issues a warning in this situation.

However, the data binding expression `myAC.getItemAt(0)` is triggered when an array element changes. Therefore, the text2 Text control is updated when you click button1, while text1 is not. When using an array element as the source of a data binding expression, you should use the `ArrayCollection.getItemAt()` method in the binding expression.

Clicking button2 copies myAC2 to myAC, and triggers all data bindings to array elements regardless of how you implemented them.

Using ActionScript in data binding expressions

You can use ActionScript in data binding expressions defined by curly braces and by the `<fx:Binding>` tag; however, you cannot use ActionScript when defining a data binding by using the `BindingUtils.bindProperty()` or the `BindingUtils.bindSetter()` method.

Using ActionScript expressions in curly braces

Binding expressions in curly braces can contain an ActionScript expression that returns a value. For example, you can use the curly braces syntax for the following types of binding.

- A single bindable property inside curly braces
- To cast the data type of the source property to a type that matches the destination property
- String concatenation that includes a bindable property inside curly braces
- Calculations on a bindable property inside curly braces
- Conditional operations that evaluate a bindable property value

The following example shows a data model that uses each type of binding expression:

```
<?xml version="1.0"?>
<!-- binding/AsInBinding.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Declarations>
        <fx:Model id="myModel">
            <myModel>
              <!-- Perform simple property binding. -->
              <a>{nameInput.text}</a>
              <!-- Perform string concatenation. -->
              <b>This is {nameInput.text}</b>
              <!-- Perform a calculation. -->
              <c>{(Number(numberInput.text)) * 6 / 7}</c>
              <!-- Perform a conditional operation using a ternary operator. -->
              <d>{(isMale.selected) ? "Mr." : "Ms."} {nameInput.text}</d>
            </myModel>
        </fx:Model>
    </fx:Declarations>
    <s:Form>
        <s:FormItem label="Last Name:">
```

```
            <s:TextInput id="nameInput"/>
        </s:FormItem>
        <s:FormItem label="Select sex:">
            <s:RadioButton id="isMale"
                label="Male"
                groupName="gender"
                selected="true"/>
            <s:RadioButton id="isFemale"
                label="Female"
                groupName="gender"/>
        </s:FormItem>
        <s:FormItem label="Enter a number:">
            <s:TextInput id="numberInput" text="0"/>
        </s:FormItem>
    </s:Form>

    <s:Label
        text="{'Calculation: '+numberInput.text+' * 6 / 7 = '+myModel.c}"/>
    <s:Label text="{'Conditional: '+myModel.d}"/>
</s:Application>
```

Using ActionScript expressions in Binding tags

The `source` property of an `<fx:Binding>` tag can contain curly braces. When there are no curly braces in the `source` property, the value is treated as a single ActionScript expression. When there are curly braces in the `source` property, the value is treated as a concatenated ActionScript expression. The `<fx:Binding>` tags in the following example are valid and equivalent to each other:

```
<?xml version="1.0"?>
<!-- binding/ASInBindingTags.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            public function whatDogAte():String {
                return "homework";
            }
        ]]>
    </fx:Script>
    <fx:Binding
        source="'The dog ate my '+ whatDogAte()"
        destination="field1.text"/>
    <fx:Binding
        source="{'The dog ate my '+ whatDogAte()}"
        destination="field2.text"/>
    <fx:Binding
        source="The dog ate my {whatDogAte()}"
        destination="field3.text"/>
    <s:TextArea id="field1"/>
    <s:TextArea id="field2"/>
    <s:TextArea id="field3"/>
</s:Application>
```

The `source` property in the following example is not valid because it is not an ActionScript expression:

```
<fx:Binding source="The dog ate my homework" destination="field1.text"/>
```

Using an ampersand character in a data binding expression

Because of the parsing rules of XML, if you want to use an ampersand character, `&`, in a data binding expression in an MXML file, you must replace it with the hexadecimal equivalent character, `&amp;`. For example, if you want to use a logical AND expression, written in ActionScript as `&&`, then you have to write is as `&amp;&amp;`, as the following example shows:

```
<s:Button label="Test" enabled="{authorized &amp;&amp; cc}" />
```

Using an E4X expression in a data binding expression

A binding expression in curly braces or an `<fx:Binding>` tag can contain an ECMAScript for XML (E4X) expression when the source of a binding is a bindable property of type XML. You cannot use E4X when defining a data binding by using the `BindingUtils.bindProperty()` or the `BindingUtils.bindSetter()` method.

Using an E4X expression in curly braces

A binding expression in curly braces automatically calls the `toString()` method when the binding destination is a String property. A binding expression in curly braces or an `<fx:Binding>` tag can contain an ECMAScript for XML (E4X) expression when the source of a binding is a bindable property of type XML; for more information, see “Using an E4X expression in an <fx:Binding> tag” on page 317.

In the code in the following example, there are three binding expressions in curly braces that bind data from an XML object. The first uses . (dot) notation, the second uses .. (dot dot) notation, and the third uses || (or) notation.

```
<?xml version="1.0"?>
<!-- binding/E4XInBraces.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    width="750">
    <s:layout>
        <s:HorizontalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[

            [Bindable]
            public var xdata:XML = <order>
                <item id = "3456">
                    <description>Big Screen Television</description>
                    <price>1299.99</price><quantity>1</quantity>
                </item>
                <item id = "56789">
                    <description>DVD Player</description>
                    <price>399.99</price>
                    <quantity>1</quantity>
                </item>
            </order>;
        ]]>
    </fx:Script>
    <mx:Label text="Using .. notation."/>
    <!-- Inline databinding will automatically call the
        toString() method when the binding destination is a string. -->
    <mx:List width="25%"
        dataProvider="{xdata..description}"/>

    <mx:Label text="Using . notation."/>
    <mx:List width="25%"
        dataProvider="{xdata.item.description}"/>
    <mx:Label text="Using || (or) notation."/>
    <mx:List width="25%"
        dataProvider="{xdata.item.(@id=='3456'||@id=='56789').description}"/>
</s:Application>
```

Using an E4X expression in an <fx:Binding> tag

Unlike an E4X expression in curly braces, when you use an E4X expression in an `<fx:Binding>` tag, you must explicitly call the `toString()` method when the binding destination is a String property.

In the code in the following example, there are three binding expressions in curly braces that bind data from an XML object. The first uses . (dot) notation, the second uses .. (dot dot) notation, and the third uses || (or) notation.

```
<?xml version="1.0"?>
<!-- binding/E4XInBindingTag.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    width="600" height="900">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            [Bindable]
            public var xdata:XML =
                <order>
                    <item id = "3456">
                        <description>Big Screen Television</description>
                        <price>1299.99</price><quantity>1</quantity>
                    </item>
                    <item id = "56789">
                        <description>DVD Player</description>
                        <price>399.99</price>
                        <quantity>1</quantity>
                    </item>
                </order>;
        ]]>
    </fx:Script>
    <mx:Label text="Using .. notation."/>
    <!-- This will update because what is
        binded is actually the String and XMLList. -->
    <mx:List width="75%" id="txts"/>
    <mx:Label text="Using . notation."/>
    <mx:List width="75%" id="txt2s"/>
    <mx:Label text="Using || (or) notation."/>
    <mx:List width="75%" id="txt3s"/>
    <fx:Binding
        source="xdata..description"
        destination="txts.dataProvider"/>
    <fx:Binding
        source="xdata.item.description"
        destination="txt2s.dataProvider"/>
    <fx:Binding
        source="xdata.item.(@id=='3456'||@id=='56789').description"
        destination="txt3s.dataProvider"/>
</s:Application>
```

Defining data bindings in ActionScript

You can define a data binding in ActionScript by using the mx.binding.utils.BindingUtils class. This class defines static methods that let you create a data binding to a property implemented as a variable, by using the `bindProperty()` method, or to a method, by using the `bindSetter()` method. For an example using the `bindProperty()` method, see “About data binding” on page 299.

Differences between defining bindings in MXML and ActionScript

There are a few differences between defining data bindings in MXML at compile time and in defining them at runtime in ActionScript:

- You cannot include ActionScript code in a data binding expression defined by the `bindProperty()` or `bindSetter()` method. Instead, use the `bindSetter()` method to specify a method to call when the binding occurs.
- You cannot include an E4X expression in a data binding expression defined in ActionScript.
- You cannot include functions or array elements in property chains in a data binding expression defined by the `bindProperty()` or `bindSetter()` method.
- The MXML compiler has better warning and error detection support than runtime data bindings defined by the `bindProperty()` or `bindSetter()` method.

Example: Defining a data binding in ActionScript

The following example uses the `bindSetter()` method to set up a data binding. The arguments to the `bindSetter()` method specify the following:

- The source object
- The name of the source property
- A method that is called when the source property changes

In the following example, as you enter text in the TextInput control, the text is converted to upper case as it is copied to the TextArea control:

```
<?xml version="1.0"?>
<!-- binding/BindSetterAS.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import mx.binding.utils.*;
            import mx.events.FlexEvent;
            // Method called when myTI.text changes.
            public function updateMyString(val:String):void {
                myTA.text = val.toUpperCase();
            }
            <!-- Event listener to configure binding. -->
            public function mySetterBinding(event:FlexEvent):void {
                var watcherSetter:ChangeWatcher =
                    BindingUtils.bindSetter(updateMyString, myTI, "text");
            }
        ]]>
    </fx:Script>
    <s:Label text="Bind Setter using setter method"/>
    <s:TextInput id="myTI"
        text="Hello Setter" />
    <s:TextArea id="myTA"
        initialize="mySetterBinding(event);"/>
</s:Application>
```

Defining binding watchers

Flex includes the mx.binding.utils.ChangeWatcher class that you can use to define a data-binding watcher. Typically, a data-binding watcher invokes an event listener when a binding occurs. To set up a data-binding watcher, you use the static `watch()` method of the ChangeWatcher class, as the following example shows:

```
<?xml version="1.0"?>
<!-- binding/DetectWatcher.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    initialize="initWatcher();">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
          import mx.binding.utils.*;
          import mx.events.FlexEvent;
          import mx.events.PropertyChangeEvent;
          public var myWatcher:ChangeWatcher;
          // Define binding watcher.
          public function initWatcher():void {
            // Define a watcher for the text binding.
              myWatcher = ChangeWatcher.watch(textarea, "text", watcherListener);
          }
          // Event listener when binding occurs.
          public function watcherListener(event:Event):void {
            myTA1.text="binding occurred";

            // Use myWatcher.unwatch() to remove the watcher.
          }
        ]]>
    </fx:Script>
    <!-- Define a binding expression to watch. -->
    <s:TextInput id="textinput" text="Hello"/>
    <s:TextArea id="textarea" text="{textinput.text}"/>
    <!-- Trigger a binding. -->
    <s:Button label="Submit" click="textinput.text='Goodbye';"/>
    <s:TextArea id="myTA1"/>
</s:Application>
```

You define an event listener for the data-binding watcher, where the event listener takes a single argument that contains the event object. The data type of the event object is determined by the property being watched. Each bindable property can dispatch a different event type and the associated event object. For more information on determining the event type, see “Using the Bindable metadata tag” on page 320.

Many event listeners take an event object of type PropertyChangeEvent because that is the default data type of the event dispatched by bindable properties. You can always specify an event type of flash.events.Event, the base class for all Flex events.

Using the Bindable metadata tag

When a property is the source of a data binding expression, Flex automatically copies the value of the source property to any destination property when the source property changes. To signal to Flex to perform the copy, you must use the `[Bindable]` metadata tag to register the property with Flex, and the source property must dispatch an event.

The `[Bindable]` metadata tag has the following syntax:

```
[Bindable]
[Bindable(event="eventname")]
```

If you omit the event name, Flex automatically creates an event named `propertyChange` of type PropertyChangeEvent.

You can use the `[Bindable]` metadata tag in three places:

1 Before a public class definition.

   The `[Bindable]` metadata tag makes usable as the source of a binding expression all public properties that you defined as variables, and all public properties that are defined by using both a setter and a getter method. In this case, `[Bindable]` takes no parameters, as the following example shows:

   ```
   [Bindable]
   public class TextAreaFontControl extends TextArea {}
   ```

   The compiler automatically generates an event named `propertyChange`, of type PropertyChangeEvent, for all public properties so that the properties can be used as the source of a data binding expression.

   If the property value remains the same on a write, Flex does not dispatch the event or update the property, where *not the same* translates to the following test:

   ```
   (oldValue !== value)
   ```

   That means if a property contains a reference to an object, and that reference is modified to reference a different but equivalent object, the binding is triggered. If the property is not modified, but the object that it points to changes internally, the binding is not triggered.

   ***Note:** When you use the `[Bindable]` metadata tag before a public class definition, it only applies to public properties; it does not apply to private or protected properties, or to properties defined in any other namespace. You must insert the `[Bindable]` metadata tag before a nonpublic property to make it usable as the source for a data binding expression.*

2 Before a public, protected, or private property defined as a variable to make that specific property support binding.

   The tag can have the following forms:

   ```
   [Bindable]
   public var foo:String;
   ```

   The Flex compiler automatically generates an event named `propertyChange`, of type PropertyChangeEvent, for the property. If the property value remains the same on a write, Flex does not dispatch the event or update the property.

   You can also specify the event name, as the following example shows:

   ```
   [Bindable(event="fooChanged")]
   public var foo:String;
   ```

   In this case, you are responsible for generating and dispatching the event, typically as part of some other method of your class. You can specify a `[Bindable]` tag that includes the `event` specification if you want to name the event, even when you already specified the `[Bindable]` tag at the class level.

3 Before a public, protected, or private property defined by a getter or setter method.

You must define both a setter and a getter method to use the `[Bindable]` tag with the property. If you define just a setter method, you create a write-only property that you cannot use as the source of a data-binding expression. If you define just a getter method, you create a read-only property that you can use as the source of a data-binding expression without inserting the `[Bindable]` metadata tag. This is similar to the way that you can use a variable, defined by using the `const` keyword, as the source for a data binding expression.

The tag can have the following forms:

```
[Bindable]
public function set shortNames(val:Boolean):void {
    ...
}

public function get shortNames():Boolean {
    ...
}
```

The Flex compiler automatically generates an event named `propertyChange`, of type PropertyChangeEvent, for the property. If the property value remains the same on a write, Flex does not dispatch the event or update the property. To determine if the property value changes, Flex calls the getter method to obtain the current value of the property.

You can specify the event name, as the following example shows:

```
[Bindable(event="changeShortNames")]
public function set shortNames(val:Boolean):void {
    ...
    // Create and dispatch event.
    dispatchEvent(new Event("changeShortNames"));
}

// Get method.
public function get shortNames():Boolean {
    ...
}
```

In this case, you are responsible for generating and dispatching the event, typically in the setter method, and Flex does not check to see if the old value and the new value are different. You can specify a `[Bindable]` tag that includes the `event` specification to name the event, even when you already specified the `[Bindable]` tag at the class level.

The following example makes the `maxFontSize` and `minFontSize` properties that you defined as variables that can be used as the sources for data bindings:

```
 // Define public vars for tracking font size.
 [Bindable]
public var maxFontSize:Number = 15;
 [Bindable]
public var minFontSize:Number = 5;
```

In the following example, you make a public property that you defined by using a setter and a getter method that is usable as the source for data binding The `[Bindable]` metadata tag includes the name of the event broadcast by the setter method when the property changes:

```
    // Define private variable.
    private var _maxFontSize:Number = 15;

    [Bindable(event="maxFontSizeChanged")]
    // Define public getter method.
    public function get maxFontSize():Number {
        return _maxFontSize;
    }

    // Define public setter method.
    public function set maxFontSize(value:Number):void {
        if (value <= 30) {
            _maxFontSize = value;
        } else _maxFontSize = 30;

        // Create event object.
        var eventObj:Event = new Event("maxFontSizeChanged");
        dispatchEvent(eventObj);

    }
```

In this example, the setter updates the value of the property, and then creates and dispatches an event to invoke an update of the destination of the data binding.

In an MXML file, you can make all public properties that you defined as variables usable as the source for data binding by including the `[Bindable]` metadata tag in an `<fx:Metadata>` block, as the following example shows:

```
<fx:Metadata>
    [Bindable]
</fx:Metadata>
```

You can also use the `[Bindable]` metadata tag in an `<fx:Script>` block in an MXML file to make individual properties that you defined as variables usable as the source for a data binding expression. Alternatively, you can use the `[Bindable]` metadata tag with properties that you defined by using setter and getter methods.

Using read-only properties as the source for data binding

You can automatically use a read-only property defined by a getter method, which means no setter method, as the source for a data-binding expression. Flex performs the data binding once when the application starts.

Because the data binding from a read-only property occurs only once at application start up, you omit the `[Bindable]` metadata tag for the read-only property.

Using static properties as the source for data binding

You can use a static variable as the source for a data-binding expression. Flex performs the data binding once when the application starts, and again when the property changes.

You can automatically use a static constant as the source for a data-binding expression. Flex performs the data binding once when the application starts. Because the data binding occurs only once at application start up, you omit the `[Bindable]` metadata tag for the static constant. The following example uses a static constant as the source for a data-binding expression:

```
<?xml version="1.0"?>
<!-- binding/StaticBinding.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
      <![CDATA[
        // This syntax casues a compiler error.
        // [Bindable]
        // public static var varString:String="A static var.";
        public static const constString:String="A static const.";
      ]]>
    </fx:Script>
    <!-- This binding occurs once at application startup. -->
    <s:Button label="{constString}"/>
</s:Application>
```

Working with bindable property chains

When you specify a property as the source of a data binding expression, Flex monitors not only that property for changes, but also the chain of properties leading up to it. The entire chain of properties, including the source property, is called a *bindable property chain*. In the following example, `firstName.text` is a bindable property chain that includes both a `firstName` object and its `text` property:

```
<s:Label id="myText" text="{firstName.text}"/>
```

You can have a fairly long bindable property chain, as the following example shows:

```
<s:Label id="myText" text="{user.name.firstName.text}"/>
```

For the data binding mechanism to detect changes to the `text` property, only the `text` property has to be bindable. However, if you want to assign a new value to any part of the chain at runtime, every element in the chain must be bindable. Otherwise, modifying the `user`, `name`, or `firstName` property at runtime results in the data binding mechanism no longer being able to detect changes to the `text` property.

When using the `BindingUtils.bindProperty()` or `BindingUtils.bindSetter()` method, you specify the bindable property chain as an argument to the method. For example, the `bindProperty()` method has the following signature:

```
public static function bindProperty(site:Object, prop:String, host:Object, chain:Object,
    commitOnly:Boolean = false):ChangeWatcher
```

The *`host`* and *`chain`* arguments specify the source of the data binding expression. You can define a data binding expression by using the `bindProperty()` method, as the following example shows:

```
bindProperty(myText, 'text', user, ["name","firstName","text"]);
```

In this example, `["name","firstName","text"]` defines the bindable property chain relative to the user object. Notice that `user` is not part of the bindable property change in this example.

In an MXML data-binding expression, the bindable property chain is always relative to `this`. Therefore, to define a data binding equivalent to the MXML data binding expression shown above, you write the `bindProperty()` method as the following example shows:

```
bindProperty(myText, 'text', this, ["user", "name","firstName","text"]);
```

Considerations for using the binding feature

Consider the following when using the binding feature:

- You cannot bind to style properties, but you can bind to the `getStyle()` method, as the following example shows:

  ```
  <s:Button label="Button 1" id="b1" color="green"/>
  <s:Button label="Button 2" color="{b1.getStyle('color')}"/>
  <s:Button label="Button 3" click="b1.setStyle('color', 'red');"/>
  ```

  In this example, Button 2 uses data binding to set its `color` style property to the same value as the `color` style of Button 1.

- If you bind a model into the `dataProvider` property of a component, you should not change items in the model directly. Instead, change the items through the Collections API. Otherwise, the component to which the model is bound is not redrawn to show the changes to the model. For example, instead of using the following:

  ```
  myGrid.getItemAt(itemIndex).myField = 1;
  ```

  You would use the following:

  ```
  myGrid.dataProvider.editField(itemIndex, "myField", 1);
  ```

- Array elements cannot function as binding sources at run time. Arrays that are bound do not stay updated if individual fields of a source Array change. Binding copies values during instantiation after variables are declared in an `<fx:Script>` tag, but before event listeners execute.

Debugging data binding

In some situations, data binding may not appear to function correctly, and you may need to debug them. The following list contains suggestions for resolving data binding issues:

1 Pay attention to warnings.

  It is easy to see a warning and think that it doesn't matter, especially if binding appears to work at startup, but warnings are important.

  If a warning is about a missing `[Bindable]` on a getter/setter property, even if the binding works at startup, subsequent changes to the property are not noticed.

  If a warning is about a static variable or a built-in property, changes aren't noticed.

2 Ensure that the source of the binding actually changed.

  When your source is part of a larger procedure, it is easy to miss the fact that you never assigned the source.

3 Ensure that the bindable event is being dispatched.

  You can use the Flex command-line debugger (fdb), or the Adobe® Flash® Builder™ debugger to make sure that the `dispatchEvent()` method is called. Also, you can add a normal event listener to that class to make sure it gets called. If you want to add the event listener as a tag attribute, you must place the `[Event('`*myEvent*`')]` metadata at the top of your class definition or in an `<fx:Metadata>` tag in your MXML.

4 Create a setter function and use a `<fx:Binding>` tag to assign into it.

  You can then put a trace or an alert or some other debugging code in the setter with the value that is being assigned. This technique ensures that the binding itself is working. If the setter is called with the right information, you will know that it's your destination that is failing, and you can start debugging there.

Introduction to containers

Containers provide a hierarchical structure that lets you control the layout characteristics of child components.

About containers

A *container* defines a rectangular region of the drawing surface of Adobe® Flash® Player. Within this region, you define the components, including controls and containers, that you want to appear. Components defined within a container are called *children*. Adobe® Flex® provides a wide variety of containers, ranging from simple boxes, panels, and forms to accordions that provide built-in navigation among its children.

At the root of an application written in Flex is a single container, called the application container, that represents the entire Flash Player drawing surface. The application container holds all other containers and controls. For more information, see "Application containers" on page 393.

A container uses a set of rules to control the layout of its children, including sizing and positioning. Flex defines layout rules to simplify the design and implementation of rich Internet applications, while also providing enough flexibility to let you create a diverse set of applications.

About layout containers and navigator containers

Flex defines two types of containers:

Layout containers Control the sizing and positioning of the children defined within them. Children can be controls or other containers. For more information on Spark layout containers, see "Spark containers" on page 417. For more information on MX layout containers, see "MX layout containers" on page 574.

Navigator containers Control user movement, or navigation, among multiple child containers. Navigators only take MX containers or the Spark NavigatorContent container as children. The individual child containers, not the navigator container itself, control the layout and positioning of their children. For more information, see "MX navigator containers" on page 628.

About Spark and MX containers

Flex defines two sets of containers: MX and Spark. The Spark containers are defined in the spark.components package. The MX containers are defined in the mx.core and mx.containers packages.

While you can use MX containers to perform most of the same layout that you can perform using the Spark containers, Adobe recommends that you use the Spark containers when possible.

About container children

One of the main differences between Spark and MX containers is that an MX container can only use components that implement the IUIComponent interface as its children. The UIComponent class implements the IUIComponent interface, so you can use all Flex components and containers as children of an MX container.

The Spark Group and SkinnableContainer containers can hold children that implement the IVisualElement interface. These components include all subclasses of the UIComponent class, and any subclasses of the GraphicElement class. Many of the classes in the spark.primitives package, such as Rect and Ellipse, are subclasses of the GraphicElement class. Therefore, you can use those classes as children of a Spark container to add graphics to the container.

The Spark SkinnableDataContainer and Spark DataGroup containers can hold children that implement the IUIComponent interface, and hold data items such as a String, Number, or Object. You must define an item renderer to control the display of the data item. For more information, see "The Spark DataGroup and Spark SkinnableDataContainer containers" on page 466.

About layout

Containers implement a default layout algorithm so you do not have to spend time defining it. Instead, you concentrate on the information that you deliver, and the options that you provide for your users, and not worry about implementing all the details of user action and application response. In this way, Flex provides the structure that lets you quickly and easily develop an application with a rich set of features and interactions.

Layout rules also offer the advantage that your users soon grow accustomed to them. That is, by standardizing the rules of user interaction, your users do not have to think about how to navigate the application, but can instead concentrate on the content that the application offers.

One of the main differences between Spark and MX containers is that the layout algorithm for MX containers is fixed, but for Spark containers it is selectable. Therefore, MX defines a different container for each type of layout. Spark defines a smaller set of containers, but lets you switch the layout algorithm to make them more flexible.

The MX Canvas, MX Application, and MX Panel containers, and all Spark containers, can use *absolute* layout. With absolute layout, you explicitly specify the children's *x* and *y* positions in the container. Alternatively, you can use *constraint-based layout* to anchor the sides, baseline, or center of the children relative to the parent.

Absolute layout provides a greater level of control over sizing and positioning than does automatic layout. But absolute layout provides this control at the cost of making you explicitly specify the positions of all container children.

Spark and MX containers let you define custom layout rules. For Spark, you can define a custom layout class and apply it to a Spark container. For MX, create a subclass of one of the MX containers and override its layout mechanism.

For more information on layout, see "Laying out components" on page 359.

About skinning

Skinning is the process of changing the appearance of a component by modifying or replacing its visual elements. These elements can be made up of bitmap images, SWF files, or vector images. All MX containers are skinnable.

Most, but not all, Spark containers are skinnable. The Spark Group and DataGroup containers are not skinnable. These containers provide a lightweight mechanism that you use to perform layout. They do not support skinning to ensure that they add minimal overhead to your application. If you need to modify the visual appearance, use a skinnable Spark container instead.

For more information, see "Spark Skinning" on page 1602"Improving startup performance" on page 2333 and "Skinning MX components" on page 1655.

About the creation policy

Containers define a creation policy that specifies when its children are created. By default, a container delays creating its children until they are needed by the application. This process is called *deferred instantiation*. Since all children are not created at application start up, your application appears to run faster.

You can control the creation policy for a container. For example, you can create all children at startup, or you can explicitly determine when a child is created.

You can use the following creation policies:

- `ContainerCreationPolicy.AUTO` The container delays creating children until they are needed.

  For navigator containers such as the MX ViewStack, MX TabNavigator, and MX Accordion containers, the container creates its direct children immediately, but waits to create the descendants of each child until the child needs to be displayed. As a result, only the initially required child or children of a container get processed past the preinitialization stage. An auto creation policy produces the best startup time because fewer components are created initially.

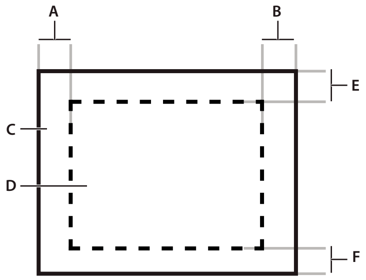
- `ContainerCreationPolicy.ALL` All container children are created and initialized before the container is initialized.
- `ContainerCreationPolicy.NONE` Requires the container to explicitly create every child instance.

For detailed information on creation policies, see "Improving startup performance" on page 2333.

Using containers

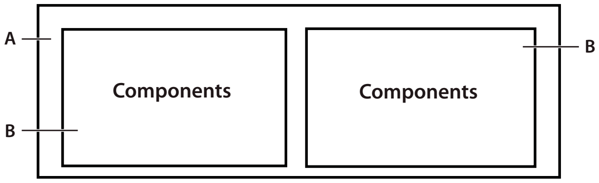
The rectangular region of a container encloses its *content area*, the area that contains its child components. The size of the region around the content area is defined by the container. That region can include extra space, or padding, around the content area and an optional border around the container.

The following image shows a container and its content area, padding, and borders:



A. *Left padding* ***B.*** *Right padding* ***C.*** *Container* ***D.*** *Content area* ***E.*** *Top padding* ***F.*** *Bottom padding*

Although you can create an entire application by using a single container, typical applications use multiple containers. For example, the following image shows an application that uses three containers:

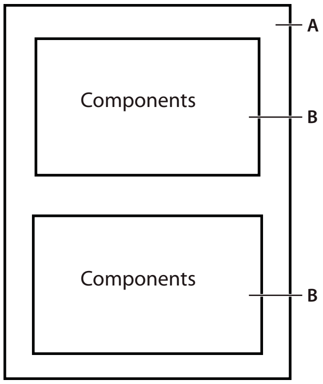


A. *Parent container* ***B.*** *Child containers*

In this example, the two child containers are nested within a parent container and are referred to as children of the parent container. The child containers themselves contain child UI components.

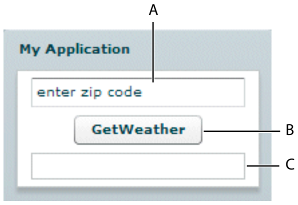
The parent container in the previous figure arranges its children in a single horizontal row and oversees the sizing and positioning characteristics of the child containers. For example, you can control the distance, or gap, between children in a container by using the `horizontalGap` and `verticalGap` properties. The two child containers are responsible for laying out their own children.

The following image shows the preceding example with the parent container configured to use a vertical layout:



A. *Parent container* *B.* *Child containers*

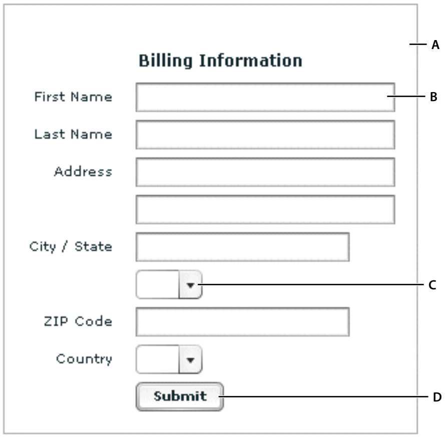
The primary use of a container is to arrange its children, where the children are either controls or other containers. The following image shows a Spark Panel container that has three child components:



A. *TextInput control* *B.* *Button control* *C.* *TextArea control*

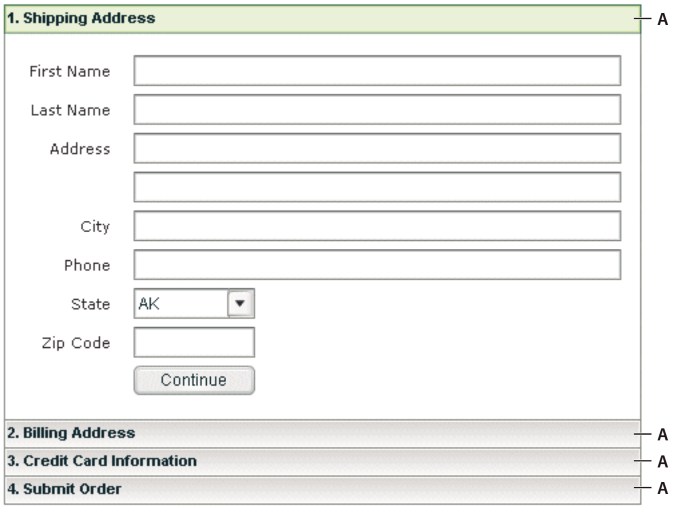
In this example, a user enters a ZIP code into the TextInput control, and then clicks the Button control to see the current temperature for the specified ZIP code in the TextArea control.

Flex supports form-based applications through its MX Form layout container. In a Form container, Flex can automatically align labels, uniformly size text input controls, and display input error notifications. The following image shows a Form container:



A. *Form container* *B.* *TextInput control* *C.* *ComboBox control* *D.* *Button control*

Navigator containers, such as the MX TabNavigator and MX Accordion containers, have built-in navigation controls that let you organize information from multiple child containers in a way that makes it easy for a user to move through it. The following image shows an Accordion container:



***A.** Accordion buttons*

You use the Accordion buttons to move among the different child containers. The Accordion container defines a sequence of child panels, but displays only one panel at a time. To navigate a container, the user clicks the navigation button that corresponds to the child panel that they want to access.

Accordion containers support the creation of multistep procedures. The preceding image shows an Accordion container that defines four panels of a complex form. To complete the form, the user enters data into all four panels. Accordion containers let users enter information in the first panel, click the Accordion button to move to the second panel, and then move back to the first if they want to edit the information. For more information, see "MX Accordion navigator container" on page 639.

Spark containers

The following table describes the Spark containers defined in the spark.components package:

Container	Type	Description	For more information
Application	Layout	The first container in an application. The default layout is absolute.	"Application containers" on page 393
BorderContainer	Layout	Defines a set of CSS styles that control the appearance of the border and background fill of the container.	"The Spark BorderContainer container" on page 430
DataGroup	Layout	Simple container that lays out it children, including data items, based on the specified layout. The default layout is absolute.	"The Spark DataGroup and Spark SkinnableDataContainer containers" on page 466
Group	Layout	Simple container that lays out it children, including graphic children, based on the specified layout. The default layout is absolute. Flex defines subclasses of Group: HGroup with horizontal layout, VGroup with vertical layout, and TileGroup with tile layout.	"The Spark Group and Spark SkinnableContainer containers" on page 425
NavigatorContent	Layout	Simple container that can be used in an MX navigator container, such as the ViewStack, TabNavigator and Accordion containers.	"The Spark NavigatorContent container" on page 433
Panel	Layout	Displays a title bar, a caption, a border, and its children. The default layout is absolute.	"The Spark Panel container" on page 434

Container	Type	Description	For more information
SkinnableContainer	Layout	Skinnable container that lays out it children, including graphic children, based on the specified layout. This container supports skinning. The default layout is vertical.	"The Spark Group and Spark SkinnableContainer containers" on page 425
SkinnableDataContainer	Layout	Skinnable container that lays out it children, including data items, based on the specified layout. This container supports skinning. The default layout is vertical.	"The Spark DataGroup and Spark SkinnableDataContainer containers" on page 466
SkinnablePopUpContainer	Layout	Skinnable container that lays out its children in a skinnable container opened as a pop up window.	"The Spark SkinnablePopUpContainer container" on page 437
TitleWindow	Layout	Skinnable Panel container that is optimized for use as a pop-up window.	"The Spark TitleWindow container" on page 443

MX containers

The following table describes the MX containers defined in the mx.core and mx.components packages:

Container	Type	Description	For more information
Accordion	Navigator	Organizes information in a series of child panels, where one panel is active at any time.	"MX Accordion navigator container" on page 639
Application	Layout	The first container in an application. The default layout is absolute.	"Application containers" on page 393
ApplicationControlBar	Layout	Holds components that provide global navigation and application commands. Can be docked at the top of an Application container.	"MX ApplicationControlBar layout container" on page 582
Box (HBox and VBox)	Layout	Displays content in a uniformly spaced row or column. An HBox container horizontally aligns its children; a VBox container vertically aligns its children. Adobe recommends that you use the Spark containers when possible, instead of the MX Box container.	"MX Box, HBox, and VBox layout containers" on page 579
Canvas	Layout	Defines a container in which you must explicitly position its children. Adobe recommends that you use the Spark containers with BasicLayout when possible, instead of the MX Canvas container.	"MX Canvas layout container" on page 574
ControlBar	Layout	Places controls at the lower edge of a Panel or TitleWindow container.	"MX ControlBar layout container" on page 581
DividedBox (HDividedBox and VDividedBox)	Layout	Lays out its children horizontally or vertically, much like a Box container, except that it inserts an adjustable divider between the children.	"MX DividedBox, HDividedBox, and VDividedBox layout containers" on page 584
Form	Layout	Arranges its children in a standard form format.	"MX Form, FormHeading, and FormItem layout containers" on page 586
Grid	Layout	Arranges children as rows and columns of cells, much like an HTML table.	"MX Grid layout container" on page 603

Container	Type	Description	For more information
Panel	Layout	Displays a title bar, a caption, a border, and its children. Adobe recommends that you use the Spark Panel container when possible, instead of the MX Panel container.	"MX Panel layout container" on page 608
TabNavigator	Navigator	Displays a container with tabs to let users switch between different content areas.	"MX TabNavigator container" on page 636
Tile	Layout	Defines a layout that arranges its children in multiple rows or columns. Adobe recommends that you use the Spark containers with the TileLayout when possible, instead of the MX Tile container.	"MX Tile layout container" on page 612
TitleWindow	Layout	Displays a popup window that contains a title bar, a caption, border, a close button, and its children. The user can move the container.	"MX TitleWindow layout container" on page 614
ViewStack	Navigator	Defines a stack of containers that displays a single container at a time.	"MX ViewStack navigator container" on page 630

Container example

The following example creates an application that uses a Spark Group container with three child controls, where the Group container lays out its children vertically:

```
<?xml version="1.0"?>
<!-- containers\intro\Panel3Children.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:Group>
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <s:TextInput id="myinput" text="enter zip code"/>
        <s:Button id="mybutton" label="GetWeather"/>
        <s:TextArea id="mytext" height="20"/>
    </s:Group>
</s:Application>
```

The Group container uses basic layout by default. Use the `layout` property of a Spark container to configure its layout. In the previous example, you set the layout of the Group container to vertical.

The Group container has subclasses that you can use as shortcuts in your application: HGroup defines a Group container with horizontal layout, VGroup defines a Group container with veritical layout, and TileGroup defines a Group container with tile layout. The following example modifies the previous example to use the VGroup container:

```
<?xml version="1.0"?>
<!-- containers\intro\Panel3Children.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:VGroup>
        <s:TextInput id="myinput" text="enter zip code"/>
        <s:Button id="mybutton" label="GetWeather"/>
        <s:TextArea id="mytext" height="20"/>
    </s:VGroup>
</s:Application>
```

To actually retrieve weather information, you must set up a web service, pass it the entered ZIP code from a `click` event, and use the returned information to populate the TextArea control.

Using container events

All containers and components support events. Containers dispatch the following events:

Spark container	MX container	Description
`elementAdd`	`childAdd`	Dispatched after a child is added to the container.
`elementRemove`	`childRemove`	Dispatched before a child is removed from the container.
	`childIndexChanged`	Dispatched after a child's index in the container has changed. Spark containers dispatch multiple `itemAdd` and `itemRemove` events.
	`scroll`	Dispatched when the user manually scrolls the container.
`contentCreationComplete`		Dispatched after all container children are created, and before the children dispatch the `creationComplete` event. This event is not available for Group and DataGroup.

All components dispatch the following events after they are added to or removed from a container:

Event	Description
`add`	Dispatched by a component after the component has been added to its container and the parent and the child are in a consistent state. This event is dispatched after the container has dispatched the `childAdd` event and all changes that need to be made as a result of the addition have happened.
`remove`	Dispatched by a component after the component has been removed from its parent container. This event is dispatched after the container has dispatched the `childRemove` event and all changes that need to be made as a result of the removal have happened.

Several events are dispatched by all components, but need special consideration when dispatched by containers. This is particularly true for navigator containers, such as TabNavigator, where some children might not be created when the container is created. These events include the following:

Event	Description
`preinitialize`	Dispatched when the component has been attached to its parent container, but before the component has been initialized, or any of its children have been created. In most cases, this event is dispatched too early for an application to use to configure a component.
`initialize`	Dispatched when a component has finished its construction and its initialization properties have been set. At this point, all the component's immediate children have been created (they have at least dispatched their `preinitialize` event), but they have not been laid out. Exactly when initialize events are dispatched depends on the container's creation policy. Flex dispatches the `initialize` event for a container after it attaches all the container's direct child controls and the container's initially required children have dispatched a `preinitialize` event. When a container or control dispatches the `initialize` event, its initial properties have been set, but its width and height have not yet been calculated, and its position has not been calculated. The `initialize` event is useful for configuring a container's children. For example, you can use the container's `initialize` event to programmatically add children or set a container scroll bar's styles. You can use a container or component's `initialize` event to initialize the data provider for a control.
`creationComplete`	Dispatched when the component, and all its child components, and all their children, and so on, have been created, laid out, and are visible. Flex dispatches the `creationComplete` event for a container when those children that are initially required are fully processed and drawn on the screen, including all required children of the children, and so on. Create a listener for the `creationComplete` event, for example, if you must have the children's dimensions and positions in your event handler. Do not use the `creationComplete` event for actions that set layout properties, as doing so results in excess processing time.

The following example uses the `creationComplete` event to open an Alert box when the children of the HGroup container are fully processed and drawn:

```
<?xml version="1.0"?>
<!-- containers\intro\Panel3ChildrenEvent.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <fx:Script>
        <![CDATA[
            import mx.controls.Alert;

            private function handleCreationComplete():void {
                Alert.show("MyHGroup created.");
            }
        ]]>
    </fx:Script>
    <s:HGroup id="MyHGroup"
        creationComplete="handleCreationComplete();">
        <s:TextInput id="myinput" text="enter zip code"/>
        <s:Button id="mybutton" label="GetWeather"/>
        <s:TextArea id="mytext" height="20"/>
    </s:HGroup>
</s:Application>
```

To better understand the order in which Flex dispatches events, consider the following application outline.

```
OuterSkinnableContainer
    InnerSkinnableContainer1
        InnerLabel1
    InnerSkinnableContainer2
        InnerLabel2
```

The `preinitialize`, `initialize`, `contentCreationComplete`, and `creationComplete` events for the containers and controls are dispatched in the following order. The indentation corresponds to the indentation in the previous outline:

```
OuterSkinnableContainer preinitialize
    InnerSkinnableContainer1 preinitialize
        InnerLabel1 preinitialize
        InnerLabel1 initialize
    InnerSkinnableContainer1 contentCreationComplete
    InnerSkinnableContainer1 initialize
    InnerSkinnableContainer2 preinitialize
        InnerLabel2 preinitialize
        InnerLabel2 initialize
    InnerSkinnableContainer2 contentCreationComplete
    InnerSkinnableContainer2 initialize
OuterSkinnableContainer contentCreationComplete
OuterSkinnableContainer initialize
        InnerLabel2 creationComplete
        InnerLabel1 creationComplete
    InnerSkinnableContainer2 creationComplete
    InnerSkinnableContainer1 creationComplete
OuterSkinnableContainer creationComplete
```

Notice that for the terminal controls, such as the Label controls, the controls are preinitialized and then immediately initialized. For containers, preinitialization starts with the outermost container and works inward on the first branch, and then initialization works outward on the same branch. This process continues until all initialization is completed.

Then, the `creationComplete` event is dispatched first by the leaf components, and then by their parents, and so on, until the application dispatches the `creationComplete` event. The order of the `creationComplete` event is the most deeply nested components dispatch the event first, then the next most deeply nested, up to the application container. For components at the same nesting level, the order of the `creationComplete` events is undefined.

The `initialize` event is useful with a container that is an immediate child of a navigator container with the `ContainerCreationPolicy.AUTO` creation policy. For example, by default, when an MX ViewStack is initialized, the first visible child container dispatches an `initialize` event. Then, as the user moves to each additional child of the container, the event gets dispatched for that child container.

The following example defines an event listener for the `creationComplete` event, which is dispatched when the user first navigates to Pane 2 of an MX Accordion navigator container:

```
<?xml version="1.0"?>
<!-- containers\intro\AccordionInitEvent.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
            import mx.controls.Alert;
            public function pane2_initialize():void {
                Alert.show("Pane 2 has been created.");
            }
        ]]>
    </fx:Script>
    <mx:Accordion width="200" height="100" creationPolicy="auto">
        <mx:VBox id="pane1" label="Pane 1">
            <mx:Label text="This is pane 1."/>
        </mx:VBox>
        <mx:VBox id="pane2"
            label="Pane 2"
            creationComplete="pane2_initialize();">
            <mx:Label text="This is pane 2."/>
        </mx:VBox>
    </mx:Accordion>
</s:Application>
```

Disabling containers

All containers support the `enabled` property. By default, this property is set to `true` to enable user interaction with the container and with the container's children. If you set `enabled` to `false`, Flex dims the color of the container and of all its children, and blocks user input to the container and to all its children.

Defining a default button

You use the `defaultButton` property of a container to define a default Button control within a container. Pressing the Enter key while focus is on any control activates the Button control as if it was explicitly selected.

For example, a login form displays TextInput controls for a user name and password and a submit Button control. Typically, the user types a user name, tabs to the password field, types the password, and presses the Enter key to submit the login information without explicitly selecting the Button control. To define this type of interaction, set the `defaultButton` property of the Form control to the `id` of the submit Button control, as the following example shows:

```
<?xml version="1.0"?>
<!-- containers\intro\ContainerDefaultB.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            public function submitLogin():void {
                text1.text="You just tried to log in.";
            }
        ]]>
    </fx:Script>
    <s:Panel title="Default Button Example">
        <s:Form defaultButton="{mySubmitBtn}">
            <s:FormItem label="Username:">
                <s:TextInput id="username" width="100"/>
            </s:FormItem>
            <s:FormItem label="Password:">
                <s:TextInput id="password" width="100"
                    displayAsPassword="true"/>
            </s:FormItem>
            <s:FormItem>
                <s:Button id="mySubmitBtn" label="Login"
                    click="submitLogin();"/>
            </s:FormItem>
        </s:Form>
    </s:Panel>
    <s:Label id="text1" width="150"/>
</s:Application>
```

***Note:** The Enter key has a special purpose in the ComboBox control. When the drop-down list of a ComboBox control is open, pressing Enter selects the currently highlighted item in the ComboBox control; it does not activate the default button. Also, when the cursor is in a TextArea control, pressing Enter adds a newline; it does not activate the default button.*

Spark containers

Spark containers provide a hierarchical structure to arrange and configure their children.

Layout with Spark containers

Spark containers have a default layout scheme, but let you switch the layout to suit your application requirements. The layout classes are defined in the spark.layouts package, and include the following classes:

- BasicLayout   Use absolute positioning, or layout constraints.
- HorizontalLayout   Lay out children in a single horizontal row.
- TileLayout   Lay out children in multiple rows and columns.
- VerticalLayout   Lay out children in a single vertical column.

For example, the default layout of the Group container is BasicLayout, which means you must set the position of each container child. For the SkinnableContainer container, the default layout is BasicLayout. You can use any of the layout classes with the Spark containers.

For more information, see “Spark containers” on page 417.

Skinning Spark containers

The Spark Group, DataGroup, and BorderContainer containers do not support skinning. All other Spark containers support skinning so that you can control the visual aspects of the container.

For more information, see “Spark Skinning” on page 1602.

Scrolling Spark containers

The following example shows a Spark Group container that contains a child Image control:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkNoViewportNoSB.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:Group width="100" height="100">
        <s:Image width="300" height="400"
            source="@Embed(source='/assets/logo.jpg')"/>
    </s:Group>
</s:Application>
```

The size of the Image control is larger than that of its parent Group container. By default, the child extends past the boundaries of the parent container.

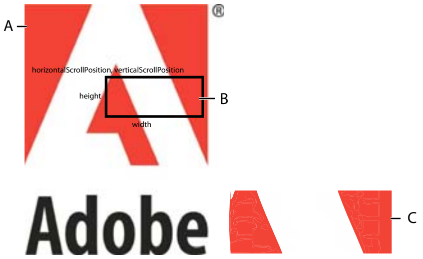
Rather than allow the child to extend past the boundaries of the parent container, you can clip the child to the container boundaries. With clipping enabled, you can control the part of the underlying image to show in the container. To clip the children to the container boundaries, use a viewport and scroll bars.

Configuring a Spark viewport

A viewport is any class that implements the IViewport interface. The Spark Group and DataGroup containers implement this interface, so they can function as viewports. All subclasses of Group and DataGroup can also function as viewports.

A viewport defines a logical content area that encompasses all of the children of the container. It also defines a rectangular area, called the visible window, of the logical content area. The visible window is the subset of the logical area of a container that you want to display.

The following figure shows a Group container with a child Image control that is larger than the area of the Group container:



A. Group container B. Area of the visible window C. Visible window of the Group container that appears in the application

The application user only sees that part of the container enclosed by the visible window.

You use the following properties of the Spark container to configure the viewport:

- `contentHeight` and `contentWidth` specify the size of the logical content area of the container. This is the area occupied by all of the container's children.
- `height` and `width` specify the size of the visible window of the container.
- `verticalScrollPosition` and `horizontalScrollPosition` specify the origin of the visible window in the container's coordinate system. The default value is (0,0) corresponding to the upper-left corner of the container.
- `clipAndEnableScrolling`, if `true`, specifies to clip the children to the boundaries of the container. If `false`, the container children extend past the container boundaries, regardless of the size specification of the container. The default value is `false`.

The following example sets the `clipAndEnableScrolling` property to `true` to clip the container's children to the container boundaries:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkViewport.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:Group width="100" height="100"
        clipAndEnableScrolling="true">
        <s:Image width="300" height="400"
            source="@Embed(source='/assets/logo.jpg')"/>
    </s:Group>
</s:Application>
```

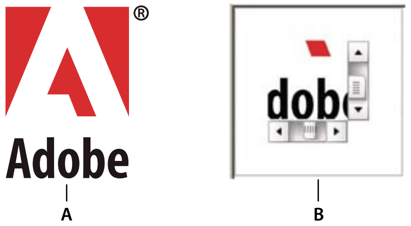
In this example, you set the `width` and `height` of the container, corresponding to the visible window, to 100 by 100 pixels.

By default, the visible window is located at the coordinates (0,0) in the container. Use the `verticalScrollPosition` and `horizontalScrollPosition` properties to set its location, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkViewportSet.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark" >
    <s:Group width="100" height="100"
        horizontalScrollPosition="50" verticalScrollPosition="50"
        clipAndEnableScrolling="true">
        <s:Image width="300" height="400"
            source="@Embed(source='/assets/logo.jpg')"/>
    </s:Group>
</s:Application>
```

Adding scroll bars to a Spark container

The visible window of a viewport on its own is not movable by the application user. However, you can combine a viewport with scroll bars so the user can scroll the visible window to see the entire container. Scroll bars let you display an object that is larger than the available screen space or display more objects than fit in the current size of the container, as the following image shows:



A. *Image at full size* *B.* *Image in a container with scroll bars*

Add scroll bars to Spark containers in the following ways:

- For viewport containers such as Group and DataGroup, add HScrollBar and VScrollBar components.
- For viewport containers such as Group and DataGroup, wrap the container in a Scroller component. The Scroller component displays a single child component with horizontal and vertical scroll bars.
- For any skinnable Spark container, create a skin for the container that uses the Scroller component. For information on creating a scrollable skin, see "Adding scroll bars to Spark containers" on page 1637.

In the following example, you add the HScrollBar and VScrollBar components to the application:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkScrollViewportSetSB.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark" >
    <s:layout>
        <s:HorizontalLayout/>
    </s:layout>

    <s:VGroup>
        <s:Group id="myGroup" width="100" height="100"
            clipAndEnableScrolling="true"
            horizontalScrollPosition="50" verticalScrollPosition="50">
            <s:Image width="300" height="400"
                source="@Embed(source='/assets/logo.jpg')"/>
        </s:Group>
        <s:HScrollBar viewport="{myGroup}" width="100"/>
    </s:VGroup>
    <s:VScrollBar viewport="{myGroup}" height="100"/>
</s:Application>
```

Use the `viewport` property of a scroll bar component to specify the viewport associated with it. In this example, you associate the myGroup container with the scoll bars. As you manipulate the HScrollBar component, it modifies the `horizontalScrollPosition` property of the group container. The VScrollBar component modifies the `verticalScrollPosition` property.

In the following example, you add scroll bars to the Spark Group container by wrapping the container in the Scroller component:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkScroll.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark" >

    <s:Scroller width="100" height="100">
        <s:Group>
            <s:Image width="300" height="400"
                source="@Embed(source='/assets/logo.jpg')"/>
        </s:Group>
    </s:Scroller>
</s:Application>
```

The Scroller component can only wrap a single component. The child of a Scroller tag must implement the IViewport interface, which is implemented by the Spark Group and DataGroup containers.

The Scroller component sets the `height` and `width` properties, rather than its child. Alternatively, you can omit the size settings on the Scroller component and let the application determine its size.

To ensure that scroll bars appear, do not set explicit sizes on the child of the Scroller. If you set the size of the child explicitly, then that size becomes the size of the child and no scroll bars appear. Instead, use constraints to size the Scroller (such as setting the `height` property to 100%).

If the Scroller is unconstrained, it sizes itself to be as big as the viewport. When you constrain the size of the Scroller a size smaller than the child, the Scroller displays scroll bars so that you can view the entire child.

Notice that the Group container did not set the `clipAndEnableScrolling` property to `true`. The Scroller component automatically sets the `clipAndEnableScrolling` property to `true` for any viewport within it. Scroll bars only appear if required by the viewport.

Use the `Scroller.ensureElementIsVisible()` method to scroll a component into view. Simply pass the component as an argument to the `ensureElementIsVisible()` method.

The default skin for the scroll bars defines the minimum height of a vertical scroll bar and the minimum width of a vertical scroll bar as 35 pixels. If the size of the scroll bar is less than 35 pixels, the thumb is hidden.

The default property of the Scroller tag is `viewport`. The previous example omits this tag, but you can specify it explicitly, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkScrollViewport.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:Scroller width="100" height="100">
        <s:viewport>
            <s:Group>
                <s:Image width="300" height="400"
                    source="@Embed(source='/assets/logo.jpg')"/>
            </s:Group>
        </s:viewport>
    </s:Scroller>
</s:Application>
```

You can combine scroll bars with explicit settings for the container's viewport. The viewport settings determine the initial position of the viewport, and then you can use the scroll bars to move it, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkScrollViewportSet.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark" >
    <s:Scroller width="100" height="100">
        <s:Group
            horizontalScrollPosition="50"
            verticalScrollPosition="50">
            <s:Image width="300" height="400"
                source="@Embed(source='/assets/logo.jpg')"/>
        </s:Group>
    </s:Scroller>
</s:Application>
```

Not all Spark containers implement the IViewPort interface. Therefore, those containers, such as the BorderContainer and SkinnableContainer containers, cannot be used as the direct child of the Scroller component.

However, all Spark containers can have a Scroller component as a child component. For example, to use scroll bars on a child of the Spark BorderContainer container, wrap the child in a Scroller component, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkScrollBorder.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark" >
    <s:BorderContainer width="100" height="100"
        borderWeight="3" borderStyle="solid">
        <s:Scroller width="100%" height="100%">
            <s:Group
                horizontalScrollPosition="50"
                verticalScrollPosition="50">
                <s:Image width="300" height="400"
                    source="@Embed(source='/assets/logo.jpg')"/>
            </s:Group>
        </s:Scroller>
    </s:BorderContainer>
</s:Application>
```

The previous example used the Scroller component to make a child of the BorderContainer container scrollable. To make the entire BorderContainer container scrollable, wrap it in a Group container. Then, make the Group container the child of the Scroller component, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkScrollBorderOuter.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark" >
    <s:Scroller width="100" height="100">
        <s:Group>
            <s:BorderContainer
                borderWeight="3" borderStyle="solid">
                    <s:Image width="300" height="400"
                        source="@Embed(source='/assets/logo.jpg')"/>
            </s:BorderContainer>
        </s:Group>
    </s:Scroller>
</s:Application>
```

MX containers

MX containers include layout containers and navigators. MX navigators can only take MX components as children.

Layout with MX containers

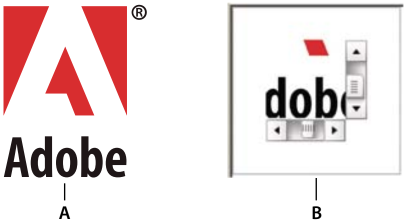
All MX containers have a predefined layout. Some containers, such as Application and Panel do let you switch among several possible layouts, but most containers do not. For example, the VBox container always lays out its children in a vertical column, and the Tile container always lays out its children multiple rows and columns.

Skinning MX containers

MX containers support skinning so that you can control the visual aspects of the container. For more information on skinning MX containers, see “Skinning MX components” on page 1655.

Scrolling MX containers

MX containers support automatic scroll bars, which let you display an object that is larger than the available screen space or display more objects than fit in the current size of the container, as the following image shows:



A. *Image at full size* ***B.*** *Image in an HBox container*

Automatic scroll bars appear by default when the container children are larger than the container, and the `clipContent` property of the container is `true`. The default value of `clipContent` is `true`.

In the following example, you use an HBox container to let users scroll an image, rather than rendering the complete image at its full size. In this example, you explicitly set the size of the HBox container to 75 by 75 pixels, a size smaller than the imported image. If you omit the sizing restrictions on the HBox container, it attempts to use its default size, which is a size large enough to hold the image:

```
<?xml version="1.0"?>
<!-- containers\intro\HBoxScroll.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <mx:HBox width="75" height="75">
        <mx:Image source="@Embed(source='assets/logo.jpg')"/>
    </mx:HBox>
</s:Application>
```

By default, Flex draws scroll bars only when the contents of a container are larger than that container. To force the container to draw scroll bars, you can set the `horizontalScrollPolicy` and `verticalScrollPolicy` properties to `on`.

Using container scroll properties

The following container properties and styles control scroll bar appearance and behavior:

- The `horizontalScrollPolicy` and `verticalScrollPolicy` properties control the display of scroll bars. By default, both properties are set to `auto`, which configures Flex to include scroll bars only when necessary. You can set these properties to `on` to configure Flex to always include scroll bars, or set the properties to `off` to configure Flex to never include scroll bars. In ActionScript, you can use constants in the ScrollPolicy class, such as `ScrollPolicy.ON`, to represent these values.
- The `horizontalLineScrollSize` and `verticalLineScrollSize` properties determine how many pixels to scroll when the user selects the scroll bar arrows. The `verticalLineScrollSize` property also controls the amount of scrolling when using the mouse wheel. The default value is five pixels.
- The `horizontalPageScrollSize` and `verticalPageScrollSize` properties determine how many pixels to scroll when the user selects the scroll bar track. The default value is 20 pixels.

  Note: *If the `clipContent` property is `false`, a container lets its child extend past its boundaries. Therefore, no scroll bars are necessary, and Flex never displays them, even if you set `horizontalScrollPolicy` and `verticalScrollPolicy` to `on`.*

Scroll bar layout considerations

Your configuration of scroll bars can affect the layout of your application. For example, if you set the horizontalScrollPolicy and verticalScrollPolicy properties to on, the container always includes scroll bars, even if they are not necessary. Each scroll bar is 16 pixels wide. Therefore, turning them on when they are not needed is similar to increasing the size of the right and bottom padding of the container by 16 pixels.

If you keep the default values of auto for the horizontalScrollPolicy and verticalScrollPolicy properties, Flex lays out the application as if the properties are set to off. That is, the scroll bars are not counted as part of the layout.

If you do not keep in mind this behavior, your application might have an inappropriate appearance. For example, if you have an HBox container that is 30 pixels high and 100 pixels wide and has two buttons that are each 22 pixels high and 40 pixels wide, the children are contained fully inside the HBox container, and no scroll bars appear. However, if you add a third button, the children exceed the width of the HBox container, and Flex adds a horizontal scroll bar at the bottom of the container. The scroll bar is 16 pixels high, which reduces the height of the content area of the container from 30 pixels to 14 pixels. This means that the Button controls, which are 22 pixels high, are too tall for the HBox, and Flex, by default, adds a vertical scroll bar.

Consider the following example:

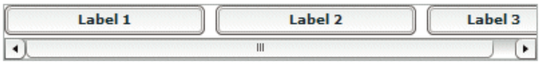
```
<?xml version="1.0"?>
<!-- components\ScrollHBox.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <mx:HBox width="400">
        <mx:Button label="Label 1"
            width="50%"
            minWidth="200"/>
        <mx:Button label="Label 2"
            width="40%"
            minWidth="150"/>
        <mx:Button label="Label 3"/>
    </mx:HBox>
</s:Application>
```

In this example, the default width of the fixed-size button is 66 pixels, so there are 324 pixels of space available for the percentage-based buttons after accounting for the gap between components. The minimum widths of the first and second buttons are greater than the percentage-based values, so Flex assigns those buttons the set widths of 200 and 150 pixels, even though the HBox container only has 324 pixels free. The HBox container uses scroll bars to provide access to its contents because they now consume more space than the container itself.

Notice that the addition of the scroll bar doesn’t increase the height of the container from its initial value. Flex considers scroll bars in its sizing calculations only if you explicitly set the scroll policy to ScrollPolicy.ON. So, if you use an auto scroll policy (the default), the scroll bar overlaps the buttons. To prevent this behavior, you can set the height property for the HBox container or allow the HBox container to resize by setting a percentage-based width. Remember that changing the height of the HBox container causes other components in your application to move and resize according to their own sizing rules. The following example adds an explicit height and permits you to see the buttons and the scroll bar:

```
<?xml version="1.0"?>
<!-- components\ScrollHBoxExplicitHeight.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <mx:HBox width="400" height="42">
        <mx:Button label="Label 1"
            width="50%"
            minWidth="200"/>
        <mx:Button label="Label 2"
            width="40%"
            minWidth="150"/>
        <mx:Button label="Label 3"/>
    </mx:HBox>
</s:Application>
```

Flex draws the following application:



Alternatively, you can set the HBox control’s `horizontalScrollPolicy` property to `ScrollPolicy.ON`. This reserves space for the scroll bar during the initial layout pass, so it fits without overlapping the buttons or setting an explicit height. This also correctly handles the situation where the scroll bars change their size when you change skinning or styles. This technique places an empty scroll bar area on the container if it does not need scrolling, however.

Controlling scroll delay and interval

Scroll bars have two styles that affect how they scroll:

- The `repeatDelay` style specifies the number of milliseconds to wait after the user selects a scroll button before repeating scrolling.
- The `repeatInterval` style specifies the number of milliseconds to wait between each repeated scroll while the user keeps the scroll arrows selected.

  These settings are styles of the scroll bar subcontrol, not of the container, and, therefore, require a different treatment than properties such as `horizontalScrollPolicy`. The following example sets the scroll policy consistently for all scroll bars in the application:

```
<?xml version="1.0"?>
<!-- containers\intro\HBoxScrollDelay.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Style>
        @namespace s "library://ns.adobe.com/flex/spark";
        @namespace mx "library://ns.adobe.com/flex/mx";
        mx|HScrollBar, mx|VScrollBar {
            repeatDelay: 2000;
            repeatInterval:1000;
        }
    </fx:Style>
    <mx:HBox id="hb1" width="75" height="75">
        <mx:Image source="@Embed(source='assets/logo.jpg')"/>
    </mx:HBox>
</s:Application>
```

This example results in the same scrollable logo as shown in “Scrolling MX containers” on page 343, but the scroll bars behave differently. When the user clicks and holds the mouse button down over any of the scroll bar arrows or the scroll bar track, the image initially scrolls once, waits two seconds, and then scrolls at a rate of one line or page a second.

To set a style on a single scroll bar, use a line such as the following in the event listener for the `initialize` event for the application or the control with the scroll bar:

```
ScrollBar(hb1.horizontalScrollBar).setStyle("repeatDelay", 2000);
```

In this case, `hb1` is an HBox control. All containers have `horizontalScrollBar` and `verticalScrollBar` properties that represent the container’s ScrollBar subcontrols, if they exist. Cast these properties to the ScrollBar class, because their type is the IScrollBar interface, not the ScrollBar class.

Creating and managing container children at run time

You typically use MXML to lay out the user interface of your application, and use ActionScript for event handling and run-time control of the application. You can also use ActionScript to create component instances at run time. For example, you could use MXML to define an empty Accordion container and use ActionScript to add panels to the container in response to user actions.

About the display list and container children

Flash Player maintains a tree of visible (or potentially visible) objects that make up your application. The root of the tree is the Spark Application or MX Application object, and child containers and components are branches and leaf nodes of the tree. That tree is known as the *display list*. When you add child components to a container or remove child components from a container, you are adding and removing them from the display list. You can also change their relative positions by changing their positions in the display list.

Although the display list is a tree rooted at the top of the application, when you manipulate a container’s children by ’s methods and properties, you only access the container’s direct children. Treat the container’s children as items in a list, where the first child has an index of 0.

Using the container API for managing container children

Spark Group and SkinnableContainer containers, and all MX containers, provide properties and methods that you use to manage the container’s children. Because the Spark Group and SkinnableContainer containers can hold many types of children, the methods that you use to manipulate its children refer to the children by a generic name of *element*.

Note: *This section does not apply to the Spark DataGroup and Spark SkinnableDataContainer. Those containers use a data provider to define their children. You manage the children of those containers in the same way that you manage any data provider control. For more information, see "Data providers and collections" on page 898 and "The Spark DataGroup and Spark SkinnableDataContainer containers" on page 466.*

The following table shows these properties and methods:

Spark container	**MX container**	**Description**
`numElements`	`numChildren`	Number of children in the container.
`addElement()`	`addChild()`	Adds a child to the container as the last child.
`addElementAt()`	`addChildAt()`	Add a child at a specific index in the container.
	`getChildren()`	Returns an Array containing all children.
`getElementAt()`	`getChildAt()`	Return a child at the specified index.
	`getChildByName()`	Return a child with the specified id.
`getElementIndex()`	`getChildIndex()`	Returns the index of a child.
`removeAllElements()`	`removeAllChildren()`	Removes all container children.
`removeElement()`	`removeChild()`	Remove the first child.
`removeElementAt()`	`removeChildAt()`	Remove the child at the specified index
`setElementIndex()`	`setChildIndex()`	Set the index of a child.
`swapElements()`	`swapChildren()`	Swap the indexes of two children
`swapElementsAt()`	`swapChildrenAt()`	Swap the indexes of two children.

Note: *Make sure that you use the correct method for your type of container, either Spark or MX. Using the wrong method can cause unexpected results.*

Obtaining the number of child components in a container or application

Use the `numElements` or `numChildren` property to obtain a count of the number of direct child components that the container has in the display list. The following application gets the number of children in the application and a Group container. The Group control has five label controls, and therefore has five children. The Application container has the Group and Button controls as its children, and therefore has two children.

```
<?xml version="1.0"?>
<!-- containers\intro\VBoxNumChildren.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
      <![CDATA[
            // Import the Alert class.
            import mx.controls.Alert;

            public function calculateChildren():void {
                var myText:String = new String();
                myText="The Group container has " +
                    myGroup.numElements + " children.";
                myText+="\nThe application has " +
                    numElements + " children.";
                Alert.show(myText);
            }
        ]]>
    </fx:Script>
    <s:VGroup id="myGroup">
        <s:Label text="This is label 1."/>
        <s:Label text="This is label 2."/>
        <s:Label text="This is label 3."/>
        <s:Label text="This is label 4."/>
        <s:Label text="This is label 5."/>
    </s:VGroup>

    <s:Button label="Show Children" click="calculateChildren();"/>
</s:Application>
```

In the main MXML application file, the file that contains the `<s:Application>` tag, the current scope is always the Application object. Therefore, the reference to the `numElements` property without an object prefix refers to the `numElements` property of the Application object. For more information on accessing the root application, see “About scope” on page 42.

Accessing display-only children

The MX Container class defines the `rawChildren` property that contains the full display list of all the children of a container. This list includes all the container’s children, plus the DisplayObjects that implement the container’s *chrome* (display elements), such as its border and the background image.

The `numChildren` property and accessor methods let you count and access only child components. However, the container might contain style elements and skins, such as the border and background. The container’s `rawChildren` property lets you access all children of a container, including the component “content children” and the skin and style “display children.” The object returned by the `rawChildren` property implements the IChildList interface. You then use methods and properties of this interface, such as `getChildAt()`, to access and manipulate all the container’s children.

Creating and removing components at run time

To create a component instance at run time, you define it, set any properties, and then add it as a child of a parent container by calling the `addElement()` or `addChild()` method on the parent container.

The `addElement()` method has the following signature:

```
addElement(element:IVisualElement):IVisualElement
```

The `element` argument specifies the component to add to the container.

The `addChild()` method has the following signature:

```
addChild(child:DisplayObject):DisplayObject
```

The `child` argument specifies the component to add to the container.

***Note:** Although the `child` argument of the `addChild()` method is specified as type DisplayObject, the argument must implement the IUIComponent interface to be added as a child of a container. All Flex components implement this interface.*

For example, the following application creates a Group container with an Button control called myButton:

```
<?xml version="1.0"?>
<!-- containers\intro\ContainerAddChild.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
            import spark.components.Button;
            public function addButton():void {
                var myButton:Button = new Button();
                myButton.label = "New Button";
                myGroup.addElement(myButton);
            }
        ]]>
    </fx:Script>
    <s:Group id="myGroup" initialize="addButton();"/>
</s:Application>
```

This example creates the control when the application is loaded rather than in response to any user action. However, you could add a new button when the user presses an existing button, as the following example shows:

```
<?xml version="1.0"?>
<!-- containers\intro\ContainerAddChild2.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
            import spark.components.Button;
            public function addButton():void {
                var myButton:Button = new Button();
                myButton.label = "New Button";
                myGroup.addElement(myButton);
            }
        ]]>
    </fx:Script>
    <s:HGroup id="myGroup">
        <s:Button label="Add Button" click="addButton();"/>
    </s:HGroup>
</s:Application>
```

You use the `removeElement()` or `removeChild()` method to remove a control from a container. If the child is no longer referenced anywhere else in your application after the call, it gets destroyed by a garbage collection process. The following example removes a button from the application when the user presses it:

```
<?xml version="1.0"?>
<!-- containers\intro\ContainerRemoveChild.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            public function removeButton():void {
                myGroup.removeElement(myButton);
            }

            private function resetApp():void {
                if (myGroup.numElements == 0) {
                    myGroup.addElement(myButton);
                }
            }
        ]]>
    </fx:Script>
    <s:Group id="myGroup">
        <s:Button id="myButton"
            label="Remove Me"
            click="removeButton();"/>
    </s:Group>
    <s:Button label="Reset" click="resetApp();"/>
</s:Application>
```

For additional methods that you can use with container children, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Example: Creating and removing a child of a container

The following example uses MXML to define a container that contains two Button controls. You use one Button control to add an CheckBox control to the container, and one Button control to delete it.

```
<?xml version="1.0"?>
<!-- containers\intro\ContainerComponentsExample.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <fx:Script>
      <![CDATA[
        // Import the CheckBox class.
        import spark.components.CheckBox;
        // Define a variable to hold the new CheckBox control.
        private var myCheckBox:CheckBox;

        // Define a variable to track if the CheckBox control
        // is in the display list.
        private var checkBoxDisplayed:Boolean = false;

        public function addCB():void {
            // Make sure the check box isn't being displayed.
            if(checkBoxDisplayed==false){
                // Create the check box if it does not exist.
                if (!myCheckBox) {
                    myCheckBox = new CheckBox();
                    myCheckBox.label = "New CheckBox";
                }
                // Add the check box.
                myGroup.addElement(myCheckBox);
                checkBoxDisplayed=true;
            }
        }

        public function delCB():void {
            // Make sure a CheckBox control exists.
            if(checkBoxDisplayed){
                myGroup.removeElement(myCheckBox);
                checkBoxDisplayed=false;
            }
        }
      ]]>
    </fx:Script>
    <s:VGroup id="myGroup">
        <s:Button label="Add CheckBox"
            click="addCB();"/>
        <s:Button label="Remove CheckBox"
            click="delCB();"/>
    </s:VGroup>
</s:Application>
```

Example: Creating and removing children of an Accordion container

The following example adds panels to and removes them from an MX Accordion container. The Accordion container initially contains one panel. Each time you select the Add HBox button, it adds a new HBox container to the Accordion container.

***Note:** MX navigators can only take MX containers and the Spark NavigatorContent container as children. You cannot use other Spark containers as direct children of a navigator container. Instead, wrap the Spark container in an MX container on in a Spark NavigatorContent container when adding the Spark container to a navigator.*

```
<?xml version="1.0"?>
<!-- containers\intro\ContainerComponentsExample2.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
            /* Import HBox class. */
            import mx.containers.HBox;

            /* Array of created containers. */
            private var myHBoxes:Array = [];
            public function addHBox():void {
                /* Create new HBox container. */
                var newHBox:HBox = new HBox();
                newHBox.label="Label: " + String(myHBoxes.length);
                /* Add it to the Accordion container, and to the
                   Array of HBox containers. */
                myHBoxes.push(myAcc.addChild(newHBox));
            }
            public function delHBox():void {
                /* If there is at least one HBox container in the Array,
                   remove it. */
                if (myHBoxes.length>= 1) {
                    myAcc.removeChild(myHBoxes.pop());
                }
            }
      ]]>
    </fx:Script>
    <s:VGroup>
        <mx:Accordion id="myAcc" height="150" width="150">
            <mx:HBox/>
        </mx:Accordion>

        <s:Button label="Add HBox" click="addHBox();"/>
        <s:Button label="Remove HBox" click="delHBox();"/>
    </s:VGroup>
</s:Application>
```

Controlling child order

You can control the order of children by adding them in a specific order. You can also control them as follows:

- By using the `addElementAt()` or `addChildAt()` method to specify where among the component's children to add a child

  ***Note:** As with the `addChild()` method, although the `child` argument of the `addChildAt()` method is specified as type DisplayObject, the argument must implement the IUIComponent interface to be added as a child of a container. All Flex components implement this interface.*

- By using the `setElementAt()` or `setChildIndex()` method to specify the location of a specific child among a component's children in the display list

The following example modifies the previous example. It uses the `addElementAt()` method to add the CheckBox control as the first child (index 0) of the VGroup. It also has a Reorder children button that uses the `setChildIndex()` method to move a CheckBox control down the display list until it is the last child in the VGroup container.

```
<?xml version="1.0"?>
<!-- containers\intro\ContainerComponentsReorder.mxml -->

    </s:VGroup>
</s:Application>
```

Flex coordinate systems

In your application, you might have to determine the location of a component, or modify its location at run time. Adobe Flash and Flex support three coordinate systems for different purposes:

- global
- local
- content

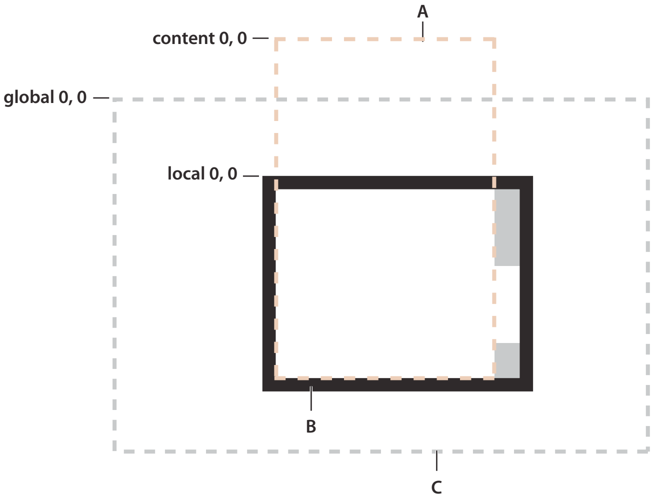
You can use Flex properties and methods to convert between coordinate systems.

About the coordinate systems

The following table describes the coordinate systems:

Coordinate system	Description
global	Coordinates are relative to the upper-left corner of the Stage in Adobe Flash Player and Adobe® AIR™, that is, the outermost edge of the application. The global coordinate system provides a universal set of coordinates that are independent of the component context. Uses for this coordinate system include determining distances between objects and as an intermediate point in converting between coordinates relative to a subcontrol into coordinates relative to a parent control. The MouseEvent class includes `stageX` and `stageY` properties that are in the global coordinate system.
local	Coordinates are relative to the upper-left corner of the component. Flex uses the local coordinate system for mouse pointer locations; all components have `mouseX` and `mouseY` properties that use the local coordinate system. The MouseEvent class includes localX and localY properties that are in the local coordinate system. Also, the Drag Manager uses local coordinates in drag-and-drop operations. The `doDrag()` method's `xOffset` and `yOffset` properties, for example, are offsets relative to the local coordinates.
content	Coordinates are relative to the upper-left corner of the component's content. Unlike the local and global coordinates, the content coordinates include all the component's content area, including any regions that are currently clipped and must be accessed by scrolling the component. Thus, if you scrolled down a Canvas container by 100 pixels, the upper-left corner of the visible content is at position 0, 100 in the content coordinates. You use the content coordinate system to set and get the positions of children of a container that uses absolute positioning. (For more information on absolute positioning, see "About component positioning" on page 361.) The UIComponent `contentMouseX` and `contentMouseY` properties report the mouse pointer location in the content coordinate system.

The following image shows these coordinate systems and how they relate to each other.



***A.** Content bounds* ***B.** Component bounds* ***C.** Stage bounds*

Using coordinate properties and methods

In some cases, you have to convert positions between coordinate systems. Examples where you convert between coordinates include the following:

- The MouseEvent class has properties that provide the mouse position in the global coordinate system and the local coordinates of the event target. You use the content coordinates to specify the locations in any container that uses absolute positioning, such as an MX Canvas container or a Spark container that uses the BasicLayout class. To determine the location of the mouse event within the Canvas container contents, not just the visible region, determine the position in the content coordinate system.

- Custom drag-and-drop handlers might have to convert between the local coordinate system and the content coordinate system when determining an object-specific drag action; for example, if you have a control with scroll bars and you want to know the drag (mouse) location over the component contents. The example in "Example: Using the mouse position in a Canvas container" on page 357 shows this use.
- Custom layout containers, where you include both visual elements, such as scroll bars or dividers, and content elements. For example, if you have a custom container that draws lines between its children, you have to know where each child is in the container's content coordinates to draw the lines.

Often, you use mouse coordinates in event handlers; when you do, you should keep in mind the following considerations:

- When you handle mouse events, it is best to use the coordinates from the MouseEvent object whenever possible, because they represent the mouse coordinates at the time the event was generated. Although you can use the container's `contentMouseX` and `contentMouseY` properties to get the mouse pointer locations in the content coordinate system, you should, instead, get the local coordinate values from the event object and convert them to the content coordinate system.
- When you use local coordinates that are reported in an event object, such as the MouseEvent `localX` and `localY` properties, remember that the event properties report the local coordinates of the mouse relative to the event target. The target component can be a subcomponent of the component in which you determine the position, such as a UITextField inside a Button component, not the component itself. In such cases, convert the local coordinates into the global coordinate system first, and then convert the global coordinates into the content coordinates container.

All Flex components provide read-only properties and methods that enable you to use and convert between coordinate systems. The following table describes these properties and methods:

Property or method	**Description**
`contentMouseX`	Returns the *x* position of the mouse, in the content coordinates of the component.
`contentMouseY`	Returns the *y* position of the mouse, in the content coordinates of the component.
`contentToGlobal (point:Point):Point`	Converts a Point object with *x* and *y* coordinates from the content coordinate system to the global coordinate system.
`contentToLocal (point:Point):Point`	Converts a Point object from the content coordinate system to the local coordinate system of the component.
`globalToContent (point:Point):Point`	Converts a Point object from the global coordinate system to the content coordinate system of the component.
`globalToLocal (point:Point):Point`	Converts a Point object from the global coordinate system to the local coordinate system of the component.
`localToContent (point:Point):Point`	Converts a Point object from the local coordinate system to the content coordinate system of the component.
`localToGlobal (point:Point):Point`	Converts a Point object from the local coordinate system to the global coordinate system.

Example: Using the mouse position in a Canvas container

The following example shows the use of the `localToGlobal()` and `globalToContent()` methods to determine the location of a mouse pointer within a Canvas container that contains multiple child Canvas containers.

This example is artificial, in that production code would use the MouseEvent class `stageX` and `stageY` properties, which represent the mouse position in the global coordinate system. The example uses the `localX` and `localY` properties, instead, to show how you can convert between local and content coordinates, including how first converting to using the global coordinates ensures the correct coordinate frame of reference.

```
<?xml version="1.0"?>
<!-- containers\intro\MousePosition.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <fx:Script>
        <![CDATA[
          import mx.controls.Alert;
          // Handle the mouseDown event generated
          // by clicking in the application.
          private function handleMouseDown(event:MouseEvent):void {

            // Convert the mouse position to global coordinates.
            // The localX and localY properties of the mouse event contain
            // the coordinates at which the event occurred relative to the
            // event target, typically one of the
            // colored internal Canvas containers.
            // A production version of this example could use the stageX
            // and stageY properties, which use the global coordinates,
            // and avoid this step.
            // This example uses the localX and localY properties only to
            // illustrate conversion between different frames of reference.
            var pt:Point = new Point(event.localX, event.localY);
            pt = event.target.localToGlobal(pt);

            // Convert the global coordinates to the content coordinates
            // inside the outer c1 Canvas container.
            pt = c1.globalToContent(pt);

            // Figure out which quadrant was clicked.
            var whichColor:String = "border area";

            if (pt.x < 150) {
                if (pt.y < 150)
                    whichColor = "red";
                else

```

Laying out components

Adobe® Flex™ lays out components by determining their sizes and positions; it provides you with multiple options for controlling both size and position.

About sizing and positioning

Component layout has two parts: component sizing and component positioning. Flex controls the layout of components by using a set of rules. These layout rules are a combination of sizing rules for individual components, and sizing and positioning rules for containers.

Because Flex defines default layout rules, you often do not have to set the size or position of components. Instead, you can concentrate on building the logic of your application and let Flex control the layout.

While Flex has default layout rules, you can use the component's properties and methods to customize the layout. For example, all components have several properties, including `height` and `width`, for specifying the component's size in absolute or container-relative terms.

Each container also has properties and styles that you can use to configure aspects of layout. You can also use different positioning techniques for laying out components in a container. For example, some containers support absolute *x*- and *y*-coordinate–based positioning.

About layout with Spark and MX containers

While the sizing and layout rules for Spark and MX containers are almost identical, there are a few differences between the two types of containers:

- Spark containers let you specify the layout class assigned to the container, such as BasicLayout, HorizontalLayout, VerticalLayout, and TileLayout.

  MX containers have a predefined layout built in to the class. Therefore, the MX VBox container always lays out its children in a vertical column, and the MX Tile container always lays out its children in rows and columns. The only exceptions to this rule are the MX Application and MX Panel containers. These containers let you switch among absolute, vertical, and horizontal layout.

- Spark containers use properties on the layout class to control the layout of the container. For example, use the `TileLayout.verticalGap` and `TileLayout.horizontalGap` properties to set the gaps between children of a Spark container that uses the TileLayout class.

  MX containers use properties and styles of the container class. Therefore, to set the gaps for a MX container, set the `verticalGap` and `horizontalGap` styles on the container.

About the Layout Manager

The Layout Manager controls layout in Flex. The manager uses the following three-stage process to determine the size and position of each component in an application:

Stage 1 - Commitment pass Determines the property settings of the application's components. This pass allows components whose contents depend on property settings to configure themselves before Flex determines their sizes and positions.

During the commitment pass, the Layout Manager causes each component to run its `commitProperties()` method, which determines the property values.

Stage 2 - Measurement pass Calculates the default size of every component in the application. This pass starts from the most deeply nested components and works out toward the application container.

The measurement pass determines the *measured*, or default, size of each component. The default size of each container is based on the default or explicit (if specified) sizes of its children. For example, an SkinnableContainer that uses the HorizontalLayout class has a default width equal to the sum of the default or explicit widths of all its children, plus the thickness of the borders, any padding, and the gaps between the children.

During the measurement pass, the Layout Manager causes each component to call its `measure()` method to determine the component's default size. All sizing properties are calculated before Flex applies any transform to the component, such as a rotation, skew, or other transform.

Stage 3 - Layout pass Lays out your application, including moving and resizing any components. This pass starts from the outermost container and works in toward the innermost component. The layout pass determines the actual size and placement of each component. It also does any programmatic drawing, such as calls to the `lineTo()` or `drawRect()` methods.

The Layout Manager causes each component to run its `updateDisplayList()` method to lay out the component's children; for this reason, this pass is also referred to as the update pass.

When lay out occurs

Flex lays out components when your application initializes. Flex also performs a layout pass when the application or a user does something that affects the sizes or positions of visual elements, including the following:

- The application changes properties that specify sizing or positioning, such as `x`, `y`, `width`, `height`, `scaleX`, `scaleY`, `rotationX`, `rotationY`, and the transform matrix.

- A change affects the calculated width or height of a component, such as when the label text for a Button control changes, or the user resizes a component.
- A child is added or removed from a container, a child is resized, or a child is moved. For example, if your application can change the size of a component, Flex updates the layout of the container to reposition its children, based on the new size of the child.
- A property or style that requires measurement and drawing, such as the `fontFamily`, changes.

Manually forcing layout

Sometimes, you might have to programmatically cause Flex to update application layout. Situations where you must force a layout include the following:

- When printing multiple page data grids by using the PrintDataGrid class.
- Before playing an effect, if the start values have just been set on the target.
- When capturing bitmap data after making property changes.

To force a layout, call the `validateNow()` method of the component to lay out. This method causes Flex to validate and update the properties, sizes, and layout of the object and all its children, and to redraw them, if necessary. Because this method is computation-intensive, be careful to call it only when it is necessary.

About component sizing

Flex provides several ways for you to control the size of controls and containers:

Default sizing Flex automatically determines the sizes of controls and containers.

Explicit sizing You set the `height` and `width` properties of the component to absolute values.

Percentage-based sizing You specify the component size as a percentage of its parent container's size.

Constraint-based layout You control size and position by anchoring component's sides to locations in their container.

For details on controlling component sizes, see "Sizing components" on page 365.

About component positioning

Flex provides two mechanisms for positioning controls:

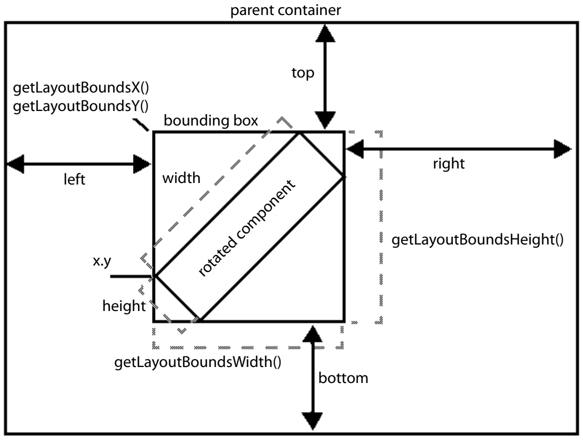
Automatic positioning Flex automatically positions a container's children according to a set of container- and component-specific rules. Most containers use automatic positioning. Automatic positioning is sometimes referred to as automatic layout. One of the differences between Spark and MX containers is that the layout algorithm for MX containers is fixed, but for Spark containers it is selectable by changing the container's `layout` property.

Absolute positioning You specify each child's `x` and `y` properties, or use a constraint-based layout that specifies the distance between one or more of the container's sides and the child's sides, baseline, or center. Absolute positioning is sometimes referred to as absolute layout. Spark containers with a layout of BasicLayout and the MX Canvas container use absolute layout. You can also choose absolute layout for the MX Application and Panel containers.

For details on controlling the positions of controls, see "Positioning components" on page 379.

About basic layout properties and methods

While Flex provides many properties that you can use to control and monitor component layout, there are a few that you use frequently. The following figure shows these properties and methods:



This figure shows how Flex lays out a component in its parent container. The `x`, `y`, `height`, and `width` properties of the component determine its size before any skins or transformations are applied to it. These are properties that you can set when defining your application.

After Flex applies any skins or transformations to the component, Flex uses the rectangular area, called the *bounding box*, to position the component in its parent container. The bounding box defines the rectangular are taken up by the component in its parent container. In the absence of any skin or transformation, the size of the bounding box is the same as the height and width of the component.

A graphical component, such as Ellipse and Rect, can define a stroke for their border. If the component defines a stroke, the center of the stroke runs along the outer edge of the component. For example, if you define a two-pixels wide border, the border appears in the area one-pixel outside the component to one-pixel inside the component. The border has to fit completely within the bounding box. Therefore, the upper-left corner of the component might be offset from the edge of the bounding box to accommodate the border.

The following table describes the basic component layout properties and methods:

Property or method	Description
`x`, `y`	The x and y coordinate of the upper-left corner of the component in the parent container. You can set these properties for the children of a container that use absolute layout. Otherwise, Flex calculates these values for you.
`height`, `width`	The height and width of the component. You can set these properties as a pixel value or as a percent of the size of the parent container. Otherwise, Flex calculates these values for you.
`top`, `bottom`, `left`, `right`	The distances between the sides of the component and sides of the parent container. Use these properties when performing constraint-based layout. Only containers that use absolute layout support constraint-based layout. For more information, see "Using constraints to control component layout" on page 384.
`getLayoutBoundsX()`, `getLayoutBoundsY()`	The x and y coordinates of the bounding box of the component in the parent container after any skins and transformations have been applied to the component.
`getlayoutBoundsHeight()`, `getLayoutBoundsWidth()`	The height hand width of the bounding box of the component in the parent container after any skins and transformations have been applied to the component. \

Basic layout rules and considerations

Flex performs layout according to the following basic rules. If you remember these rules, you should be able to easily understand the details of Flex layout. These rules help you determine why Flex lays out your application as it does and to determine how to modify your application appearance.

For a detailed description of how Flex sizes components, see “Determining and controlling component sizes” on page 367. For detailed information on component positioning, see “Positioning components” on page 379.

- Flex first determines all components’ measured (default) or explicitly set sizes *up*, from the innermost child components to the outermost (Application) component. This is done in the measurement pass.
- After the measurement pass, Flex determines all percentage-based sizes and constraints applied to the components. Flex then lays out components *down*, from the outermost container to the innermost components. This is done in the layout pass.
- Sizes that you set to a pixel value are mandatory and fixed, and override any maximum or minimum size specifications that you set for the component.
- The default sizes determined in the measurement pass specify the sizes of components that do not have explicit or percentage-based sizes (or use constraint-based layout), and are fixed.
- Percentage-based size specifications are advisory, and are relative to the size of the parent container. The layout algorithms satisfy the request if possible, and use the percentage values to determine proportional sizes, but the actual sizes can be less than the requested sizes. Percentage-based sizes are always within the component’s maximum and minimum sizes, and, subject to those bounds, don’t cause a container’s children to exceed the container size.

Component layout patterns

Flex uses different patterns to lay out different containers and their children. These patterns generally fit in the type categories listed in the following table. The table describes the general layout behavior for each type, how the default size of the container is determined, and how Flex sizes percentage-based children.

Pattern	**Container type**	**Default layout behavior**
Absolute positioning	Spark container using BasicLayout MX Canvas container or Application or Panel container with `layout="absolute"`	**General layout:** Children of the container do not interact. That is, children can overlap and the position of one child does not affect the position of any other child. You specify the child positions explicitly or use constraints to anchor the sides, baselines, or centers of the children relative to the parent container. **Default sizing:** The measurement pass finds the child with the lowest bottom edge and the child with the rightmost edge, and uses these values to determine the container size. **Percentage-based children:** Sizing uses different rules depending on whether you use constraint-based layout or *x*- and *y*- coordinate positioning. See "Flex component sizing techniques" on page 371.
Containers that arrange children linearly	Spark containers using HorizontalLayout or VerticalLayout MX Box, DividedBox, Form, Panel, TitleWindow containers	**General layout:** All children of the container are arranged in a single row or column. Each child's height and width can differ from all other children's heights or widths. **Default sizing:** The container fits the default or explicit sizes of all children and all gaps, borders, and padding. **Percentage-based children:** If children with percentage-based sizing request more than the available space, the actual sizes are set to fit in the space, proportionate to the requested percentages.

Pattern	**Container type**	**Default layout behavior**
Grid	MX Grid container	**General layout:** A container with a vertical layout of rows. Each row is a container with a horizontal layout of child controls, where all items are constrained to align with each other. The heights of all the cells in a single row are the same, but each row can have a different height. The widths of all cells in a single column are the same, but each column can have a different width. You can define a different number of cells for each row or each column of the Grid container, and individual cells can span columns or rows. **Default sizing:** The grid fits the individual rows and children at their default sizes. **Percentage-based children:** If children use percentage-based sizing, the sizing rules fit the children GridItem components within their rows, and GridRow components within the grid size according to linear container sizing rules.
Tile	Spark container using TileLayout MX Tile container	**General layout:** The container is a grid of equal-sized cells. The cells can be in row-first or column-first order. For MX, if you do not specify explicit or percentage-based dimensions, the container has as close as possible to an equal number of rows and columns, with the `direction` property determining the orientation with the larger number of items, if necessary. For Spark, if you do not specify explicit or percentage-based dimensions, the container arranges the rows and columns so that the container has an equal height and width. The `orientation` property determining the orientation with the larger number of items, if necessary. **Default sizing:** If you do not specify `tileWidth` and `tileHeight` properties (MX Tile container) or `columnWidth` and `rowHeight` (Spark Tile layout), the container uses the measured or explicit size of the largest child cell for the size of each child cell. **Percentage-based children:** The percentage-based sizes of a child component specify a percentage of the individual cell, not of the Tile container.
Navigators	MX ViewStack, Accordion, and TabNavigator containers	**General layout:** The container displays one child at a time. **Default sizing:** The container size is determined by the measured or explicit dimensions of the initially selected child, and thereafter, all children are forced to be that initial size. If you set the `resizeToChild` property to `true` the container resizes to accommodate the measured or explicit size of each child, as that child appears. **Percentage-based children:** As a general rule, you either use 100% for both height and width, which causes the children to fill the navigator bounds, or do not use percentage-based sizing.

Sizing components

Flex provides several ways for controlling the size of components. You can do the following tasks:

- Let Flex automatically determine component sizes.
- Specify pixel sizes.

- Specify component size as a percentage of the parent container.
- Combine layout and sizing by specifying a constraint-based layout.

Several Flex properties affect the size of components. As a rule, you use only a few properties for most applications, but a more complete understanding of these properties can help you understand the underlying Flex sizing mechanism and how Flex sizing properties interrelate. For information on the rules that Flex applies to determine the sizes of components based on the properties, see “Determining and controlling component sizes” on page 367.

For information on constraint-based layout, see “Using constraints to control component layout” on page 384.

Commonly used sizing properties

You typically use the following properties to specify how a component is sized:

- The `height`, `width`, `percentHeight`, and `percentWidth` properties specify the height and width of a component. In MXML tags, you use the `height` and `width` properties to specify the dimensions in pixels or as percentages of the parent container size. In ActionScript, you use the `height` and `width` properties to specify the dimensions in pixels, and use the `percentHeight` and `percentWidth` properties to specify the dimensions as a percentage of the parent container.
- The `minHeight`, `minWidth`, `maxHeight`, and `maxWidth` properties specify the minimum and maximum dimensions that a component can have if Flex determines the component size. These properties have no effect if you explicitly set the width or height in pixels.

The following characteristics and their associated properties determine the size of the component:

Characteristic	Associated properties	Description
Actual dimensions	`height`, `width`	The height and width of the displayed control, in pixels, as determined by the layout pass. If you set any explicit values, they determine the corresponding actual values.
Explicit dimensions	`explicitHeight`, `explicitWidth` Setting the `height` and `width` properties to integer values also sets the `explicitHeight` and `explicitWidth` properties.	A dimension that you set as a number of pixels. These dimensions cannot be overridden. Application developers typically use the `height` and `width` properties to set explicit dimensions. You cannot have both an explicit dimension and a percentage-based dimension; setting one unsets the other.
Percentage-based dimensions	`percentHeight`, `percentWidth` In MXML tags only, setting the `height` and `width` properties to percentage string values, such as “50%”, also sets the `percentHeight` and `percentWidth` properties.	A dimension that you set as a number in the range 0-100, as a percentage of the viewable area of the parent container. If you set a percentage-based dimension, the component is resizable, and grows or shrinks if the parent dimension changes.
Default dimensions	`measuredHeight`, `measuredWidth`	Not used directly by application developers. The dimensions of the component, as determined by the `measure()` method of the component. These values cannot be outside the range determined by the component’s maximum and minimum height and width values.

The following characteristics determine the minimum and maximum *default* and *percentage-based* dimensions that a component can have. They *do not* affect values that you set explicitly or, for MX containers only, dimensions determined by using constraint-based layout.

Characteristic	**Associated Properties**	**Description**
Minimum dimensions	`minHeight`, `minWidth` Setting the explicit minimum dimensions also sets the `minHeight` and `minWidth` properties.	The minimum dimensions a component can have. By default, Flex sets these dimensions to the values of the minimum default dimensions.
Maximum dimensions	`maxHeight`, `maxWidth` Setting the explicit maximum dimensions also sets the `maxHeight` and `maxWidth` properties.	The maximum dimensions a component can have. The default values of these properties are component-specific, but often are 10000 pixels.
Minimum default dimensions	`measuredMinHeight`, `measuredMinWidth`	Not used by application developers. The minimum valid dimensions, as determined by the `measure()` method. The default values for these properties are component-specific; for many controls, the default values are 0.

Basic sizing rules

The following rules describe how you can use Flex sizing properties to specify the size of a component:

- Any dimension property that you set overrides the corresponding default value; for example, an explicitly set `height` property overrides any default height.
- Setting the `width`, `height`, `maxWidth`, `maxHeight`, `minWidth`, or `minHeight` property to a pixel value in MXML or ActionScript also sets the corresponding explicit property, such as `explicitHeight` or `explicitMinHeight`.
- The explicit height and width and the percentage-based height and width are mutually exclusive. Setting one value sets the other to `NaN`; for example, if you set `height` or `explicitHeight` to 50 and then set `percentHeight` to 33, the value of the `explicitHeight` property is `NaN`, not 50, and the `height` property returns a value that is determined by the `percentHeight` setting.
- If you set the `height` or `width` property to a percentage value in an MXML tag, you actually set the percentage-based value, that is, the `percentHeight` or `percentWidth` property, *not* the explicit value. In ActionScript, you cannot set the `height` or `width` property to a percentage value; instead, set the `percentHeight` or `percentWidth` property.
- When you read the `height` and `width` properties at run time, the value is always the actual height or width of the control.

Determining and controlling component sizes

Flex determines the sizes of controls and containers based on the components and their properties and how you can use Flex properties to control the sizes.

Determining component size

During the measurement pass, Flex determines the components' default (also called measured) sizes. During the layout pass, Flex determines the actual sizes of the components, based on the explicit or default sizes and any percentage-based size specifications.

The following list describes sizing rules and behaviors that apply to all components, including both controls and containers. For container-specific sizing rules, see below. For detailed information on percentage-based sizing, see "Using percentage-based sizing" on page 373.

- If you specify an explicit size for any component (that is not outside the component's minimum or maximum bounds), Flex always uses that size.
- If you specify a percentage-based size for any component, Flex determines the component's actual size as part of the parent container's sizing procedure, based on the parent's size, the component's requested percentage, and the container-specific sizing and layout rules.
- The default and percentage-based sizes are always at least as large as any minimum size specifications.
- If you specify a child component size by using a percentage value and do not specify an explicit or percentage-based size for its container, the child component and the container use their default size.
- A child might require more space than is available in the parent container. The container can either let the component extend past its boundaries, or the container can clip the component to its boundaries.

  For Spark containers, the default is to let the child component extend past its boundaries. Set the `clipAndEnableScrolling` property to `true` to configure a parent to clip the child at the parent's boundaries. If you clip the children to the container boundaries, you can use the Scroller component with the container to display scroll bars. For more information, see "Scrolling Spark containers" on page 338.

  For a MX container, if a child requires more space than is available in the parent container, the parent clips the children at the parent's boundaries, and, by default, displays scroll bars on the container. Set the `clipContent` property to `false` to configure a parent to let the child extend past the parent's boundaries. Use the `scrollPolicy` property to control the display of the scroll bars. For more information, see "Scrolling MX containers" on page 343.
- If you specify a percentage-based size for a component, Flex uses the viewable area of the container in determining the sizes.
- When sizing and positioning components, Flex does not distinguish between visible and invisible components. By default, an invisible component is sized and positioned as if it were visible. To prevent Flex from considering an invisible component when it sizes and positions other components, set the component's `includeInLayout` property to `false`. This property affects the layout of the children of all containers except Accordion, FormItem, or ViewStack. For more information, see "Preventing layout of hidden controls" on page 382.

  ***Note:** Setting a component's `includeInLayout` property to `false` does not prevent Flex from displaying the component; it only prevents Flex from considering the component when it lays out other components. To prevent Flex from displaying the component, also set the visible property to `false`.*

Determining container size

Flex uses the following basic rules, in addition to the basic component sizing rules, to determine the size of a container:

- A percentage-based container size is advisory. Flex makes the container large enough to fit its children at their minimum sizes. For more information on percentage-based sizing, see "Using percentage-based sizing" on page 373.
- If you do not specify an explicit or percentage-based size for a container, Flex determines the container size by using explicit sizes that you specify for any of its children, and the default sizes for all other children.
- Flex does not consider any percentage-based settings of a container's children when sizing the container; instead, it uses the child's default size.
- If a MX container uses automatic scroll bars, Flex does not consider the size of the scroll bars when it determines the container's default size in its measurement pass. Thus, if a scroll bar is required, a default-sized container might be too small for proper appearance. For more information, see "Scrolling MX containers" on page 343.

For a Spark container, the Scroller component adds the scroll bars and are therefore separate from the container.

Each MX container and each Spark layout class for a Spark container has a set of rules that determines the container's default size. For information on default sizes of each container and layout, see the specific container sections in the *ActionScript 3.0 Reference for the Adobe Flash Platform*, and in "Application containers" on page 393; "Spark containers" on page 417; "MX layout containers" on page 574; and "MX navigator containers" on page 628.

Example: Determining a container and child sizes

The following example code shows how Flex determines the sizes of an SkinnableContainer container and its children. In this example, the SkinnableContainer uses a HorizontalLayout with three Button controls:

```
<?xml version="1.0"?>
<!-- components\HBoxSizeSpark.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <s:SkinnableContainer id="hb1">
        <s:layout>
            <s:HorizontalLayout/>
        </s:layout>
        <s:Button id="b1"
            label="Label 1"/>
        <s:Button id="b2"
            label="Label 2"
            minWidth="80"/>
        <s:Button id="b3"
            label="Label 3"/>
    </s:SkinnableContainer>

    <s:Form>
        <s:FormItem label="SkinnableContainer:">
            <s:Label text="{hb1.width}"/>
        </s:FormItem>
        <s:FormItem label="Button #1:">
            <s:Label text="{b1.width}"/>
        </s:FormItem>
        <s:FormItem label="Button #2:">
            <s:Label text="{b2.width}"/>
        </s:FormItem>
        <s:FormItem label="Button #3:">
            <s:Label text="{b3.width}"/>
        </s:FormItem>
    </s:Form>
</s:Application>
```

By default, the SkinnableContainer with a HorizontalLayout uses a 6 pixel gap between children. Since the Application container specifies no sizing properties, the Application container sizes itself large enough to hold the SkinnableContainer container and the Form container.

The default width for buttons is based on the label text width; in this example it is 70 pixels for all three buttons. However, the second button sets its `minWidth` property to 80 pixels. Therefore, the SkinnableContainer width is 70 + 80 + 70 + 12 = 232 pixels.

If you change the `minWidth` property of the second button to 65 pixels, the calculation uses the button's minimum width, 70 pixels, so the SkinnableContainer width is 222 pixels.

In the following example, you explicitly set the width of the Application container to 600 pixels. The Application container defines no left or right padding so the content area of its children is the entire area of the Application container. The SkinnableContainer width is now 450 pixels, 75% of 600 pixels.

***Note:** The MX Application container defines 24 pixels of right and left padding around its content area. Therefore, if the MX Application container has a width of 600 pixels, the maximum width of a child is 552 pixels. The container in this example would then be 414 pixels wide, 75% of 552 pixels.*

The button sizes are 92, 276, and 70 pixels, respectively. The third button uses the default size. The first and second buttons use 25% and 75% of the remaining available space in the container after deducting the default-width button and the gaps.

```
<?xml version="1.0"?>
<!-- components\HBoxSizePercentSpark.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    width="600">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <s:SkinnableContainer id="hb1" width="75%">
        <s:layout>
            <s:HorizontalLayout/>
        </s:layout>
        <s:Button id="b1"
            label="Label 1"
            width="25%"/>
        <s:Button id="b2"
            label="Label 2"
            width="75%"
            minWidth="80"/>
        <s:Button id="b3"
            label="Label 3"/>
    </s:SkinnableContainer>

    <s:Form>
        <s:FormItem label="SkinnableContainer:">
            <s:Label text="{hb1.width}"/>
        </s:FormItem>
        <s:FormItem label="Button #1:">
            <s:Label text="{b1.width}"/>
        </s:FormItem>
        <s:FormItem label="Button #2:">
            <s:Label text="{b2.width}"/>
        </s:FormItem>
        <s:FormItem label="Button #3:">
            <s:Label text="{b3.width}"/>
        </s:FormItem>
    </s:Form>
</s:Application>
```

If you set the SkinnableContainer `width` property to 20%, however, the SkinnableContainer width is *not* 120 pixels, 20% of the Application container width. This is because 120 pixels is too small to fit the container's children. Remember that percentage-based size specifications are advisory. The layout algorithms satisfy the request if possible, but the actual sizes can be different from the requested sizes.

Instead it is 183 pixels, the sum of 21 pixels for button 1 (the default minimum size), 80 pixels for button 2 (the specified minimum size), and 70 pixels (the specified minimum size) for button 2, 16 pixels for the gaps between buttons. The buttons are 21, 80, and 70 pixels wide, respectively.

For more information and examples showing sizing of containers and children, see "Flex component sizing techniques" on page 371. For detailed information on percentage-based sizing, see "Using percentage-based sizing" on page 373.

Flex component sizing techniques

You can use default sizing, explicit sizing, and percentage-based sizing techniques to control the size of components. For information on using constraint-based layout for component sizing, see "Using constraints to control component layout" on page 384.

Using default sizing

If you do not otherwise specify sizes, Flex calculates a size based on the default sizing characteristics of the particular component and the default or explicit sizes of the component's child controls.

As a rule, determine whether a component's default size (as listed for the component in the *ActionScript 3.0 Reference for the Adobe Flash Platform*) is appropriate for your application. If it is, you do not have to specify an explicit or percentage-based size.

The following example shows how you can use default sizing for Button children of an BorderContainer container. In this example, none of the children of the container specify a `width` property:

```
<?xml version="1.0"?>
<!-- components\DefaultButtonSizeSpark.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:MyComps="myComponents.*">

    <s:BorderContainer width="400" height="25">
        <s:layout>
            <s:HorizontalLayout/>
        </s:layout>
        <s:Button label="Label 1"/>
        <s:Button label="Label 2"/>
        <s:Button label="Label 3"/>
    </s:BorderContainer>
</s:Application>
```

Flex, therefore, uses the default sizes of the buttons, which accommodate the button label and default padding, and draws this application as the following image shows:

Notice the empty space to the right of the third button, because the sum of the default sizes is less than the available space.

Specifying an explicit size

Use the `width` and `height` properties of a component to explicitly set its size. In this example, Flex sets the component sizes to 300 by 40 pixels.

```
<?xml version="1.0"?>
<!-- components\ExplicitTextSize.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:Group>
        <s:TextInput id="myInput"
            text="This TextInput control is 300 by 40 pixels."
            width="300"
            height="40"/>
    </s:Group>
</s:Application>
```

The following example shows setting the sizes of a container and its child:

```
<?xml version="1.0"?>
<!-- components\ExplicitHBoxSize.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:Group width="150" height="50">
        <s:TextInput id="myInput"
            text="Enter the zip code"
            width="200" height="40"/>
    </s:Group>
</s:Application>
```

Because the specified TextInput control size is larger than that of its parent container, it extends beyond the boundaries of the container. If you set the `clipAndEnableScrolling` property of the container to `true`, the child is clipped at the container boundaries.

You can also use scroll bars to see the entire TextInput control by wrapping the Group container in the Scroller control, as the following example shows:

```
<?xml version="1.0"?>
<!-- components\ExplicitHBoxSizeScroll.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:Scroller>
        <s:Group width="150" height="50">
            <s:TextInput id="myInput"
                text="Enter the zip code"
                width="200" height="40"/>
        </s:Group>
    </s:Scroller>
</s:Application>
```

For more information on using scroll bars with Spark containers, see “Scrolling Spark containers” on page 338.

Note that for MX containers, the `clipContent` property of the container defaults to `true`. Therefore, MX containers clip the control at the container boundary and displays scroll bars. For more information on using scroll bars with MX containers, see “Scrolling MX containers” on page 343.

Using percentage-based sizing

Percentage-based sizing dynamically determines and maintains a component's size relative to its container; for example, you can specify that the component's width is 75% of the container. This sizing technique has several advantages over default or explicit fixed sizing:

- You only have to specify a size relative to the container; you don't have to determine exact measurements.
- The component size changes dynamically when the container size changes.
- The sizing mechanism automatically takes into account the remaining available space and fits components even if their requested size exceeds the space.

To specify a percentage value, use one of the following coding techniques:

1 In an MXML tag, set the `height` or `width` property to a percentage value; for example:

```
<s:TextArea id="ta1" width="70%" height="40%"/>
```

2 In an MXML tag or an ActionScript statement, set the `percentHeight` or `percentWidth` property to a numeric value; for example:

```
ta1.percentWidth=70;
```

The exact techniques Flex uses to determine the dimensions of a component that uses percentage-based sizing depend on the type of container. For example, a MX Tile container, or a Spark container using the TileLayout class, has cells that are all the largest default or explicit dimensions of the largest child. Child control percentage values specify a percentage of the tile cell size, not of the container size. The percentage sizes of most other containers is relative to the overall container size.

Sizing percentage-based children of a linear container with automatic positioning

When Flex sizes children of a container that uses automatic positioning to lay out children in a single direction, Flex does the following:

1 Determines the size of the viewable area of the parent container, and uses those dimensions for sizing calculations. The viewable area is the part of the container that is being displayed and can contain child components, text, images, or other content. For more information on calculating the size of containers, see "Determining component size" on page 367.

2 Determines the desired sizes of container children with percentage-based sizes as a percentage of the viewable area of the container, minus any padding and gaps between the children.

3 Reserves space for all children with explicit or default sizes.

4 If available space (parent container size minus all reserved space, including borders, padding, and gaps) cannot accommodate the percentage requests, divides the available space in proportion to the specified percentages.

5 If a minimum or maximum height or width specification conflicts with a calculated value, uses the minimum or maximum value, and recalculates all other percentage-based components based on the reduced available space.

6 Rounds the size down to the next integer.

The following examples show how the requested percentage can differ from the size when the component is laid out:

- Suppose that 50% of a SkinnableContainer is available after reserving space for all explicit-sized and default-sized children, and for all gaps and padding. If one component requests 20% of the parent, and another component requests 60%, the first component is sized to 12.5% (20 /(20+ 60) * 50%) of the parent container and the second component is sized to 37.5% of the parent container.
- If any component requests 100% of its parent application container's space, it occupies all the container *except* for the application's padding.

Example: Using percentage-based children

The following example specifies percentage-based sizes for the first two of three buttons in a BorderContainer container:

```
<?xml version="1.0"?>
<!-- components\PercentHBoxChildren.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:BorderContainer width="400" height="25">
        <s:layout>
            <s:HorizontalLayout/>
        </s:layout>
        <s:Button id="b1" label="Label 1" width="25%"/>
        <s:Button id="b2" label="Label 2" width="40%"/>
        <s:Button id="b3" label="Label 3"/>
    </s:BorderContainer>
</s:Application>
```

In this example, the default width of the third button is 70 pixels. The BorderContainer container has no padding by default, but has a one-pixel wide border on both sides. Therefore, of the 400 pixel width, only 398 are available for laying out children. The HorizontalLayout class uses a 6-pixel horizontal gap between each component.

The first button requests 25% of the available 398 pixels of space, or 100 pixels (All calculated values are to the nearest pixel). The second button requests 40%, or 159 pixels. There is still unused space to the right of the third button.

Flex draws the following application:

Now change the percentage values requested to 50% and 40%, respectively:

```
<?xml version="1.0"?>
<!-- components\PercentHBoxChildren5040.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:BorderContainer width="400" height="25">
        <s:layout>
            <s:HorizontalLayout/>
        </s:layout>
        <s:Button id="b1" label="Label 1" width="50%"/>
        <s:Button id="b2" label="Label 2" width="40%"/>
        <s:Button id="b3" label="Label 3"/>
    </s:BorderContainer>
</s:Application>
```

In this example, the first button requests 50% of the available space, or 200 pixels. The second button still requests 40%, or 160 pixels, for a total of 360 pixels. However, the BorderContainer container only has 318 pixels free after reserving 70 pixels for the default-width button, 2 pixels for the borders, and 12 pixels for the gaps between components.

Flex divides the available space proportionally between the two buttons, giving .5/(.5 + .4) * 318 = 176 pixels, to the first button and .4/(.5 + .4) * 318 = 140 pixels, to the second button.

Flex draws the following application:

Sizing percentage-based children of a container with absolute positioning

Spark containers with a layout of BasicLayout, or MX Canvas, MX Panel, and MX Application containers can use absolute positioning. When Flex sizes children of a container that uses absolute positioning, it does the following:

1 Determines the viewable area of the parent container, and uses the corresponding dimensions as the container dimensions for sizing calculations. For more information on calculating the size of containers, see "Determining component size" on page 367.

2 Determines the sizes of children with percentage-based sizes by multiplying the decimal value by the container dimension minus the position of the control in the dimension's direction. For example, if you specify `x="10"` and `width="100%"` for a child, the child size extends only to the edge of the viewable area, not beyond.

   ***Note:** The Spark BasicLayout class always calculates the percentage based on the size of the container, regardless of the position of the child component in the container.*

   Because controls can overlay other controls or padding, the sizing calculations do not consider padding or any other children when determining the size of a child.

3 If a minimum or maximum height or width specification conflicts with a calculated value, uses the minimum or maximum value.

4 For MX containers, round the size down to the closest integer.

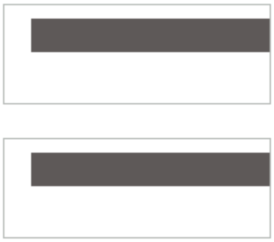
   For Spark containers, round the size up or down to the closest integer.

Example: Using percentage-based children with absolute positioning

The following code shows the percentage-based sizing behavior with absolute positioning:

```
<?xml version="1.0"?>
<!-- components\PercentSizeAbsPosit.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout gap="25"/>
    </s:layout>
    <s:BorderContainer
        width="200" height="75">
        <s:layout>
            <s:BasicLayout/>
        </s:layout>
        <s:BorderContainer
            x="20" y="10"
            width="100%" height="25"
            backgroundColor="#666666"/>
    </s:BorderContainer>
    <s:BorderContainer
        width="200" height="75">
        <s:layout>
            <s:BasicLayout/>
        </s:layout>
        <s:BorderContainer
            left="20" top="10"
            width="100%" height="25"
            backgroundColor="#666666"/>
    </s:BorderContainer>
</s:Application>
```

Flex draws the following application:



Using minimum or maximum dimensions

You can also use the `minWidth`, `minHeight`, `maxWidth`, and `maxHeight` properties with a percentage-based component to constrain its size. Consider the following example:

```
<?xml version="1.0"?>
<!-- components\PercentChildrenMin.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:BorderContainer id="bc" width="400" height="25">
        <s:layout>
            <s:HorizontalLayout/>
        </s:layout>
        <s:Button id="b1" label="Label 1" width="50%"/>
        <s:Button id="b2" label="Label 2" width="40%" minWidth="150"/>
        <s:Button id="b3" label="Label 3"/>
    </s:BorderContainer>

    <s:Form>
        <s:FormItem label="Container:">
            <s:Label text="{bc.width}"/>
        </s:FormItem>
        <s:FormItem label="Button #1:">
            <s:Label text="{b1.width}"/>
        </s:FormItem>
        <s:FormItem label="Button #2:">
            <s:Label text="{b2.width}"/>
        </s:FormItem>
        <s:FormItem label="Button #3:">
            <s:Label text="{b3.width}"/>
        </s:FormItem>
    </s:Form>
</s:Application>
```

To determine the widths of the percentage-based button sizes, Flex first determines the sizes as described in the second example in “Example: Using percentage-based children” on page 374, which results in requested values of 176 for the first button and 140 for the second button. However, the minimum width of the second button is 150, so Flex sets its size to 150 pixels, and reduces the size of the first button to occupy the remaining available space, which results in a width of 166 pixels.

Flex draws the following application:

Setting the application container size

When you size an application, you often start by setting the size of the Application or Application container. The application containers determine the boundaries of your application in the Adobe® Flash® Player or Adobe® AIR™.

If you are using Adobe® Flash® Builder™, an HTML wrapper page is generated automatically. The `width` and `height` properties specified by the application container are used to set the width and height of the `<object>` and `<embed>` tags in the HTML wrapper page. Those numbers determine the portion of the HTML page that is allocated to the Adobe Flash plug-in.

If you are not autogenerating the HTML wrapper, set the application containers `width` and `height` properties to 100%. That way, the application scales to fit the space that is allocated to the Flash plug-in.

Set the application container size as the following example shows:

```
<?xml version="1.0"?>
<!-- components\AppExplicit.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    height="100"
    width="150">

        <!-- Application children go here. -->
</s:Application>
```

In this example, you set the application container size to 100 by 150 pixels. Anything in the application larger than this window is clipped at the window boundaries. Therefore, if you define a 200 pixel by 200 pixel DataGrid control, it is clipped.

If you are using the Spark Application container, you can modify the container's skin to add scroll bars. For more information, see "Using scroll bars with the application container" on page 395. If you are using the MX Application container, it automatically displays scroll bars.

For more information on sizing the Application container, see "Application containers" on page 393.

Using padding and custom gaps

There may be situations where you want your containers to have padding around the edges. Some containers, such as the MX Application container, have padding by default; others, such as the Spark Application container, have padding values of 0 by default.

Use the `paddingTop`, `paddingBottom`, `paddingRight`,and `paddingLeft` style properties to set the padding around the content area of a MX container. To set the padding for a Spark container, you can either use the padding properties of the layout classes, such as HorizontalLayout or VerticalLayout, or define a container skin.

Also, MX containers and Spark layouts define gaps between children, which you might want to change from the default values. If your application has nonzero padding and gaps, Flex reserves the necessary pixels before it sizes any percentage-based components.

Consider the following example:

```
<?xml version="1.0"?>
<!-- components\PadContainer.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <s:BorderContainer width="400" height="25">
        <s:layout>
            <s:HorizontalLayout
                paddingLeft="5"
                paddingRight="5"
                gap="15"/>
        </s:layout>

        <s:Button id="b1"
            label="Label 1"
            width="75%"/>
        <s:Button id="b2"
            label="Label 2"
            minWidth="120"/>
        <s:Button id="b3"
            label="Label 3"/>
    </s:BorderContainer>
    <s:Form>
        <s:FormItem label="Button #1:">
            <s:Label text="{b1.width}"/>
        </s:FormItem>
        <s:FormItem label="Button #2:">
            <s:Label text="{b2.width}"/>
        </s:FormItem>
        <s:FormItem label="Button #3:">
            <s:Label text="{b3.width}"/>
        </s:FormItem>
    </s:Form>
</s:Application>
```

The left and right padding of the container is set to 5 pixels, and the gap between children is 15 pixels. The default width of the third button is 70 pixels. That leaves 288 pixels for the two percentage-based components. The second button requires its minimum size of 120 pixels, leaving 168 pixels available for the first button.

Positioning components

The position of a component is defined by the x and y coordinates of its top, left corner in its parent container. For most containers, Flex automatically determines the location of the component in its parent container. This is called *automatic positioning*.

Some containers let you explicitly specify the x and y coordinates of the component in it parent container. This is called *absolute positioning*. These containers include the following:

- A Spark container using the BasicLayout class
- The MX Canvas container
- The MX Application and Panel containers with the `layout` property set to `absolute`

Automatic positioning

With automatic positioning, Flex positions the container children according to the container's layout rules, such as the layout direction, the container padding, and the gaps between children of that container.

For containers that use automatic positioning, setting the `x` or `y` property directly on a child or calling the child's `move()` method has no effect, or only a temporary effect. This is because the container recalculates the child's position and does not use the specified value. You can, however, specify absolute positions for the children of these containers under some circumstances; for more information, see below.

You can control aspects of the layout by specifying container properties; for details on the properties, see the property descriptions for the container in the *ActionScript 3.0 Reference for the Adobe Flash Platform*. You also control the layout by controlling component sizes and by using techniques such as adding spacers.

Using the Spacer control to control layout

Flex includes a Spacer control that helps you lay out children within a parent container. The Spacer control is invisible, but it does allocate space within its parent.

In the following example, you use a percentage-based Spacer control to push the Button control to the right so that it is aligned with the right edge of the HBox container:

```
<?xml version="1.0"?>
<!-- components\SpacerHBox.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            [Embed(source="assets/flexlogo.jpg")]
            [Bindable]
            public var imgCls:Class;
        ]]>
    </fx:Script>

    <s:SkinnableContainer width="400">
        <s:layout>
            <s:HorizontalLayout/>
        </s:layout>
        <mx:Image source="{imgCls}"/>
        <s:Label  text="Company XYZ"/>
        <mx:Spacer width="100%"/>
        <s:Button label="Close"/>
    </s:SkinnableContainer>
</s:Application>
```

In this example, the Spacer control is the only percentage-based component in the parent container. Flex sizes the Spacer control to occupy all available space in the container that is not required for other components. By expanding the Spacer control, Flex pushes the Button control to the right edge of the container.

You can use all sizing and positioning properties with the Spacer control, such as `width`, `height`, `maxWidth`, `maxHeight`, `minWidth`, and `minHeight`.

Disabling automatic positioning temporarily

You can use effects, such as the Move and Zoom effects, to modify the size or position of a child in response to a user action. For example, you might define a child so that when the user selects it, the child moves to the top of the container and doubles in size. These effects modify the `x` and `y` properties of the child as part of the effect. Similarly, you might want to change the position of a control by changing its *x* or *y* coordinate value, for example, in response to a button click.

Containers that use automatic positioning ignore the values of the `x` and `y` properties of their children during a layout update. Therefore, the layout update cancels any modifications to the `x` and `y` properties performed by the effect, and the child does not remain in its new location.

You can prevent Flex from performing automatic positioning updates that conflict with the requested action of your application by setting the `autoLayout` property of a container to `false`. Setting this property to `false` prevents Flex from laying out the container's contents when a child moves or resizes. The default value is `true`, which enables Flex to update layouts.

For MX containers only, even when you set the `autoLayout` property of a container to `false`, Flex updates the layout when you add or remove a child. Application initialization, deferred instantiation, and the `<mx:Repeater>` tag add or remove children, so layout updates always occur during these processes, regardless of the value of the `autoLayout` property. Therefore, during container initialization, Flex defines the initial layout of the container children regardless of the value of the `autoLayout` property.

The following example disables layout updates for a VBox container:

```
<?xml version="1.0"?>
<!-- components\DisableVBoxLayout.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <mx:VBox id="vb1" autoLayout="false"
        width="200"
        height="200">
        <s:Button id="b1"
            label="Button 1"/>
        <s:Button id="b2"
            label="Button 2"
            click="{b2.x += 10; vb1.invalidateDisplayList();}"/>
        <s:Button id="b3"
            label="Button 3"
            creationComplete="b3.x = 100; b3.y = 75;"/>
    </mx:VBox>
</s:Application>
```

In this example, Flex initially lays out all three Button controls according to the rules of the VBox container. The `creationComplete` event listener for the third button is dispatched after the VBox control has laid out its children, but before Flex displays the buttons. Therefore, when the third button appears, it is at the *x* and *y* positions specified by the `creationComplete` listener.

After the buttons appear, Flex shifts the second button 10 pixels to the right each time a user clicks it. The button click also triggers the container to update its layout by calling the `updateDisplay()` method.

Setting the autoLayout property of a container to false prohibits Flex from updating a container's layout after a child moves or resizes, so you should set it to false only when necessary. You should always test your application with the autoLayout property set to the default value of true, and set it to false only as necessary for the specific container and specific actions of the children in that container.

For more information on effects, see "Introduction to effects" on page 1784.

Preventing layout of hidden controls

By default, Flex lays out and reserves space for all components, including hidden components, but it does not display the hidden controls. A hidden component is one with its visible property set to false. You see blank spots where the hidden controls should appear when you make them visible. In place of the hidden controls, you see their container's background.

However, you can prevent Flex from considering the child component when it lays out the container's other children by setting the child component's includeInLayout property of the component to false.

When a component's includeInLayout property is false, Flex does not include it in the layout calculations for other components. In other words, Flex does not reserve space for the component, but still draws it. As a result, the component can appear underneath the components that follow it in the layout order. To prevent Flex from drawing the component, you must also set its visible property to false.

The following example shows the effects of the includeInLayout and visible properties. It lets you toggle each of these properties independently on the middle of three Panel controls in a SkinnableContainer:

```
<?xml version="1.0"?>
<!-- components\HiddenBoxLayout.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    height="500">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <s:SkinnableContainer>
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <s:Panel id="p1"
            title="Panel 1"/>
        <s:Panel id="p2"
            title="Panel 2"/>
        <s:Panel id="p3"
            title="Panel 3"/>
    </s:SkinnableContainer>
    <s:SkinnableContainer>
        <s:layout>
            <s:HorizontalLayout/>
        </s:layout>
        <s:Button label="Toggle Panel 2 Visible"
            click="{p2.visible=!p2.visible;}"/>
        <s:Button label="Toggle Panel 2 in Layout"
            click="{p2.includeInLayout=!p2.includeInLayout;}"/>
    </s:SkinnableContainer>
</s:Application>
```

Run this application and click the buttons to see the results of different combinations of `visible` and `includeInLayout` properties. The example shows the following behaviors:

- If you include the second Panel container in the layout but make it invisible, Flex reserves space for it.
- If you exclude the second Panel container from the layout, the SkinnableContainer resizes and the third Panel container moves up. If you then include the second Panel container in the layout, the SkinnableContainer resizes again, and the third Panel container moves down.
- If you exclude the second Panel container from the layout but make it visible, Flex still draws it, but does not consider it in laying out the third Panel container, so the two panels overlap.

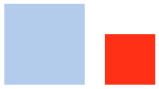
Absolute positioning

With absolute positioning, you specify the position of the child by setting its `x` and `y` properties, or you specify a constraint-based layout; otherwise, Flex places the child at position 0,0 of the parent container. When you specify the *x* and *y* coordinates, Flex repositions the controls only when you change the property values.

The following example uses absolute positioning to place two Spark BorderContainer containers inside a SkinnableContainer. Absolute positioning is the default layout of a SkinnableContainer:

```
<?xml version="1.0"?>
<!-- components\AbsoluteLayout.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:SkinnableContainer
        width="100" height="100">
        <s:BorderContainer id="b1"
            width="80" height="80"
            x="20" y="20"
            backgroundColor="#A9C0E7">
        </s:BorderContainer>
        <s:BorderContainer id="b2"
            width="50" height="50"
            x="120" y="50"
            backgroundColor="#FF0000">
        </s:BorderContainer>
    </s:SkinnableContainer>
</s:Application>
```

This example produces the following image:

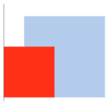


When you use absolute positioning, you have full control over the locations of the container's children. This lets you overlap components. The following example moves the second BorderContainer container so that it partially overlaps the first.

```
<?xml version="1.0"?>
<!-- components\AbsoluteLayoutOverlap.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:SkinnableContainer
        width="100" height="100">
        <s:BorderContainer id="b1"
            width="80" height="80"
            x="20" y="20"
            backgroundColor="#A9C0E7">
        </s:BorderContainer>

        <s:BorderContainer id="b2"
            width="50" height="50"
            x="0" y="50"
            backgroundColor="#FF0000">
        </s:BorderContainer>
    </s:SkinnableContainer >
</s:Application>
```

This example produces the following image:



***Note:** If you use percentage-based sizing for the children of a control that uses absolute positioning, the percentage-based components resize when the parent container resizes, and the result may include unwanted overlapping of controls.*

Using constraints to control component layout

You can manage a child component's size and position simultaneously by using constraint-based layout, or by using constraint rows and columns. Constraint-based layout lets you anchor the sides or center of a component to positions relative to the viewable region of the component's container. The *viewable region* is the part of the component that is being displayed, and it can contain child controls, text, images, or other contents.

Constraint rows and columns let you subdivide a container into vertical and horizontal constraint regions to control the size and positioning of child components with respect to each other and within the parent container.

Creating a constraint-based layout

You can use constraint-based layout to determine the position and size of the immediate children of any container that supports absolute positioning. With constraint-based layout, you can do the following:

- Anchor one or more edges of a component at a pixel offset from the corresponding edge of its container's viewable region. The anchored child edge stays at the same distance from the parent edge when the container resizes. If you anchor both edges in a dimension, such as top and bottom, the component resizes if the container resizes.
- Anchor the child's horizontal or vertical center (or both) at a pixel offset from the center of the container's viewable region. The child does not resize in the specified dimension unless you also use percentage-based sizing.
- Anchor the baseline of a component at a pixel offset from the top edge of its parent container.

You can specify a constraint-based layout for any Flex framework component (that is, any component that extends the UIComponent class). The following rules specify how to position and size components by using constraint-based layout:

- Place the component in any Spark container that uses BasicLayout, in a MX Canvas container, or in a MX Application or MX Panel container with the `layout` property set to `absolute`.
- Specify the constraints by using the `baseline`, `top`, `bottom`, `left`, `right`, `horizontalCenter`, or `verticalCenter` properties of UIComponent and GraphicElement.

  ***Note:** In previous releases of Flex, the baseline, top, bottom, left, right, horizontalCenter, or verticalCenter properties were implemented as styles. You can still use them as styles in this release.*

  The `top`, `bottom`, `left`, and `right` properties specify the distances between the component sides and the corresponding container sides.

  The `baseline` constraint specifies the distance between the baseline position of a component and the upper edge of its parent container. Every component calculates its baseline position as the y-coordinate of the baseline of the first line of text of the component. The baseline of a UIComponent object that does not contain any text is calculated as if the UIComponent object contained a UITextField object that uses the component's styles, and the top of the UITextField object coincides with the component's top.

  The `horizontalCenter` and `verticalCenter` properties specify distance between the component's center point and the container's center, in the specified direction; a negative number moves the component left or up from the center.

  The following example anchors the Form control's left and right sides 20 pixels from its container's sides:

  ```
  <mx:Form id="myForm" left="20" right="20"/>
  ```

- Do not specify a `top` or `bottom` property with a `verticalCenter` property; the `verticalCenter` value overrides the other properties. Similarly, do not specify a `left` or `right` property with a `horizontalCenter` property.
- A size determined by constraint-based layout overrides any explicit or percentage-based size specifications. If you specify `left` and `right` constraints, for example, the resulting constraint-based width overrides any width set by a `width` or `percentWidth` property.

Precedence rules for constraint-based components

- If you specify a single edge constraint (`left, right, top,` or `bottom`) without any other sizing or positioning parameter, the component size is the default size and its position is determined by the constraint value. If you specify a size parameter (width or height), the size is determined by that parameter.
- If you specify a pair of constraints (`left-right` or `top-bottom`), the size and position of the component is determined by those constraint values. If you also specify a center constraint (`horizontalCenter` or `verticalCenter`), the size of the component is calculated from the edge constraints and its position is determined by the center constraint value.
- Component size determined by a pair of constraint-based layout properties (`left-right` or `top-bottom`) overrides any explicit or percentage-based size specifications. For example, if you specify both `left` and `right` constraints, the calculated constraint-based width overrides the width set by a `width` or `percentWidth` property.
- Edge constraints override `baseline` constraints.

Example: Using constraint-based layout for a form

The following example code shows how you can use constraint-based layout for a form. In this example, the Form control uses a constraint-based layout to position its top just inside the canvas padding. The form left and right edges are 20 pixels from the outer SkinnableContainer container's left and right edges. The second, inner, SkinnableContainer that contains the buttons uses a constraint-based layout to place itself 20 pixels from the right edge and 10 pixels from the bottom edge of the outer SkinnableContainer container.

If you change the size of your browser, stand-alone Flash Player, or AIR application, you can see the effects of dynamically resizing the application container on the Form layout. The form and the buttons overlap as the application grows smaller, for example.

```
<?xml version="1.0"?>
<!-- components\ConstraintLayout.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:SkinnableContainer width="100%" height="100%">
         <!-- Anchor the top of the form at the top of the canvas.
            Anchor the form sides 20 pixels from the canvas sides. -->
        <s:Form id="myForm"
                backgroundColor="#DDDDDD"
                top="0"
                left="20"
                right="20">

            <s:FormItem label="Product:" width="100%">
                <!-- Specify a fixed width to keep the ComboBox control from
                    resizing as you change the application size. -->
                <s:ComboBox width="200"/>
            </s:FormItem>
            <s:FormItem label="User" width="100%">
                <s:ComboBox width="200"/>
            </s:FormItem>
            <s:FormItem label="Date">
                <mx:DateField/>
            </s:FormItem>
            <s:FormItem width="100%"
                    label="Hours:">
                <s:TextInput width="75"/>
            </s:FormItem>
            <s:FormItem width="100%"
                    label="Minutes:">
                <s:TextInput width="75"/>
            </s:FormItem>
        </s:Form>
        <!-- Anchor the box with the buttons 20 pixels from the canvas
            right edge and 10 pixels from the bottom. -->
        <s:SkinnableContainer id="okCancelBox"
                right="20"
                bottom="10">
            <s:layout>
                <s:HorizontalLayout/>
            </s:layout>
            <s:Button label="OK"/>
            <s:Button label="Cancel"/>
        </s:SkinnableContainer>
    </s:SkinnableContainer>
</s:Application>
```

Using constraint rows and columns with MX containers and the Spark FormLayout class

You can subdivide a container that supports absolute positioning into vertical and horizontal constraint regions to control the size and positioning of child components with respect to each other, or with respect to the parent container.

***Note:** Constraint rows and columns are only supported by the MX containers, and the Spark FormLayout class.*

You define the horizontal and vertical constraint regions of a container by using the `constraintRows` and `constraintColumns` properties. These properties contain Arrays of constraint objects that partition the container horizontally (ConstraintColumn objects) and vertically (ConstraintRow objects). ConstraintRow objects are laid out in the order they are defined, from top to bottom in their container; ConstraintColumn objects are laid out from left to right in the order they are defined.

The following example shows a `Canvas` container partitioned into two vertical regions and two horizontal regions. The first constraint column occupies 212 pixels from the leftmost edge of the `Canvas`. The second constraint column occupies 100% of the remaining Canvas width. The rows in this example occupy 80% and 20% of the Canvas container’s height from top to bottom, respectively.

```
<?xml version="1.0"?>
<!-- constraints\BasicRowColumn.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <mx:Canvas>
        <mx:constraintColumns>
            <mx:ConstraintColumn id="col1" width="212"/>
            <mx:ConstraintColumn id="col2" width="100%"/>
        </mx:constraintColumns>
        <mx:constraintRows>
            <mx:ConstraintRow id="row1" height="80%"/>
            <mx:ConstraintRow id="row2" height="20%"/>
        </mx:constraintRows>
    <!-- Position child components based on
        the constraint columns and rows. -->
    </mx:Canvas>
</s:Application>
```

Constraint rows and columns do not have to occupy 100% of the available area in a container. The following example shows a single constraint column that occupies 20% of the Canvas width; 80% of the container is unallocated:

```
<?xml version="1.0"?>
<!-- constraints\BasicColumn_20Percent.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <mx:Canvas>
        <mx:constraintColumns>
            <mx:ConstraintColumn id="col1" width="20%"/>
        </mx:constraintColumns>
    </mx:Canvas>
    <!-- Position child components based on
        the constraint column. -->
</s:Application>
```

Creating constraint rows and columns

Constraint columns and rows have three sizing options: fixed, percent, and content. These options dictate the amount of space that the constraint region occupies in the container. As child components are added to or removed from the parent container, the space allocated to each ConstraintColumn and ConstraintRow instance is computed according to its sizing option.

- *Fixed size* means the space allocated to the constraint region is a fixed pixel size. In the following example, you set the fixed with of a ConstraintColumn instance to 100 pixels:

  ```
  <mx:ConstraintColumn id="col1" width="100"/>
  ```

  As the parent container grows or shrinks, the ConstraintColumn instance remains 100 pixels wide.

- *Percent size* means that the space allocated to the constraint row or column is calculated as a percentage of the space remaining in the parent container after the space allocated to fixed and content size child objects has been deducted from the available space.

  In the following example, you set the width of a ConstraintColumn instance to 80%:

  ```
  <mx:ConstraintColumn  id="col1" width="80%"/>
  ```

  As the parent container grows or shrinks, the ConstraintColumn always takes up 80% of the available width.

  A best practice in specifying percent constraints is to ensure that the sum of all percent constraints is less than or equal to 100%. However, if the total value of percent specifications is greater than 100%, the actual allocated percentages are calculated so that the proportional values for all constraints total 100%. For example, if the percentages for two constraint objects are specified as 100% and 50%, the values are adjusted to 66.6% and 33.3% (two-thirds for the first value and one-third for the second).

- *Content size* (default) means that the space allocated to the region is dictated by the size of the child objects in that space. As the size of the content changes, so does the size of the region. Content sizing is the default when you do not specify either fixed or percentage sizing parameters.

  In the following example, you specify content size by omitting any explicit width setting:

  ```
  <mx:ConstraintColumn  id="col1"/>
  ```

  The width of this ConstraintColumn is determined by the width of its largest child. When children span multiple content sized constraint rows or constraint columns, Flex divides the space consumed by the children among the rows and columns.

For the ConstraintColumn class, you can also use the `maxWidth` and `minWidth` properties to limit the width of the column. For the ConstraintRow class, you can use the `maxHeight` and `minHeight` properties to limit the height of the row. Minimum and maximum sizes for constraint columns and rows limit how much the constraint regions grow or shrink when you resize their parent containers. If the parent container with a constraint region shrinks to less than the minimum size for that region when you resize the container, scroll bars appear to show clipped content.

***Note:** Minimum and maximum limits are only applicable to percentage and content sized constraint regions. For fixed size constraint regions, minimum and maximum values, if specified, are ignored.*

Positioning child components based on constraint rows and constraint columns

Anchor a child component to a constraint row or constraint column by prepending the constraint region's ID to any of the child's constraint parameters. For example, if the ID of a ConstraintColumn is "col1", you can specify a set of child constraints as `left="col1:10"`, `right="col1:30"`, `horizontalCenter="col1:0"`.

If you do not qualify constraint parameters (`left, right, top`, and `bottom`) a constraint region ID, the component is constrained relative to the edges of its parent container. Components can occupy a single constraint region (row or column) or can span multiple regions.

The following example uses constraint rows and constraint columns to position three Button controls in a Canvas container:

```
<?xml version="1.0"?>
<!-- constraints\ConstrainButtons.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <mx:Canvas id="myCanvas" backgroundColor="0x6699FF">
        <mx:constraintColumns>
            <mx:ConstraintColumn id="col1" width="100"/>
            <mx:ConstraintColumn id="col2" width="100"/>
        </mx:constraintColumns>
        <mx:constraintRows>
            <mx:ConstraintRow id="row1" height="100"/>
            <mx:ConstraintRow id="row2" height="100"/>
        </mx:constraintRows>
        <s:Button label="Button 1"
            top="row1:10" bottom="row1:10"
            left="10"/>
        <s:Button label="Button 2"
            left="col2:10" right="col2:10"/>
        <s:Button label="Button 3"
            top="row2:10" bottom="row2:10"
            left="col1:10" right="10"/>
    </mx:Canvas>
    <s:Label text="canvas width:{myCanvas.width}"/>
    <s:Label text="canvas height:{myCanvas.height}"/>
</s:Application>
```

The next example defines the constraint rows and columns by using percentages. As you resize the application, the Button controls resize accordingly.

```
<?xml version="1.0"?>
<!-- constraints\ConstrainButtonsPercent.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <mx:Canvas id="myCanvas"
        backgroundColor="0x6699FF"
        width="100%" height="100%">
        <mx:constraintColumns>
            <mx:ConstraintColumn id="col1" width="30%"/>
            <mx:ConstraintColumn id="col2" width="40%"/>
            <mx:ConstraintColumn id="col3" width="30%"/>
        </mx:constraintColumns>
        <mx:constraintRows>
            <mx:ConstraintRow id="row1" height="35%"/>
            <mx:ConstraintRow id="row2" height="55%"/>
        </mx:constraintRows>
        <s:Button label="Button 1"
            top="row1:10" bottom="row2:10"
            left="10"/>
        <s:Button label="Button 2"
            left="col2:10" right="col3:10"/>
        <s:Button label="Button 3"
            top="row2:10" bottom="row2:10"
            left="col3:10" right="col3:10"/>
    </mx:Canvas>
    <s:Label text="canvas width:{myCanvas.width}"/>
    <s:Label text="canvas height:{myCanvas.height}"/>
</s:Application>
```

While you can specify any combination of qualified and unqualified constraints, some constraint properties may be overridden. The priority of sizing and positioning constraints are as follows:

1 Center constraint specifications override all other constraint values when determining the position of a control.

2 Next, left edge and top positions are determined.

3 Finally, right edge and bottom positions are calculated to best fit the component.

The following table defines the behavior of constrained components when they are contained in a single constraint region. *Edge 1* is the first specified edge constraint for a child component (`left`, `right`, `top`, or `bottom`). *Edge 2* is the second specified edge constraint of a pair (`left` and `right`, `top` and `bottom`). *Size* is an explicit size for a child component (`width`, `height`). *Center* is the positioning constraint to center the child object (`horizontalCenter` or `verticalCenter`).

Constraint Parameters				Behavior	
Edge 1	**Edge 2**	**Size**	**Center**	**Size**	**Position**
x				Default component size	Relative to specified edge constraint
x	x			Calculated from specified edge constraints	Relative to specified edge constraints
x	x	x		Determined from specified edge constraints. Explicit size is overridden	Relative to specified edge constraints
x		x		Specified size	Relative to specified edge
x			x	Default component size	Centered in constraint region; edge constraint is ignored
x	x		x	Calculated from edge constraints	Centered in constraint region
x		x	x	Explicit size	Centered in constraint region; single edge constraint is ignored
			x	Default size of component	Centered in constraint region

Using Baseline property

The baseline property defines the offset between the baseline defined by the constraint row (or the top of the container) and the baseline position of the element.

The baseline property can be specified as a number or can be specified with respect to the max ascent of the row.

If the baseline value on a row is only a number, the elements contained by the row are positioned that many pixels below the top of the container. If the baseline value is defined with respect to the max ascent of the row, then it is defined in the format: "maxAscent:x". The default value is "maxAscent:0".

The following code example defines four labels in a group, where each label is constrained with a baseline alignment to row1 and maxAscent:5.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\layouts\spark\SparkFormItemLayoutBaselineAlignment.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
               xmlns:mx="library://ns.adobe.com/flex/mx"
               xmlns:s="library://ns.adobe.com/flex/spark">

    <s:Group y="200" x="30">
        <s:layout>
            <s:FormItemLayout>
                <s:constraintRows>
                    <s:ConstraintRow id="row1" />
                    <s:ConstraintRow id="row2" baseline="maxAscent:5"/>
                    <s:ConstraintRow id="row3" baseline="30"/>
                </s:constraintRows>
            </s:FormItemLayout>
        </s:layout>
        <s:Label fontSize="20" text="hello!" baseline="row1:10" x="38" color="blue"/>
        <s:Label fontSize="25" text="hello!" baseline="row1:0" x="89" color="#FF9933"/>
        <s:Label fontSize="35" text="hello!" baseline="row1:0" x="149" color="green"/>
        <s:Label fontSize="50" text="hello!" baseline="row1:0" x="234" />
    </s:Group>
</s:Application>
```

Application containers

Adobe® Flex® defines the Spark Application and MX Application containers that let you start adding content to your application without having to explicitly define another container.

The application containers support an application preloader that uses a progress bar to show the download progress of an application SWF file. You can override the default progress bar to define your own custom progress bar. For more information, see “Showing the download progress of an application” on page 408.

About the Application container

The first tag in an MXML application is either the `<s:Application>` tag for the Spark application container, or the `<mx:Application>` tag for an MX application container. The application container then becomes the default container for any content that you add to your application.

The application object, of type spark.components.Application or mx.core.Application, is the default scope for any ActionScript code in the file. Therefore, the ActionScript keyword `this` refers to the application object.

You also use the application container to define the initial size of the application. By default, the application sets its height to 375 pixels and its width to 500 pixels.

Although you might find it convenient to use an application container as the only container in your application, usually you explicitly define at least one more container before you add any controls to your application. For example, you might use a Panel container as the first child container of the application.

The application containers have the following default layout characteristics:

Characteristic	Spark Application container	MX Application container
Default size	375 pixels high and 500 pixels wide in the Standalone Flash Player, and all available space in a browser.	375 pixels high and 500 pixels wide in the Standalone Flash Player, and all available space in a browser.
Child layout	BasicLayout, meaning that you have to explicitly size and position all children.	Vertical column arrangement of children centered in the Application container.
Default padding	0 pixels.	24 pixels for the `paddingTop`, `paddingBottom`, `paddingLeft`, and `paddingRight` properties.
Scroll bars	Added by skinning the container.	Built into the container.

Sizing an application container and its children

You can set the height and width of an application container by using explicit pixel values or by using percentage values, where the percentage values are relative to the size of the browser window. By default, the application container sets its height to 375 pixels and its width to 500 pixels in the Standalone Flash Player, and sizes itself to use all available space in a browser.

The following example sets the size of the Application container to one-half of the width and height of the browser window:

```
<?xml version="1.0"?>
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    height="50%" width="50%">
    ...
</Application>
```

The advantage of using percentages to specify the size is that Flex can resize your application as the user resizes the browser window. Flex maintains the application container size as a percentage of the browser window as the user resizes it.

If you set the `width` and `height` properties of the child components to percentage values, your components can also resize as your application resizes, as the following example shows:

```
<?xml version="1.0"?>
<!-- containers\application\AppSizePercent.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    width="100%" height="100%">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:Panel title="Main Application" width="100%" height="100%">
        <mx:HDividedBox width="100%" height="100%">
            <s:TextArea text="TA1" width="50%" height="100%"/>
            <mx:VDividedBox width="50%" height="100%">
                <s:TextArea text="TA2" width="100%" height="75%"/>
                <s:TextArea text="TA3" width="100%" height="75%"/>
            </mx:VDividedBox>
        </mx:HDividedBox>
    </s:Panel>
</s:Application>
```

The following example uses explicit pixel values to size the application container:

```
<?xml version="1.0"?>
<!-- containers\application\AppSizePixel.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    width="200" height="150">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <mx:Panel title="Main Application">
        <mx:TextInput id="mytext" text="Hello"/>
        <mx:Button id="mybutton" label="Get Weather"/>
    </mx:Panel>
</s:Application>
```

If you want to set a child container to fill the entire application container, the easiest method is to set the child's `width` and `height` properties to 100% in MXML. In ActionScript, set the `percentWidth` and `percentHeight` properties to 100.

Because the Spark Application container defines 0 pixels of padding around its content area, a child sized to 100% fills the entire area of the container. In the following example, the child VBox container fills the entire application container:

```
<?xml version="1.0"?>
<!-- containers\application\AppNoPadding.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    width="100%" height="100%">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <mx:VBox width="100%" height="100%" backgroundColor="#A9C0E7">
        <!-- ... -->
    </mx:VBox>
</s:Application>
```

The MX Application container defines 24 pixels of padding around all four sides of its content area. Therefore, if you want a child to occupy the entire area of the Application container, set the container's padding properties (`paddingTop`, `paddingBottom`, `paddingLeft`, `paddingRight`) to 0.

Using scroll bars with the application container

The MX Application container has built in support for scroll bars. Therefore, if the children of the MX Application container are sized or positioned such that some or all the component is outside the visible area of the MX Application container, Flex adds scroll bars to the container.

In the following example, the VBox container in the MX Application container is larger than the available space within the Application container, which results in scroll bars:

```
<?xml version="1.0"?>
<!-- containers\application\AppVBoxSizeScroll.mxml -->
<mx:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    width="100" height="100">
    <mx:VBox width="200" height="200" backgroundColor="#A9C0E7">
        <!-- ... -->
    </mx:VBox>
</mx:Application>
```

To add scroll bars to the Spark Application container, define a skin that supports scroll bars. The following example shows a skin in the file MyAppSkin.mxml. This skin modifies the default skin for the Spark Application container, spark.skins.default.ApplicationSkin, to add the Spark Scroller component:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\application\mySkins\MyAppSkin.mxml -->
<s:Skin xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Metadata>
        [HostComponent("spark.components.Application")]
    </fx:Metadata>

    <s:states>
        <s:State name="normal" />
        <s:State name="disabled" />
    </s:states>

    <!-- fill -->
    <s:Rect id="backgroundRect" left="0" right="0" top="0" bottom="0">
        <s:fill>
            <s:SolidColor color="0xFFFFFF" />
        </s:fill>
    </s:Rect>

    <s:Scroller height="100%" width="100%">
        <s:Group id="contentGroup" left="0" right="0" top="0" bottom="0" />
    </s:Scroller>
</s:Skin>
```

The following application uses this skin:

```
<?xml version="1.0"?>
<!-- containers\application\AppSparkScroll.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    width="150" height="150"
    skinClass="mySkins.MyAppSkin">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <mx:VBox width="200" height="200" backgroundColor="#A9C0E7">
        <!-- ... -->
    </mx:VBox>

    <mx:VBox width="200" height="200" backgroundColor="#000000">
        <!-- ... -->
    </mx:VBox>
</s:Application>
```

For more information, see “Adding scroll bars to Spark containers” on page 1637.

Overriding the default Application container styles

By default, the application containers have the following properties and style properties that define the visual aspects of the application and differ from the default container values:

Property	Spark Application default value	MX Application default value
backgroundColor	The color of the Stage area of Adobe® Flash® Player or Adobe® AIR™, which is visible during application loading and initialization. This color is also visible if the application skin does not define any other background color or image. The default value is 0xFFFFFF (white).	The color of the Stage area of Adobe® Flash® Player or Adobe® AIR™, which is visible during application loading and initialization. This color is also visible if the application background is transparent. The default value is 0xFFFFFF (white).
backgroundGradientAlphas	Not implemented; define in the container skin.	[1.0, 1.0], a fully opaque background.
backgroundGradientColors	Not implemented; define in the container skin.	undefined, which means background gradient is generated based on the backgroundColor property. By default, the backgroundColor property defines a white background.
backgroundImage	Not implemented; define in the container skin.	A gradient controlled by the backgroundGradientAlphas and backgroundGradientColors styles. The default value is mx.skins.halo.ApplicationBackground.
backgroundSize	Not implemented; define in the container skin.	100%. When you set this property at 100%, the background image takes up the entire Application container.
horizontalAlign	Not implemented; set in the layout class associated with the Application container.	Centered.
paddingBottom	0 pixels.	24 pixels.

Property	**Spark Application default value**	**MX Application default value**
`paddingLeft`	0 pixels.	24 pixels.
`paddingRight`	0 pixels.	24 pixels.
`paddingTop`	0 pixels.	24 pixels.

Changing the Spark Application container background

The Spark `Application.backgroundColor` style defines the default background color of the Application container during application loading and initialization. If the Application skin does not set a different color, the `backgroundColor` style also defines the background color of the application when it is running. The default value is 0xFFFFFF (white).

To set the background color of the Spark Application container to something other than a solid color, or to set a background image, you define a skin for the container. For example, the following skin defines a gradient fill for the background of the Application container that goes from blue to gray:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\application\mySkins\MyAppBackgroundSkin.mxml -->
<s:Skin xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Metadata>
        [HostComponent("spark.components.Application")]
    </fx:Metadata>

    <s:states>
        <s:State name="normal" />
        <s:State name="disabled" />
    </s:states>
    <!-- Define a gradient fill for the background of the Application container. -->
    <s:Rect id="backgroundRect" left="0" right="0" top="0" bottom="0">
        <s:fill>
            <s:LinearGradient>
                <s:entries>
                    <s:GradientEntry color="0x0000FF" ratio="0.00" alpha="0.5"/>
                    <s:GradientEntry color="0xCCCCCC" ratio="0.5" alpha="0.5"/>
                </s:entries>
            </s:LinearGradient>
        </s:fill>
    </s:Rect>

    <s:Group id="contentGroup" left="0" right="0" top="0" bottom="0" />
</s:Skin>
```

You then use the `skinClass` style property to apply the skin to the Application, as the following example shows:

```
<?xml version="1.0"?>
<!-- containers\application\AppSparkBackground.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    skinClass="mySkins.MyAppBackgroundSkin">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

</s:Application>
```

The next skin example uses the Image control to embed an image for the background of the Application container:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\application\mySkins\MyAppBackgroundImageSkin.mxml -->
<s:Skin xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Metadata>
        [HostComponent("spark.components.Application")]
    </fx:Metadata>

    <s:states>
        <s:State name="normal" />
        <s:State name="disabled" />
    </s:states>

    <!-- Use an Image control to embed an image for the
            background of the Application container. -->
    <mx:Image source="@Embed(source='logo.jpg')"
        left="0" right="0" top="0" bottom="0"
        maintainAspectRatio="false" />

    <s:Group id="contentGroup" left="0" right="0" top="0" bottom="0" />
</s:Skin>
```

For more information on skinning, see “Spark Skinning” on page 1602.

Changing the MX Application container background

The Application container `backgroundGradientAlphas`, `backgroundGradientColors`, and `backgroundImage` styles control the container background. By default, these properties define an opaque gray gradient background.

You specify an image for the application background by using the `backgroundImage` property. If you set both the `backgroundImage` property and the `backgroundGradientColors` property, Flex ignores `backgroundGradientColors`.

You can specify a gradient background for the application in two ways:

1 Set the `backgroundGradientColors` property to two values, as in the following example:

```
<mx:Application xmlns="http://ns.adobe.com/mxml/2009"
    backgroundGradientColors="[0x0000FF, 0xCCCCCC]">
```

Flex calculates the gradient pattern between the two specified values.

2 Set the `backgroundColor` property to the desired value, as in the following example:

```
<mx:Application xmlns="http://ns.adobe.com/mxml/2009"
    backgroundColor="red">
```

Flex sets the gradient background to solid red.

To set a solid background to the application by using the `backgroundGradientColors` property, specify the same two values to the `backgroundGradientColors` property, as the following example shows:

```
<mx:Application xmlns="http://ns.adobe.com/mxml/2009"
    backgroundGradientColors="[#FFFFFF, #FFFFFF]">
```

This example defines a solid white background.

The `backgroundColor` property specifies the background color of the Stage area in Flash Player, which is visible during application loading and initialization, and a background gradient while the application is running. By default, the `backgroundColor` property is set to `0xFFFFFF` (white).

If you use the `backgroundGradientColors` property to set the application background, set the `backgroundColor` property to compliment the `backgroundGradientColors` property, as the following example shows:

```
<mx:Application xmlns="http://ns.adobe.com/mxml/2009"
    backgroundGradientColors="[0x0000FF, 0xCCCCCC]"
    backgroundColor="0x0000FF">
```

In this example, you use the `backgroundGradientColors` property to set a gradient pattern from a dark blue to gray, and the `backgroundColor` property to set the Stage area in Flash Player to dark blue, which is visible during application loading and initialization.

Adding a control bar area to the application container

An application control bar contains a group of controls outside of the main content area of an application container. The control bar is always visible, and cannot be scrolled like other container children.

For the MX Application container, create a control bar area by adding the ApplicationControlBar container as a child of the MX Application container. For more information and examples, see “MX ApplicationControlBar layout container” on page 582.

For the Spark Application container, use the `controlBarContent` property to define the controls that appear in the control bar area, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\application\AppSparkCB.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    width="600">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:controlBarContent>
        <mx:MenuBar height="100%"
            dataProvider="{menuXML}"
            labelField="@label"
            showRoot="true"/>
        <mx:HBox paddingBottom="5"
            paddingTop="5">
            <mx:ComboBox dataProvider="{cmbDP}"/>
            <mx:Spacer width="100%"/>
            <mx:TextInput id="myTI" text=""/>
            <mx:Button id="srch1"
                label="Search"
                click="Alert.show('Searching');"/>
        </mx:HBox>
    </s:controlBarContent>

    <fx:Script>
        <![CDATA[
            import mx.controls.Alert;
        ]]>
    </fx:Script>

    <fx:Declarations>
        <fx:XMLList id="menuXML">
            <fx:menuitem label="File">
                <fx:menuitem label="New" data="New"/>
                <fx:menuitem label="Open" data="Open"/>
                <fx:menuitem label="Save" data="Save"/>
                <fx:menuitem label="Exit" data="Exit"/>
            </fx:menuitem>
            <fx:menuitem label="Edit">
                <fx:menuitem label="Cut" data="Cut"/>
                <fx:menuitem label="Copy" data="Copy"/>
                <fx:menuitem label="Paste" data="Paste"/>
            </fx:menuitem>
            <fx:menuitem label="View"/>
        </fx:XMLList>

        <fx:Array id="cmbDP">
            <fx:String>Item 1</fx:String>
            <fx:String>Item 2</fx:String>
            <fx:String>Item 3</fx:String>
        </fx:Array>
    </fx:Declarations>

    <s:Button label="Button"/>
    <mx:TextArea width="300" height="200"/>
</s:Application>
```

The location and appearance of the control bar area of the Spark Application container is determined by the spark.skins.spark.ApplicationSkin class, the skin class for the Spark Application container. By default, the ApplicationSkin class defines the control bar area to appear at the top of the content area of the Application container with a grey background. Create a custom skin to change the default appearance of the control bar.

By default, the controls in the control bar area use horizontal layout. Use the `Application.controlBarLayout` property to specify a different layout, as the following example shows:

```
<s:controlBarLayout>
    <s:HorizontalLayout paddingLeft="12" gap="5"/>
</s:controlBarLayout>
```

Application events

The following events are dispatched only by the application containers:

- `applicationComplete` Dispatched after the application has been initialized, processed by the LayoutManager, and attached to the display list. This is the last event dispatched during an application's startup sequence. It is later than the application's `creationComplete` event, which gets dispatched before the preloader has been removed and the application has been attached to the display list.
- `error` Dispatched when an HTTPService call fails.

Viewing the application source code

You can use the `viewSourceURL` property of the application containers to specify a URL to the application's source code. If you set this property, Flex adds a View Source menu item to the application's context menu, which you open by right-clicking anywhere in your application. Select the View Source menu item to open the URL specified by the `viewSourceURL` property in a new browser window.

Set the `viewSourceURL` property by using MXML, not ActionScript, as the following example shows:

```
<?xml version="1.0"?>
<!-- containers\application\AppSourceURL.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    viewSourceURL="assets/AppSourceURL.txt">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <s:Button label="Click Me"/>
</s:Application>
```

You typically deploy your source code not as an MXML file, but as a text or HTML file. In this example, the source code is in the file AppSourceURL.txt. If you use an HTML file to represent your source code, you can add formatting and coloring to make it easier to read.

Specifying options of the Application container

You can specify several options of the application container to control your application. The following table describes these options:

Option	**Type**	**Description**
`frameRate`	Number	Specifies the frame rate of the application, in frames per second. The default value is 24.
`pageTitle`	String	Specifies a String that appears in the title bar of the browser. This property provides the same functionality as the HTML `<title>` tag.
`preloader`	String	Specifies the path of a SWC component class or ActionScript component class that defines a custom progress bar. A SWC component must be in the same directory as the MXML file or in the WEB-INF/flex/user_classes directory of your Flex web application. For more information, see “Showing the download progress of an application” on page 408.
`scriptRecursionLimit`	Number	Specifies the maximum depth of Flash Player or AIR call stack before Flash Player or AIR stops. This is essentially the stack overflow limit. The default value is 1000.
`scriptTimeLimit`	Number	Specifies the maximum duration, in seconds, that an ActionScript event listener can execute before Flash Player or AIR assumes that it has stopped processing and aborts it. The default value is 60 seconds, which is also the maximum allowable value that you can set.
`useDirectBlit`	Boolean	Specifies whether hardware acceleration is used to copy graphics to the screen (if such acceleration is available). This option only applies to applications running in the standalone Flash Player. For applications running in a browser, setting `useDirectBlit` to `true` is equivalent to setting `wmode` to `"direct"` in the HTML wrapper. For AIR applications, use the `renderMode` application descriptor tag. The default value is `false`.
`useGPU`	Boolean	Specifies whether GPU (Graphics Processing Unit) acceleration is used when drawing graphics (if such acceleration is available). This option only applies to applications running in the standalone Flash Player. For applications running in a browser, setting `useGPU` to `true` is equivalent to setting `wmode` to `"gpu"` in the HTML wrapper. For AIR applications, use the `renderMode` application descriptor tag. The default value is `false`.
`usePreloader`	Boolean	Specifies whether to disable the application preloader (`false`) or not (`true`). The default value is `true`. To use the default preloader, your application must be at least 160 pixels wide. For more information, see “Showing the download progress of an application” on page 408.

***Note:** Properties `frameRate`, `pageTitle`, `preloader`, `scriptRecursionLimit`, and `usePreloader`, cannot be set in ActionScript; they must be set in MXML code.*

About the application object

Flex compiles your application into a SWF file that contains a single application object, of type spark.components.Application or mx.core.Application. In most cases, your application has one application object. Some applications use the SWFLoader control to add more applications.

An application object has the following characteristics:

- The file defining the application object is the first file loaded by the application.
- You can refer to the application object as `mx.core.FlexGlobals.topLevelApplication` from anywhere in the application.

- If you load multiple nested applications by using the SWFLoader control, you can access the scope of each higher application in the nesting hierarchy by using `parentApplication`, `parentApplication.parentApplication`, and so on.

About documents

Every MXML file used in an application is referred to as a *document class*. For example, you define an MXML file named MyForm.mxml that contains the following code:

```
<?xml version="1.0"?>
<mx:Form xmlns:mx="library://ns.adobe.com/flex/mx">
    ...
</mx:Form>
```

MyForm.mxml is the document class and instances of MyForm.mxml are referred to as *documents*. An MXML file that includes the `<s:Application>` or `<mx:Application>` tag is the document class that defines the application object. MXML files that omit the `<s:Application>` or `<mx:Application>` tag are custom controls.

A document has the following characteristics:

- All MXML files that an application uses are document classes, including the MXML file that includes the `<s:Application>` or `<mx:Application>` tag.
- Custom ActionScript component files are document classes.
- The Flex compiler cannot compile a SWF file from a file that does not contain the `<s:Application>` or `<mx:Application>` tag.
- You can access the scope of a document's parent document by using `parentDocument`, `parentDocument.parentDocument`, and so on.
- Flex provides a `UIComponent.isDocument` property so that you can detect if any given object is a document.

Accessing document and application scopes

In your application's main MXML file, the file that contains the `<s:Application>` or `<mx:Application>` tag, you can access the methods and properties of the application object by using the `this` keyword. However, in custom ActionScript and MXML components, event listeners, or external ActionScript class files, Flex executes in the context of those components and classes, and the `this` keyword refers to the current document and not to the application object. You cannot refer to a control or method in the application from one of these child documents without specifying the location of the parent document.

Flex provides the following properties that you can use to access parent documents:

mx.core.FlexGlobals.topLevelApplication The top-level application object, regardless of where in the document tree your object executes. This object is of type spark.components.Application or mx.core.Application.

mx.core.UIComponent.parentDocument The parent document of the current document. You can use `parentDocument.parentDocument` to walk up the tree of multiple documents.

mx.core.UIComponent.parentApplication The Application object in which the current object exists. Applications can load other applications, therefore, you can access the immediate parent application by using this property. You can use `parentApplication.parentApplication` to walk up the tree of multiple applications.

Using the mx.core.FlexGlobals.topLevelApplication property

To access properties and methods of the top-level application object from anywhere in your application, you can use the `topLevelApplication` property of the FlexGlobals class. For example, you define an application that contains the method, as the following code shows:

```
<?xml version="1.0"?>
<!-- containers\application\AppDoSomething.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:MyComps="myComponents.*">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            import mx.controls.Alert;

            // Open an Alert control.
            public function doSomething():void {
                Alert.show("The doSomething() method was called.");
            }
        ]]>
    </fx:Script>

    <!-- Include the ButtonMXML.mxml component. -->
    <MyComps:ButtonMXML/>
</s:Application>
```

You can then use the `FlexGlobals.topLevelApplication` property in the ButtonMXML.mxml component to reference the `doSomething()` method, as the following example shows:

```
<?xml version="1.0"?>
<!-- containers\application\myComponents\ButtonMXML.mxml -->
<s:SkinnableContainer xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:HorizontalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            // To refer to the members of the Application class,
            // you must import mx.core.Application.
            import mx.core.FlexGlobals;
        ]]>
    </fx:Script>
    <s:Button  label="MXML Button"
        click="FlexGlobals.topLevelApplication.doSomething();"/>
</s:SkinnableContainer>
```

The `topLevelApplication` property is especially useful in applications that have one or more custom MXML or ActionScript components that each use a shared set of data. At the application level, you often store shared information and provide utility functions that any of the components can access.

For example, suppose that you store the user's name at the application level and implement a utility function, `getSalutation()`, which returns the string "Hi, *userName*". The following example MyApplication.mxml file shows the application source that defines the `getSalutation()` method:

```
<?xml version="1.0"?>
<!-- containers\application\AppSalutation.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:MyComps="myComponents.*">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            public var userName:String="SMG";

            public function getSalutation():String {
                return "Hi, " + userName;
            }
        ]]>
    </fx:Script>
    <!-- Include the ButtonGetSalutation.mxml component. -->
    <MyComps:ButtonGetSalutation/>

</s:Application>
```

To access the `userName` and call the `getSalutation()` method in your MXML components, you can use the `topLevelApplication` property, as the following example from the MyComponent.mxml component shows:

```
<?xml version="1.0"?>
<!-- containers\application\myComponents\ButtonGetSalutation.mxml -->
<s:SkinnableContainer xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    width="100%" height="100%">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            /* To refer to the members of the Application class,
               you must import mx.core.Application. */
            import mx.core.FlexGlobals;
        ]]>
    </fx:Script>
    <mx:Label id="myL"/>
    <s:Button label="Click Me"
        click="myL.text=FlexGlobals.topLevelApplication.getSalutation();"/>
</s:SkinnableContainer>
```

In this example, clicking the Button control executes the `getSalutation()` function to populate the Label control.

Using the parentDocument property

To access the parent document of an object, you can use the parentDocument property. The parent document is the object that contains the current object. All classes that inherit from the UIComponent class have a `parentDocument` property.

In the following example, the application references the custom AccChildObject.mxml component:

```
<?xml version="1.0"?>
<!-- containers\application\AppParentDocument.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:MyComps="myComponents.*"
    width="100%" height="100%">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <!-- Include the AccChildObject.mxml component. -->
    <MyComps:AccChildObject/>
</s:Application>
```

In this example, the application is the parent document of the AccChildObject.mxml component. The following code from the AccChildObject.mxml component uses the `parentDocument` property to define an Accordion container that is slightly smaller than the Application container:

```
<?xml version="1.0"?>
<!-- containers\application\myComponents\AccChildObject.mxml -->
<mx:Accordion xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    width="{parentDocument.width*.80}"
    height="{parentDocument.height*.50}">

    <mx:HBox label="Child HBox"/>

</mx:Accordion>
```

You use the `parentDocument` property in MXML scripts to go up a level in the chain of parent documents. You can use the `parentDocument` to walk this chain by using multiple `parentDocument` properties, as the following example shows:

```
parentDocument.parentDocument.doSomething();
```

The `parentDocument` property of the application object is a reference to the application.

The `parentDocument` is typed as Object so that you can access properties and methods on ancestor document objects without casting.

Every UIComponent class has an `isDocument` property that is set to `true` if that UIComponent class is a document object, and `false` if it is not.

If a UIComponent class is a document object, it has a `documentDescriptor` property. This is a reference to the descriptor at the top of the generated descriptor tree in the generated document class.

For example, suppose that AddressForm.mxml component creates a subclass of the Form container to define an address form, and the MyApp.mxml component creates two instances of it: `<AddressForm id="shipping">` and `<AddressForm id="billing">`.

In this example, the shipping object is a document object. Its `documentDescriptor` property corresponds to the `<mx:Form>` tag at the top of the AddressForm.mxml file (the definition of the component), while its descriptor corresponds to the `<AddressForm id="shipping">` tag in MyApp.mxml file (an instance of the component).

Walking the document chain by using the `parentDocument` property is similar to walking the application chain by using the `parentApplication` property.

Using the parentApplication property

Applications can load other applications; therefore, you can have a hierarchy of applications, similar to the hierarchy of documents within each application. Every UIComponent class has a `parentApplication` read-only property that references the application object in which the object exists. The `parentApplication` property of an application object is never itself; it is either the application object into which it was loaded, or it is `null` (for the application object).

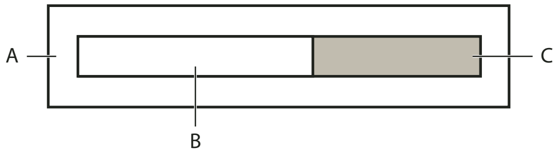
Walking the application chain by using the `parentApplication` property is similar to walking the document chain by using the `parentDocument` property.

Showing the download progress of an application

The application containers support an application preloader that uses a download progress bar to show the download and initialization progress of an application SWF file. By default, the application preloader is enabled. The preloader tracks how many bytes have been downloaded and continually updates the progress bar.

The download progress bar displays information about two different phases of the application: the download phase and the initialization phase. The application container's `creationComplete` event dismisses the preloader.

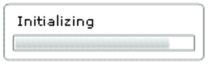
Flex includes two download progress bar classes: the SparkDownloadProgressBar (Spark) and the DownloadProgressBar (MX). The following image shows the Spark download progress bar:



A. Spark download progress bar. B. Initialization progress track. C. Download progress track.

When the SWF file is downloading, download progress track expands. When the application is initializing, the initilization progress track expands. The SparkDownloadProgressBar class does not contain text.

The following example shows the MX download progress bar during the initialization phase:



The MX download progress bar supports text. The bar displays the text "Downloading app" during the SWF download. It displays the text "Initializing app" during application initialization.

The download progress bar is not displayed if the SWF file is on your local host or if it is already cached. If the SWF file is not on your local host and is not cached, the progress bar is displayed if less than half of the application is downloaded after 700 milliseconds of downloading.

Adding a splash screen

As an alternative to the preloader, you can display a splash screen instead. The splash screen appears during the time of application startup. For information on using a splash screen, see Add a splash screen to an application.

Setting the download progress bar class

By default, an Application container uses the SparkDownloadProgressBar class. To configure the Application container to use the MX class, DownloadProgressBar, use the `preloader` property as the following example shows:

```
<s:Application ... preloader="mx.preloaders.DownloadProgressBar">
```

Disabling the download progress bar

To disable the download progress bar, set the `usePreloader` property of the Application container to `false`, as the following example shows:

```
<s:Application ... usePreloader="false">
```

Creating a custom progress bar

To create a custom download progress bar, you can create a subclass of the SparkDownloadProgressBar or DownloadProgressBar class, or create a subclass of the flash.display.Sprite class that implements the mx.preloaders.IPreloaderDisplay interface.

You can implement a download progress bar component as a SWC component or an ActionScript component. A custom download progress bar component that extends the Sprite class should not use any of the standard Flex components because it would load too slowly to be effective. Do not implement a download progress bar as an MXML component because it also would load too slowly.

To use a custom download progress bar class, you set the `preloader` property of the application container to the path of a SWC component class or ActionScript component class. A SWC component must be in the same directory as the MXML file or in a directory on the classpath of your application. An ActionScript component can be in one of those directories or in a subdirectory of one of those directories. When a class is in a subdirectory, you specify the subdirectory location as the package name in the `preloader` value; otherwise, you specify the class name.

The code in the following example specifies a custom download progress bar called CustomBar that is located in the myComponents/mybars directory below the application's root directory:

```
<s:Application ... preloader="myComponents.mybars.CustomBar">
```

Download progress bar events

The operation of the download progress bar is defined by a set of events. These events are dispatched by the Preloader class. The SparkDownloadProgressBar and DownloadProgressBar classes defines an event listener for all these events.

Within your custom class, you can optionally override the default behavior of the event listener. If you create a custom download progress bar as a subclass of the Sprite class, define an event listener for each of these events.

The following table describes the download progress bar events:

Event	Description
`ProgressEvent.PROGRESS`	Dispatched when the application SWF file is being downloaded. The first `PROGRESS` event signifies the beginning of the download process.
`Event.COMPLETE`	Dispatched when the SWF file has finished downloading. Either zero or one `COMPLETE` event is dispatched.
`FlexEvent.INIT_COMPLETE`	Dispatched when the application finishes initialization. This event is always dispatched once, and is the last event that the Preloader dispatches. The download progress bar must dispatch a `COMPLETE` event after it has received an `INIT_COMPLETE` event. The `COMPLETE` event informs the Preloader that the download progress bar has completed all operations and can be dismissed. The download progress bar can perform additional tasks, such as playing an animation, after receiving an `INIT_COMPLETE` event, and before dispatching the COMPLETE event. Dispatching the COMPLETE event should be the last action of the download progress bar.
`FlexEvent.INIT_PROGRESS`	Dispatched when the application completes an initialization phase, as defined by calls to the `measure()`, `commitProperties()`, or `updateDisplayList()` methods. This event describes the progress of the application in the initialization phase.

Event	Description
`RSLEvent.RSL_ERROR`	Dispatched when a Runtime Shared Library (RSL) fails to load.
`RSLEvent.RSL_LOADED`	Dispatched when an RSL finishes loading. The total bytes and total loaded bytes are included in the event object. This event is dispatched for every RSL that is successfully loaded.
`RSLEvent.RSL_PROGRESS`	Dispatched when an RSL is being downloaded. The first progress event signifies the beginning of the RSL download. The event object for this event is of type RSLEvent.

Creating a simple download progress bar class

The easiest way to create your own download progress bar is to create a subclass of the SparkDownloadProgressBar or DownloadProgressBar class, and then modify it for your application requirements.

The following example shows a custom download progress bas based on the SparkDownloadProgressbar class. This class overrides the getter methods for the `SparkDownloadProgressbar.backgroundImage` and `SparkDownloadProgressbar.backgroundSize` properties to show an image during application download and inititialization:

```
package myComponents
{
    import mx.preloaders.*;
    import flash.events.ProgressEvent;
    public class SparkDownloadProgressBarSubClassMin extends SparkDownloadProgressBar
    {
        public function SparkDownloadProgressBarSubClassMin() {
            super();
        }

        // Embed the background image.
        [Embed(source="logo.jpg")]
        [Bindable]
        public var imgCls:Class;
        // Override to set a background image.
        override public function get backgroundImage():Object{
            return imgCls;
        }

        // Override to set the size of the background image to 100%.
        override public function get backgroundSize():String{
            return "100%";
        }

        // Override to return true so progress bar appears
        // during initialization.
        override protected function showDisplayForInit(elapsedTime:int,
            count:int):Boolean {
                return true;
        }
        // Override to return true so progress bar appears during download.
        override protected function showDisplayForDownloading(
            elapsedTime:int, event:ProgressEvent):Boolean {
                return true;
        }
    }
}
```

The following application uses this custom class:

```
<?xml version="1.0"?>
<!-- containers\application\SparkMainDPBMin.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    preloader="myComponents.SparkDownloadProgressBarSubClassMin">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <!-- Add a couple of controls that don't do anything. -->
    <s:Button label="Click Me"/>
    <s:TextInput text="This is a TextInput control."/>
</s:Application>
```

The Spark download progress bar does not support text, but the MX one does. The next example creates a subclass of the MX DownloadProgressBar class to define custom strings for the download progress bar, and set the minimum time that it appears, as the following example shows:

```
package myComponents
{
    import mx.preloaders.*;
    import flash.events.ProgressEvent;
    public class DownloadProgressBarSubClassMin extends DownloadProgressBar
    {
        public function DownloadProgressBarSubClassMin()
        {
            super();
            // Set the download label.
            downloadingLabel="Downloading app..."
            // Set the initialization label.
            initializingLabel="Initializing app..."
            // Set the minimum display time to 2 seconds.
            MINIMUM_DISPLAY_TIME=2000;
        }

        // Override to return true so progress bar appears
        // during initialization.
        override protected function showDisplayForInit(elapsedTime:int,
            count:int):Boolean {
                return true;
        }
        // Override to return true so progress bar appears during download.
        override protected function showDisplayForDownloading(
            elapsedTime:int, event:ProgressEvent):Boolean {
                return true;
        }
    }
}
```

You can use your custom class in an application, as the following example shows:

```
<?xml version="1.0"?>
<!-- containers\application\MainDPBMin.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    preloader="myComponents.DownloadProgressBarSubClassMin">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <!-- Add a couple of controls that don't do anything. -->
    <s:Button label="Click Me"/>
    <s:TextInput text="This is a TextInput control."/>
</s:Application>
```

Creating an advanced subclass of the DownloadProgressBar class

In the following example, you create a subclass of the DownloadProgressBar class to display text messages that describe the status of the downloading and initialization of the application. This example defines event listeners for the events dispatched by the download progress bar to write the messages to flash.text.TextField objects.

```
package myComponents
{
    import flash.display.*;
    import flash.text.*;
    import flash.utils.*;
    import flash.events.*;
    import mx.preloaders.*;
    import mx.events.*;
    public class MyDownloadProgressBar extends DownloadProgressBar
    {
        // Define a TextField control for text messages
        // describing the download progress of the application.
        private var progressText:TextField;

        // Define a TextField control for the final text message.
        // after the application initializes.
        private var msgText:TextField;

        public function MyDownloadProgressBar()
        {
            super();
            // Configure the TextField for progress messages.
            progressText = new TextField();
            progressText.x = 10;
            progressText.y = 90;
            progressText.width = 400;
            progressText.height = 400;

            addChild(progressText);

            // Configure the TextField for the final message.
            msgText = new TextField();
            msgText.x = 10;
            msgText.y = 10;
            msgText.width = 400;
            msgText.height = 75;

            addChild(msgText);
        }

        // Define the event listeners for the preloader events.
        override public function set preloader(preloader:Sprite):void {
            // Listen for the relevant events
            preloader.addEventListener(
                ProgressEvent.PROGRESS, myHandleProgress);
            preloader.addEventListener(
                Event.COMPLETE, myHandleComplete);
            preloader.addEventListener(
                FlexEvent.INIT_PROGRESS, myHandleInitProgress);
            preloader.addEventListener(
                FlexEvent.INIT_COMPLETE, myHandleInitEnd);
        }

        // Event listeners for the ProgressEvent.PROGRESS event.
        private function myHandleProgress(event:ProgressEvent):void {
            progressText.appendText("\n" + "Progress l: " +
                event.bytesLoaded + " t: " + event.bytesTotal);
        }

        // Event listeners for the Event.COMPLETE event.
        private function myHandleComplete(event:Event):void {
            progressText.appendText("\n" + "Completed");
        }

        // Event listeners for the FlexEvent.INIT_PROGRESS event.
        private function myHandleInitProgress(event:Event):void {
            progressText.appendText("\n" + "App Init Start");
        }

        // Event listeners for the FlexEvent.INIT_COMPLETE event.
        private function myHandleInitEnd(event:Event):void {
            msgText.appendText("\n" + "App Init End");

            var timer:Timer = new Timer(2000,1);
            timer.addEventListener(TimerEvent.TIMER, dispatchComplete);
            timer.start();
        }

        // Event listener for the Timer to pause long enough to
        // read the text in the download progress bar.
        private function dispatchComplete(event:TimerEvent):void {
            dispatchEvent(new Event(Event.COMPLETE));
        }
    }
}
```

You can use your custom class in a application, as the following example shows:

```
<?xml version="1.0"?>
<!-- containers\application\MainDPB.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    preloader="myComponents.MyDownloadProgressBar">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <!-- Add a couple of controls that don't do anything. -->
    <s:Button label="Click Me"/>
    <s:TextInput text="This is a TextInput control."/>
</s:Application>
```

Creating a subclass of Sprite as a download progress bar

You can define a custom download progress bar as a subclass of the Sprite class. By implementing your download progress bar as a subclass of Sprite, you can create a custom look and feel to it, rather than overriding the behavior built into the DownloadProgressBar class.

One common use for this type of download progress bar is to have it display a SWF file during application initialization. For example, you could display a SWF file that shows a running clock, or other type of image.

The following example displays a SWF file as the download progress bar. This class must implement the IPreloaderDisplay interface.

```
package myComponents
{
    import flash.display.*;
    import flash.utils.*;
    import flash.events.*;
    import flash.net.*;
    import mx.preloaders.*;
    import mx.events.*;

    public class MyDownloadProgressBarSWF extends Sprite
        implements IPreloaderDisplay
    {
        // Define a Loader control to load the SWF file.
        private var dpbImageControl:flash.display.Loader;

        public function MyDownloadProgressBarSWF() {
            super();
        }

        // Specify the event listeners.
        public function set preloader(preloader:Sprite):void {
            // Listen for the relevant events
            preloader.addEventListener(
                ProgressEvent.PROGRESS, handleProgress);
            preloader.addEventListener(
                Event.COMPLETE, handleComplete);

            preloader.addEventListener(
                FlexEvent.INIT_PROGRESS, handleInitProgress);
            preloader.addEventListener(
                FlexEvent.INIT_COMPLETE, handleInitComplete);
        }

        // Initialize the Loader control in the override
        // of IPreloaderDisplay.initialize().
        public function initialize():void {
            dpbImageControl = new flash.display.Loader();
            dpbImageControl.contentLoaderInfo.addEventListener(
                Event.COMPLETE, loader_completeHandler);
            dpbImageControl.load(new URLRequest("assets/dpbSWF.swf"));
        }
        // After the SWF file loads, set the size of the Loader control.
        private function loader_completeHandler(event:Event):void
        {
            addChild(dpbImageControl);
            dpbImageControl.width = 50;
            dpbImageControl.height= 50;
            dpbImageControl.x = 100;
            dpbImageControl.y = 100;
        }

        // Define empty event listeners.
        private function handleProgress(event:ProgressEvent):void {
        }

        private function handleComplete(event:Event):void {
        }
        private function handleInitProgress(event:Event):void {
        }

        private function handleInitComplete(event:Event):void {
            var timer:Timer = new Timer(2000,1);
            timer.addEventListener(TimerEvent.TIMER, dispatchComplete);
            timer.start();
        }

        private function dispatchComplete(event:TimerEvent):void {
            dispatchEvent(new Event(Event.COMPLETE));
        }
        // Implement IPreloaderDisplay interface

        public function get backgroundColor():uint {
            return 0;
        }

        public function set backgroundColor(value:uint):void {
        }

        public function get backgroundAlpha():Number {
            return 0;
        }

        public function set backgroundAlpha(value:Number):void {
        }

        public function get backgroundImage():Object {
            return undefined;
        }

        public function set backgroundImage(value:Object):void {
        }

        public function get backgroundSize():String {
            return "";
        }

        public function set backgroundSize(value:String):void {
        }

        public function get stageWidth():Number {
            return 200;
        }

        public function set stageWidth(value:Number):void {
        }

        public function get stageHeight():Number {
            return 200;
        }

        public function set stageHeight(value:Number):void {
        }
    }
}
```

Spark containers

Spark containers provide a hierarchical structure to arrange and configure their children.

Flex also provides a set of MX layout and MX navigator containers. Adobe recommends that you use the Spark containers when possible. For more information on the MX layout and MX navigator containers, see “MX layout containers” on page 574 and “MX navigator containers” on page 628.

For an introduction to containers, including Spark containers, see “Introduction to containers” on page 326.

About Spark containers

Spark includes the following containers:

- Group (including HGroup, VGroup, and TileGroup) and DataGroup
- SkinnableContainer, SkinnableDataContainer, Panel, TitleWindow, NavigatorContent, BorderContainer, and Application

  ***Note:** The Panel and NavigatorContent classes are subclasses of the SkinnableContainer class. The information below for SkinnableContainer applies also to the Panel and NavigatorContent classes.*

For more information on the Application container, see “Application containers” on page 393.

Interchangeable layouts

Most Spark containers support interchangeable layouts. That means you can set the layout of a container to any of the supported layout types, such as basic, horizontal, vertical, or tiled layout. You can also define a custom layout.

***Note:** Some Spark containers, such as HGroup, VGroup, and TileGroup, have a predefined layout that you cannot change.*

Skinning

To improve performance and minimize application size, some Spark containers do not support skinning. Use the Group and DataGroup containers to manage child layout. Use SkinnableContainer and SkinnableDataContainer to manage child layout and to support custom skins.

Visual child components

The Group and SkinnableContainer classes can take any visual components as children. Visual components implement the IVisualElement interface, and include subclasses of the UIComponent class and the GraphicElement class.

The UIComponent class is the base class of all Flex components. Therefore, you can use any Flex component as a child of the Group and SkinnableContainer class.

The GraphicElement class is the base class for the Flex drawing classes, such as the Ellipse, Line, and Rect classes. Therefore, you can use subclass of the GraphicElement class as a child of the Group and SkinnableContainer class.

The DataGroup and SkinnableDataContainer classes take as children visual components that implement the IVisualElement interface and are subclasses of DisplayObject. This includes subclasses of the UIComponent class.

Data items

However, the DataGroup and SkinnableDataContainer containers are optimized to hold data items. Data items can be simple data items such as String and Number objects, and more complicated data items such as Object and XMLNode objects. Therefore, while these containers can hold visual children, use Group and SkinnableContainer for children that are visual components.

Main characteristics of Spark containers

The following table lists the main characteristics of the Spark containers:

Container	Children	Skinnable	Scrollable	Creation policy	Primary use
Group (including HGroup, VGroup, and TileGroup)	IVisualElement	No	As a child of Scroller	All	Lay out visual children.
DataGroup	Data Item IVisualElement and DisplayObject	No	As a child of Scroller	All	Render and lay out data items.
SkinnableContainer	IVisualElement	Yes	By skinning	Selectable	Lay out visual children in a skinnable container.
SkinnablePopUpContainer	IVisualElement	Yes	By skinning	Selectable	Lay out visual children in a skinnable container opened as a pop up window.
SkinnableDataContainer	Data item IVisualElement and DisplayObject	Yes	By skinning	Selectable	Render and lay out data items in a skinnable container.
BorderContainer	IVisualElement	Yes	No	Selectable	Lay out visual children in a basic container that includes a border.
Form	IVisualElement	Yes	Yes	Selectable	Lay out FormItem and FormHeading children similar to an HTML form.
NavigatorContent	IVisualElement	Yes	By skinning	Inherited from parent container	Subclass of SkinnableContainer that can be used as the child of an MX navigator container.

Container	Children	Skinnable	Scrollable	Creation policy	Primary use
Panel	IVisualElement	Yes	By skinning	Selectable	Subclass of SkinnableContainer that adds a title bar and other visual elements to the container.
TitleWindow	IVisualElement	Yes	By skinning	Selectable	Subclass of Panel that is optimized for use as a pop-up window.

For information on skinning, see "Spark Skinning" on page 1602.

Adobe Evangelist Renaun Erickson explores the Flex 4 container classes in Migrating to Flex 4: Containers.

Creation policy

Container creation policy determines how and when children of containers are created. For information on creation policy, see "About the creation policy" on page 327.

About container children

All Spark containers can take as children visual components that implement the IVisualElement interface. All Spark and MX components implement the IVisualElement interface and can therefore be used as container children.

The following example uses the Spark SkinnableContainer to hold Spark Button components:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkContainerSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:SkinnableContainer>
        <s:layout>
            <s:HorizontalLayout/>
        </s:layout>
        <s:Button label="Button 1"/>
        <s:Button label="Button 2"/>
        <s:Button label="Button 3"/>
        <s:Button label="Button 4"/>
    </s:SkinnableContainer>
</s:Application>
```

The Spark Group, SkinnableContainer, and subclasses can take as children any subclass of the GraphicElement class. This lets you add graphical elements as children of the container. The following example shows a SkinnableContainer with a Line component between two Button components:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkContainerGraphic.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:SkinnableContainer>
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <s:Button label="Button 1"/>
        <s:Line
            xFrom="0" xTo="100">
            <s:stroke>
                <s:LinearGradientStroke weight="2"/>
            </s:stroke>
        </s:Line>
        <s:Button label="Button 2"/>
    </s:SkinnableContainer>
</s:Application>
```

The DataGroup and SkinnableDataContainer classes are designed primarily to display data items as children. The following example shows a SkinnableDataContainer displaying an Array of Strings as children:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkDataContainerSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:SkinnableDataContainer itemRenderer="spark.skins.spark.DefaultItemRenderer">
        <mx:ArrayList>
            <fx:String>Dave Jones</fx:String>
            <fx:String>Mary Davis</fx:String>
            <fx:String>Debbie Cooper</fx:String>
        </mx:ArrayList>
    </s:SkinnableDataContainer>
</s:Application>
```

About Spark layouts

All Spark containers define a default layout, but let you switch the layout to suit your application requirements. To switch layout, assign a layout class to the `layout` property of the container.

Flex ships with several layout classes that you can use with the Spark containers. Additionally, you can define custom layout classes. The layout classes are defined in the spark.layouts package, and include the following classes:

- BasicLayout Uses absolute positioning. You explicitly position all container children, or use constraints to position them.
- HorizontalLayout Lays out children in a single horizontal row. The height of the row is fixed to the same height for all children and is typically the height of the tallest child. The width of each child is either fixed to the same value for all children, or each child can calculate its own width. By default, each child calculates its own width.
- TileLayout Lays out children in one or more vertical columns or horizontal rows, starting new rows or columns as necessary. The `orientation` property determines the layout direction. The valid values for the orientation property are `columns` for a column layout and `rows` (default) for a row layout.

  All cells of the tile layout have the same size, which is the height of the tallest child and the width of the widest child.

- VerticalLayout Lays out children in a single vertical column. The width of the column is fixed to the same width for all children and is typically the width of the widest child. The height of each child is either fixed to the same value for all children, or each child can calculate its own height. By default, each child calculates its own height.

Blogger Xavi Beumala blogged about a custom layout: a 3D accordion.

Blogger Brian Telintelo blogged about Flex: Spark TileLayout Finally Pays off for Multi-Screen Apps.

Evtim Georgiev on the Flex SDK team has several blog entries on Spark layouts, including creating layout animations and extending HorizontalLayout.

Set the layout of a Spark container

By default, the Group container uses the BasicLayout class. The following example uses the `layout` property of the container to set its layout to the HorizontalLayout class:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkGroupContainerHorizontal.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:Group>
        <s:layout>
            <s:HorizontalLayout/>
        </s:layout>
        <s:Button label="Button 1"/>
        <s:Button label="Button 2"/>
        <s:Button label="Button 3"/>
        <s:Button label="Button 4"/>
    </s:Group>
</s:Application>
```

To simplify the use of layouts with the Group container, Flex defines subclasses of Group: HGroup with a horizontal layout, VGroup with a vertical layout, and TileGroup with a tile layout. Therefore, you can rewrite the previous example as shown below, replacing the HorizontalLayout definition inside Group with an HGroup container:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkHGroupContainer.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:HGroup>
        <s:Button label="Button 1"/>
        <s:Button label="Button 2"/>
        <s:Button label="Button 3"/>
        <s:Button label="Button 4"/>
    </s:HGroup>
</s:Application>
```

Set the padding and gap of a layout

Most Spark layout classes support padding and gap properties. The padding properties define the space between the container boundaries and the children. The gap properties define the space between the children, either horizontally or vertically. The BasicLayout class does not support padding properties because this layout requires that you explicitly position each child.

The following example sets the padding to 10 pixels, and the gap to 5 pixels, for the children of a Panel container that uses the HorizontalLayout class:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkPanelPadding.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:Panel>
        <s:layout>
            <s:HorizontalLayout
                paddingLeft="10" paddingRight="10"
                paddingTop="10" paddingBottom="10"
                gap="5"/>
        </s:layout>
        <s:Button label="Button 1"/>
        <s:Button label="Button 2"/>
        <s:Button label="Button 3"/>
        <s:Button label="Button 4"/>
    </s:Panel>
</s:Application>
```

For all Group containers, you set the padding with the `paddingLeft`, `paddingTop`, `paddingRight`, and `paddingBottom` properties. For VGroup and HGroup containers, you set the `gap` property. For the TileGroup container, you set the gap with the `horizontalGap` and `verticalGap` properties.

Set the alignment of a layout

The layout classes provide the `horizontalAlign` and `verticalAlign` properties for aligning the children of a container. For example, you can use these properties to align children to the top of a container using HorizontalLayout, or to the left side of a container using VerticalLayout.

horizontalAlign values

The `horizontalAlign` property takes the following values:

- `left` Align children to the left side of the container. This is the default value for HorizontalLayout.
- `right` Align children to the right side of the container.
- `center` Align the children to the horizontal center of the container.
- `justify` Set the width of all children to be the same width as the container.
- `contentJustify` Set the width of all children to be the *content width* of the container. The content width of the container is the width of the largest child. If all children are smaller than the width of the container, then set the width of all the children to the width of the container.

  Not supported by TileLayout. Use `columnAlign` and `rowAlign` instead.

verticalAlign values

The `verticalAlign` property takes the following values:

- `top` Align children to the top of the container. This is the default value for VerticalLayout.
- `bottom` Align children to the bottom of the container.
- `middle` Align children to the vertical middle of the container.
- `baseline` Align the elements such that their text is aligned to the maximum of the elements' text ascent.
- `justify` Set the height of all children to be the same height as the container.

- `contentJustify` Set the height of all children to be the *content height* of the container. The content height of the container is the height of the largest child. If all children are smaller than the height of the container, then set the height of all the children to the height of the container.

  Not supported by TileLayout. Use `columnAlign` and `rowAlign` instead.

The following example overrides the default vertical alignment of top for the HorizontalLayout to align the children of a Group container to the bottom of the container:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkContainerSimpleAlignment.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:SkinnableContainer>
        <s:layout>
            <s:HorizontalLayout verticalAlign="bottom"/>
        </s:layout>
        <s:Button label="Button 1" fontSize="24"/>
        <s:Button label="Button 2"/>
        <s:Button label="Button 3" fontSize="36"/>
        <s:Button label="Button 4"/>
    </s:SkinnableContainer>
</s:Application>
```

The following example overrides the default vertical alignment of top for the HorizontalLayout to use justify. Notice that all buttons have the same height:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkContainerSimpleAlignment.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:SkinnableContainer>
        <s:layout>
            <s:HorizontalLayout verticalAlign="justify"/>
        </s:layout>
        <s:Button label="Button 1" fontSize="24"/>
        <s:Button label="Button 2"/>
        <s:Button label="Button 3" fontSize="36"/>
        <s:Button label="Button 4"/>
    </s:SkinnableContainer>
</s:Application>
```

Set the row height or column width of a layout

You control the way the container lays out children with different sizes by using the `VerticalLayout.variableRowHeight` and `HorizontalLayout.variableColumnWidth` properties. By default, these properties are set to `true` which lets each child determine its height (VerticalLayout) or width (HorizontalLayout).

In the following example, the Group container holds four buttons. By default, buttons use a 12 point font size. However, two of the buttons in this example define a larger font size. Because the `variableRowHeight` property is set to `true` by default, the container sets the height of each button appropriately for its font size:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkGroupContainerVarRowHeightTrue.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:Group>
        <s:layout>
            <s:VerticalLayout />
        </s:layout>
        <s:Button label="Button 1"/>
        <s:Button label="Button 2"/>
        <s:Button label="Button 3" fontSize="36"/>
        <s:Button label="Button 4" fontSize="24"/>
    </s:Group>
</s:Application>
```

Variable row and column sizes

If your container has many children, setting the `variableRowHeight` or `variableColumnWidth` properties to `true` can affect application performance. The reason is because the container calculates the size of every child as it appears on the screen.

Rather than having each child calculate its size, you can set the `variableRowHeight` or `variableColumnWidth` property to `false` so that each child has the same size.

***Note:** The following paragraphs describe setting the `variableRowHeight` property for the VerticalLayout class. This discussion is the same as setting the `variableColumnWidth` property for the HorizontalLayout class.*

If you set the `variableRowHeight` property to `false`, the VerticalLayout class uses the following procedure to determine the height of each child:

1. If specified, use the `VerticalLayout.rowHeight` property to specify an explicit height of all children. Make sure that the specified height is suitable for all children.
2. If specified, use the `VerticalLayout.typicalLayoutElement` property to define the height of all children. This property references a component that Flex uses to define the height of all container children.
3. Use the preferred height of the first container child as the height of all container children. This technique is useful if the children of the container are all similar.

In the following example, a group container uses the VerticalLayout class to lay out four Button controls. The `variableRowHeight` property is `false` so that every button has the same height:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkGroupContainerVarRowHeightFalse.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:Group>
        <s:layout>
            <s:VerticalLayout variableRowHeight="false"/>
        </s:layout>
        <s:Button label="Button 1"/>
        <s:Button label="Button 2"/>
        <s:Button label="Button 3" fontSize="36"/>
        <s:Button label="Button 4" fontSize="24"/>
    </s:Group>
</s:Application>
```

Because you did not specify an explicit value for the `VerticalLayout.rowHeight` property or the `VerticalLayout.typicalLayoutElement` property, the VerticalLayout class uses the preferred height of the first button control as the height for all container children. However, because the third button and fourth button controls define a large font size, the text is truncated to the size of the button.

Alternatively, you can set the `rowHeight` property to a pixel value large enough for all the children, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkGroupContainerVarRowHeightFalseRowHeight.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:Group>
        <s:layout>
            <s:VerticalLayout variableRowHeight="false"
                rowHeight="40"/>
        </s:layout>
        <s:Button label="Button 1"/>
        <s:Button label="Button 2"/>
        <s:Button label="Button 3" fontSize="36"/>
        <s:Button label="Button 4" fontSize="24"/>
    </s:Group>
</s:Application>
```

In this example, all buttons are 40 pixels tall.

The following example uses the `typicalLayoutElement` property to specify to use the third button to determine the height of all container children:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkGroupContainerVarRowHeightFalseTypicalLE.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:Group>
        <s:layout>
            <s:VerticalLayout variableRowHeight="false"
                typicalLayoutElement="{b3}"/>
        </s:layout>
        <s:Button id="b1" label="Button 1"/>
        <s:Button id="b2" label="Button 2"/>
        <s:Button id="b3" label="Button 3" fontSize="36"/>
        <s:Button id="b4" label="Button 4" fontSize="24"/>
    </s:Group>
</s:Application>
```

You can use two common strategies for determining the typical item. One option is to use the largest item as the typical item. Another option is to calculate the average size of all items, and use the data item closest to that average size.

The Spark Group and Spark SkinnableContainer containers

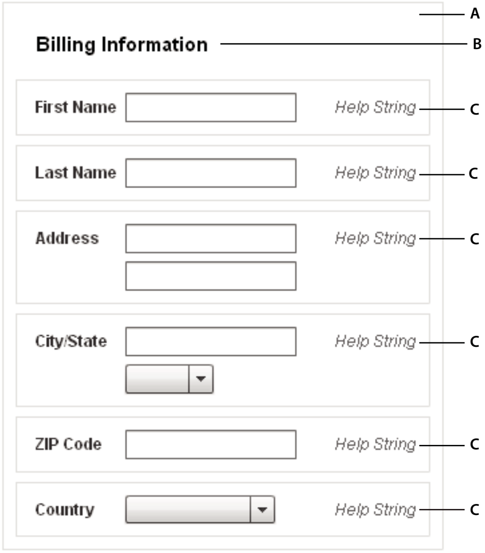
The Spark Group and Spark SkinnableContainer containers take as children any components that implement the IVisualElement interface. Use these containers when you want to manage visual children, both visual components and graphical components.

The main differences between the Group and SkinnableContainer containers are:

- SkinnableContainer can be skinned. The Group container is designed for simplicity and minimal overhead, and cannot be skinned.
- Group can be a child of the Scroller control to support scroll bars. Create a skin for the SkinnableContainer to add scroll bars.

One of the uses of the Group container is to import graphic elements from Adobe design tools, such as Adobe Illustrator. For example, if you use a design tool to create graphics imported into Flex, the graphics are often represented using FXG statements in a Group container. For more information, see “FXG and MXML graphics” on page 1714.

The default layout class of the Group and SkinnableContainer container is BasicLayout. The following example shows a Group container with a horizontal layout and one with a vertical layout:



For complete reference information, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Creating a Spark Group container

You use the `<s:Group>` tag to define a Group container. Specify an `id` value if you intend to refer to a component elsewhere in your MXML, either in another tag or in an ActionScript block.

The following example shows a Group container with four Button controls as its children:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkGroupContainerSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:Group>
        <s:Button label="Button 1"
            left="10" top="13" bottom="10"/>
        <s:Button label="Button 2"
            left="110" top="13" bottom="10"/>
        <s:Button label="Button 3"
            left="210" top="13" bottom="10"/>
        <s:Button label="Button 4"
            left="310" top="13" bottom="10" right="10"/>
    </s:Group>
</s:Application>
```

In this example, the Group container uses its default layout specified by the BasicLayout class, which means it uses absolute layout. The four button controls then use constraints to set their positions in the container. For more information on constraints, see “Using constraints to control component layout” on page 384.

You can add a graphic element to the container to define a background for the buttons, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkGroupContainerRect.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:Group>
        <s:Rect x="0" y="0"
            radiusX="4" radiusY="4"
            height="100%" width="100%">
            <s:stroke>
                <s:LinearGradientStroke weight="1" scaleMode="normal"/>
            </s:stroke>
            <s:fill>
                <s:LinearGradient>
                    <s:entries>
                        <mx:GradientEntry color="0x999999"/>
                    </s:entries>
                </s:LinearGradient>
            </s:fill>
        </s:Rect>
        <s:Button label="Button 1"
            left="10" top="13" bottom="10"/>
        <s:Button label="Button 2"
            left="110" top="13" bottom="10"/>
        <s:Button label="Button 3"
            left="210" top="13" bottom="10"/>
        <s:Button label="Button 4"
            left="310" top="13" right="10" bottom="10"/>
    </s:Group>
</s:Application>
```

In this example, you add an instance of the Rect class, a subclass of GraphicElement, that defines a gray background and one pixel border around the container. In this example the Rect is located a coordinates 0,0 in the Group container, and sized to fill the entire container.

Creating a Spark SkinnableContainer container

You use the `<s:SkinnableContainer>` tag to define a SkinnableContainer container. Specify an `id` value if you intend to refer to a component elsewhere in your MXML, either in another tag or in an ActionScript block.

The following example shows a SkinnableContainer container with four Button controls as its children:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkContainerSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:SkinnableContainer>
        <s:layout>
            <s:HorizontalLayout/>
        </s:layout>
        <s:Button label="Button 1"/>
        <s:Button label="Button 2"/>
        <s:Button label="Button 3"/>
        <s:Button label="Button 4"/>
    </s:SkinnableContainer>
</s:Application>
```

The default layout class of the SkinnableContainer class is BasicLayout. In this example, the SkinnableContainer uses the HorizontalLayout class to arrange the buttons in a single row.

If the SkinnableContainer uses BasicLayout, you can use a Rect component as a child of the container to add a background color and border. For an example, see “Creating a Spark Group container” on page 426.

However, the SkinnableContainer class lets you apply a skin to define the visual characteristics of the container. For example, the following skin defines a gray background and a one pixel border for the container:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\mySkins\MyBorderSkin.mxml -->
<s:Skin xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    alpha.disabled="0.5">
    <fx:Metadata>
        [HostComponent("spark.components.SkinnableContainer")]
    </fx:Metadata>

    <!-- Define the skin states. -->
    <s:states>
        <s:State name="normal" />
        <s:State name="disabled" />
    </s:states>

    <!-- Define a Rect to fill the area of the skin. -->
    <s:Rect x="0" y="0"
        radiusX="4" radiusY="4"
        height="100%" width="100%">
        <s:stroke>
            <s:LinearGradientStroke weight="1"/>
        </s:stroke>
        <s:fill>
            <s:LinearGradient>
                <s:entries>
                   <mx:GradientEntry color="0x999999"/>
                </s:entries>
            </s:LinearGradient>
        </s:fill>
    </s:Rect>
    <!-- Define the content area of the container. -->
    <s:Group id="contentGroup"
        left="5" right="5" top="5" bottom="5">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
    </s:Group>
</s:Skin>
```

All SkinnableContainer skins must implement the view states defined by the SkinnableContainer. Because the SkinnableContainer class supports the normal and disabled view states, the skin must also support them.

The Rect component adds the border and gray background to the skin.

All the container's children are added to the `contentGroup` skin part of the skin. In this example, the `contentGroup` container is a Group container with a vertical layout. Setting the `layout` property of the SkinnableContainer overrides the layout specified in the skin.

The advantage to defining a skin for the SkinnableContainer, rather than adding the visual elements in the SkinnableContainer definition, is that the skin is reusable. For example, you typically define a consistent look for all SkinnableContainer containers in an application. By encapsulating that look in a reusable skin class, you can apply it to all containers in your application.

Use the `skinClass` property to apply the skin to the SkinnableContainer, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkContainerSkin.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:SkinnableContainer
        skinClass="mySkins.MyBorderSkin">
        <s:layout>
            <s:HorizontalLayout gap="10"/>
        </s:layout>
        <s:Button label="Button 1"/>
        <s:Button label="Button 2"/>
        <s:Button label="Button 3"/>
        <s:Button label="Button 4"/>
    </s:SkinnableContainer>
</s:Application>
```

For more information on skinning, see “Spark Skinning” on page 1602.

The Spark BorderContainer container

To change the visible appearance of a SkinnableContainer, create a custom skin. However, to make it simple to add a border or change the background of a container, Flex defines the Spark BorderContainer container as a subclass of the SkinnableContainer. The BorderContainer container provides a set of CSS styles and class properties to control the border and background of the container.

***Note:** Because you use CSS styles and class properties to control the appearance of the BorderContainer container, you typically do not create a custom skin for it. If you do create a custom skin, your skin class should apply any styles to control the appearance of the container.*

The following example uses the `backgroundColor`, `borderStyle`, `borderWeight`, and `cornerRadius` styles of the BorderContainer container to control the appearance of the BorderContainer container:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkBorderSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:BorderContainer
        backgroundColor="red" cornerRadius="10"
        borderStyle="inset" borderWeight="4" >
        <s:layout>
            <s:HorizontalLayout
                paddingLeft="5" paddingRight="5"
                paddingTop="5" paddingBottom="5"/>
        </s:layout>
        <s:Button label="Button 1"/>
        <s:Button label="Button 2"/>
        <s:Button label="Button 3"/>
        <s:Button label="Button 4"/>
    </s:BorderContainer>
</s:Application>
```

Use the `backgroundImage` style to specify an image as the background of the container, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkBorderImage.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <fx:Script>
        <![CDATA[
            [Embed(source="/assets/logo.jpg")]
            [Bindable]
            public var imgCls:Class;
        ]]>
    </fx:Script>

    <s:BorderContainer
        backgroundImage="{imgCls}"
        borderStyle="inset" borderWeight="2"
        width="150" height="180">
    </s:BorderContainer>
</s:Application>
```

The BorderContainer container defines two properties that also let you control the appearance of the container:

- The `backgroundFill` property, of type IFill, defines the fill of the container. If you set the `backgroundFill` property, then the container ignores the `backgroundAlpha`, `backgroundColor`, `backgroundImage`, and `backgroundImageResizeMode` styles.
- The `borderStroke` property, of type IStroke, defines the stroke of the border. If you set the `borderStroke` property, then the container ignores the `borderAlpha`, `borderColor`, `borderStyle`, `borderVisible`, and `borderWeight` styles.

The following example sets the `backgroundFill` and `borderStroke` properties:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkBorderFillStroke.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:BorderContainer cornerRadius="10">
        <s:layout>
            <s:HorizontalLayout
                paddingLeft="5" paddingRight="5"
                paddingTop="5" paddingBottom="5"/>
        </s:layout>
        <s:backgroundFill>
            <s:SolidColor
                color="red"
                alpha="100"/>
        </s:backgroundFill>
        <s:borderStroke>
            <mx:SolidColorStroke
                color="black"
                weight="3"/>
        </s:borderStroke>

        <s:Button label="Button 1"/>
        <s:Button label="Button 2"/>
        <s:Button label="Button 3"/>
        <s:Button label="Button 4"/>
    </s:BorderContainer>
</s:Application>
```

Because the BorderContainer container does not implement the IViewport interface, it does not directly support scroll bars. However, you can wrap the Scroller control inside the BorderContainer container to add scroll bars, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkScrollBorder.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark" >
    <s:BorderContainer width="100" height="100"
        borderWeight="3" borderStyle="solid">
        <s:Scroller width="100%" height="100%">
            <s:Group
                horizontalScrollPosition="50"
                verticalScrollPosition="50">
                <s:Image width="300" height="400"
                    source="@Embed(source='/assets/logo.jpg')"/>
            </s:Group>
        </s:Scroller>
    </s:BorderContainer>
</s:Application>
```

The Spark NavigatorContent container

The MX navigator containers include the Accordion, TabNavigator, and ViewStack containers. Navigator containers let users switch between multiple children, where the children are other containers. The child containers of a navigator can be any MX container and the Spark NavigatorContent container.

***Note:** You cannot use Spark containers other than NavigatorContent as a child of an MX navigator container. To use any other Spark container in a navigator container, wrap it in an MX container or in the Spark NavigatorContent container.*

For more information on MX navigator containers, see "MX navigator containers" on page 628.

Do not use a NavigatorContent container outside an MX navigator container. A NavigatorContent must be the child of an MX navigator container, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkNavContent.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <mx:Accordion>
        <s:NavigatorContent label="Pane 1"
            width="100" height="100">
            <s:layout>
                <s:VerticalLayout paddingTop="10" paddingLeft="5"/>
            </s:layout>
            <s:Label text="Text for Pane 1"/>
            <s:Button label="Button 1"/>
        </s:NavigatorContent>
        <s:NavigatorContent label="Pane 2"
            width="100" height="100">
            <s:layout>
                <s:VerticalLayout paddingTop="10" paddingLeft="5"/>
            </s:layout>
            <s:Label text="Text for Pane 2"/>
            <s:Button label="Button 2"/>
        </s:NavigatorContent>
        <s:NavigatorContent label="Pane 3"
            width="100" height="100">
            <s:layout>
                <s:VerticalLayout paddingTop="10" paddingLeft="5"/>
            </s:layout>
            <s:Label text="Text for Pane 3"/>
            <s:Button label="Button 3"/>
        </s:NavigatorContent>
    </mx:Accordion>
</s:Application>
```

The value of the `label` property of each NavigatorContent child of the Accordion container defines the text that appears in the button area of the Accordion. You can use the `NavigatorContent.icon` property to specify an icon in the button area.

The creation policy of the NavigatorContent container is based on the creation policy of its parent navigator container, as the following table shows:

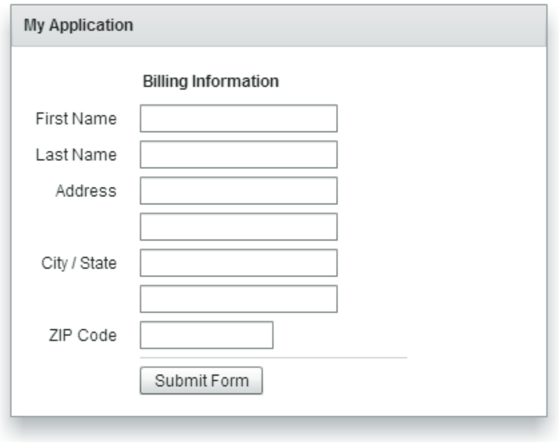
Creation policy of the parent navigator container	Creation policy of the NavigatorContent container
none	none
all	all
auto	none

For information on creation policy, see “About the creation policy” on page 327.

The Spark Panel container

A Panel container includes a title bar, a title, a border, and a content area for its children. Typically, you use Panel containers to wrap self-contained application modules. For example, you could define several Panel containers in your application where one Panel container holds a form, a second holds a shopping cart, and a third holds a catalog.

The default layout class of the Panel container is BasicLayout. The following example shows a Panel container with a vertical layout:



For complete reference information, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Creating a Spark Panel container

You use the `<s:Panel>` tag to define a Panel container. Specify an `id` value if you intend to refer to a component elsewhere in your MXML, either in another tag or in an ActionScript block.

The following example defines a Panel container that contains a form as the top-level container in your application. In this example, the Panel container provides you with a mechanism for including a title bar, as in a standard GUI window.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkPanelSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark" >
    <s:Panel id="myPanel" title="My Application" x="20" y="20">
        <s:Form id="myForm" width="400">
            <s:FormHeading label="Billing Information"/>
            <s:FormItem label="First Name">
                <s:TextInput id="fname" width="100%"/>
            </s:FormItem>
            <s:FormItem label="Last Name">
                <s:TextInput id="lname" width="100%"/>
            </s:FormItem>
            <s:FormItem label="Address">
                <s:TextInput id="addr1" width="100%"/>
                <s:TextInput id="addr2" width="100%"/>
            </s:FormItem>
            <s:FormItem label="City">
                <s:TextInput id="city"/>
            </s:FormItem>

            <s:FormItem label="State">
                <s:TextInput id="state"/>
            </s:FormItem>

            <s:FormItem label="ZIP Code">
                <s:TextInput id="zip" width="100"/>
            </s:FormItem>
            <s:FormItem>
                <mx:HRule width="200" height="1"/>
                <s:Button label="Submit Form"/>
            </s:FormItem>
        </s:Form>
    </s:Panel>
</s:Application>
```

Adding a control bar to the Spark Panel container

A control bar contains a group of controls outside the main content area of a Spark Panel container. The control bar is always visible at the bottom of the Panel container. Therefore, if the Panel container uses scroll bars, the control bar is not scrolled along with the other container children.

Set the `controlBarVisible` property to `true` (the default value) to make the control bar visible. You use the `Panel.controlBarContent` property to define the controls that appear in the control bar area, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkPanelCB.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    width="750">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            import mx.controls.Alert;
        ]]>
    </fx:Script>

    <fx:Declarations>
        <fx:XMLList id="menuXML">
            <fx:menuitem label="File">
                <fx:menuitem label="New" data="New"/>
                <fx:menuitem label="Open" data="Open"/>
                <fx:menuitem label="Save" data="Save"/>
                <fx:menuitem label="Exit" data="Exit"/>
            </fx:menuitem>
            <fx:menuitem label="Edit">
                <fx:menuitem label="Cut" data="Cut"/>
                <fx:menuitem label="Copy" data="Copy"/>
                <fx:menuitem label="Paste" data="Paste"/>
            </fx:menuitem>
            <fx:menuitem label="View"/>
        </fx:XMLList>

        <fx:Array id="cmbDP">
            <fx:String>Item 1</fx:String>
            <fx:String>Item 2</fx:String>
            <fx:String>Item 3</fx:String>
        </fx:Array>
    </fx:Declarations>
    <s:Panel title="Spark Panel">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <s:controlBarContent>
            <mx:MenuBar height="100%"
                dataProvider="{menuXML}"
                labelField="@label"
                showRoot="true"/>
            <mx:HBox paddingBottom="5"
                 paddingTop="5">
                <mx:ComboBox dataProvider="{cmbDP}"/>
                <mx:Spacer width="100%"/>
                <mx:TextInput id="myTI" text=""/>
                <mx:Button id="srch1"
                    label="Search"
                    click="Alert.show('Searching');"/>
            </mx:HBox>
        </s:controlBarContent>
        <s:Button label="Button"/>
        <s:TextArea width="300" height="200"/>
    </s:Panel>
</s:Application>
```

By default, the controls in the control bar area use horizontal layout. Use the `Panel.controlBarLayout` property to specify a different layout, as the following example shows:

```
<s:controlBarLayout>
    <s:HorizontalLayout paddingLeft="12" gap="5"/>
</s:controlBarLayout>
```

The location and appearance of the control bar area of the Panel container is determined by the spark.skins.spark.PanelSkin class, the skin class for the Panel container. By default, the PanelSkin class defines the control bar area to appear at the bottom of the content area of the Panel container with a grey background. Create a custom skin to change the default appearance of the control bar.

The Spark SkinnablePopUpContainer container

You use the SkinnablePopUpContainer container as a pop-up in your application. One typical use for a SkinnablePopUpContainer container is to open a simple window in an application, such as an alert window, to indicate that the user must perform some action.

The SkinnablePopUpContainer container can be modal or nonmodal. A modal container takes all keyboard and mouse input until it is closed. A nonmodal container lets other components accept input while the pop-up window is open.

Flex also defines the Spark TitleWindow container that you can use as a pop-up. A TitleWindow container consists of a title bar, a caption and status area in the title bar, a border, content area, and optional close button. Users can drag the TitleWindow container to move it around the application window. For more information, see “The Spark TitleWindow container” on page 443.

Unlike the TitleWindow container, the SkinnablePopUpContainer does not support dragging. It is a light-weight container that you use for simple pop-ups. You can define a custom skin class to control the visual aspects of the SkinnablePopUpContainer, such as the transitions and effects that play when the container opens and closes.

Creating a simple Spark SkinnablePopUpContainer container

The SkinnablePopUpContainer container appears as a pop-up window on top of its parent container. Therefore, you do not create a SkinnablePopUpContainer container as part of the normal MXML layout code of its parent container.

Instead, you can define the SkinnablePopUpContainer container as a custom MXML component in an MXML file. In the following example, you define it in the file MyAlertPopUp.mxml:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\myComponents\MyAlertPopUp.mxml -->
<s:SkinnablePopUpContainer xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx" width="400" height="300">
    <s:Panel title="My Alert Panel">
        <s:VGroup width="100%" horizontalAlign="center"
            paddingTop="20" gap="20">
                <s:Label text="Your custom alert box"/>
                <s:Button label="OK" click="close();"/>
        </s:VGroup>
    </s:Panel>
</s:SkinnablePopUpContainer>
```

The MyAlertPopUp.mxml component creates a SkinnablePopUpContainer that contains a Panel container. Notice that the Button control calls the `close()` method to close the pop-up.

At runtime, you create an instance of the SkinnablePopUpContainer in ActionScript, then call the following methods of the SkinnablePopUpContainer class to open and close it:

- `open()`

  Opens a SkinnablePopUpContainer container. The `open()` method takes two arguments: the first specifies the parent container of the SkinnablePopUpContainer container, and the second specifies if the container is modal.

  Opening the SkinnablePopUpContainer container dispatches the `open` event.

- `close()`

  Closes a SkinnablePopUpContainer container. The `close()` method takes two arguments: the first specifies whether the container passes back any data to the main application, and the second specifies an object containing the returned data.

  Closing the SkinnablePopUpContainer container dispatches the `close` event.

The following example shows the main application file that uses MyAlertPopUp.mxml:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkSkinnablePopUpContainerComponents.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Script>
        <![CDATA[
            // Import the MyAlertPopUp class.
            import myComponents.MyAlertPopUp;

            // Create an instance of MyAlertPopUp.
            public var alertDB:MyAlertPopUp = new MyAlertPopUp();
        ]]>
    </fx:Script>

    <!-- Open the MyAlertPopUp instance. -->
    <s:Button label="Open Alert" click="alertDB.open(this, false);"/>
</s:Application>
```

In this application, you first import the MyAlertPopUp component, then create an instance of it. The Button control calls the `open()` method to open the pop-up in response to a `click` event.

The first argument to the `open()` method specifies `this`. Therefore, the parent container of the SkinnablePopUpContainer container is the Application container. The second argument is `false` to specify a nonmodal window.

In this example, the application creates a single instance of the MyAlertPopUp component. It then reuses that instance every time the user selects the Button control. Therefore, the pop-up component stays in memory between uses.

If the pop-up component is large, or you want to reduce the memory use of the application, create a new instance of the component for each pop-up. The component is then destroyed when it closes. However, make sure to remove all references to the components, especially event handlers, or else the component is not destroyed.

Creating an inline Spark SkinnablePopUpContainer container

You do not have to define the SkinnablePopUpContainer container in a separate file. The following example uses the `<fx:Declaration>` tag to define an inline component:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkSkinnablePopUpContainerSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Declarations>
        <fx:Component className="MyAlert">
            <s:SkinnablePopUpContainer>
                <s:Panel title="My Alert Panel">
                    <s:VGroup width="100%" horizontalAlign="center"
                        paddingTop="20" gap="20">
                        <s:Label text="Your custom alert box"/>
                        <s:Button label="OK" click="close();"/>
                    </s:VGroup>
                </s:Panel>
            </s:SkinnablePopUpContainer>
        </fx:Component>
    </fx:Declarations>

    <s:Button label="Open Alert" click="(new MyAlert()).open(this, false);"/>
</s:Application>
```

The `<fx:Component>` tag defines a class named MyAlert. Notice that the `click` event handler for the Button control first creates a new instance of the MyAlert class, then opens the pop-up.

Alternatively, you could write the inline component so that it creates a single instance of the pop-up that is reused every time, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkSkinnablePopUpContainerInlineReuse.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
               xmlns:s="library://ns.adobe.com/flex/spark"
               xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Declarations>
        <s:SkinnablePopUpContainer id="alert">
            <s:Panel title="My Alert Panel">
                <s:VGroup width="100%" horizontalAlign="center"
                          paddingTop="20" gap="20">
                    <s:Label text="Your custom alert box"/>
                    <s:Button label="OK" click="alert.close();"/>
                </s:VGroup>
            </s:Panel>
        </s:SkinnablePopUpContainer>
    </fx:Declarations>

    <s:Button label="Open Alert" click="alert.open(this, false);"/>
</s:Application>
```

Controlling the pop-up window

You can use properties of the SkinnablePopUpContainer and the mx.managers.PopUpManager class to control the pop-up window. In the following example, you modify the width and height of the pop-up by setting properties of the SkinnablePopUpContainer. You then use the `PopUpManager.centerPopUp()` method to center it in its parent container:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkSkinnablePopUpContainerMoveResize.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;
            import mx.managers.PopUpManager;

            protected function button1_clickHandler(event:MouseEvent):void {

                // Create an instance of MyAlert.
                var alert:MyAlert = new MyAlert();
                alert.open(this, true);

                // Increase the width and height.
                alert.width += 100;
                alert.height += 100;

                // Center the pop-up in the parent container.
                PopUpManager.centerPopUp(alert);
            }
        ]]>
    </fx:Script>

    <fx:Declarations>
        <fx:Component className="MyAlert">
            <s:SkinnablePopUpContainer>
                <s:Panel title="My Alert Panel" width="100%" height="100%">
                    <s:VGroup width="100%" horizontalAlign="center"
                              paddingTop="20" gap="20">
                        <s:Label text="Your custom alert box"/>
                        <s:Button label="OK" click="close();"/>
                    </s:VGroup>
                </s:Panel>
            </s:SkinnablePopUpContainer>
        </fx:Component>
    </fx:Declarations>

    <s:Button label="Open Alert SMG" click="button1_clickHandler(event);"/>
</s:Application>
```

Passing data back from the Spark SkinnablePopUpContainer container

Use the `close()` method of the SkinnablePopUpContainer container to pass data back to the main application from the pop-up. The `close()` method has the following signature:

```
public function close(commit:Boolean = false, data:*):void
```

where:

- `commit` contains `true` if the returned data should be committed by the application.
- `data` specifies the returned data.

The `close()` method dispatches the `close` event. The event object associated with the `close` event is an object of type spark.events.PopUpEvent.

The PopUpEvent class defines two properties, `commit` and `data`, that contain the values of the corresponding arguments to the `close()` method. In the event handler of the `close` event, you use these properties to inspect any data returned from the pop-up.

The following example of the Spark SkinnablePopUpContainer contains a List control. If the user selects an item in the List, then the `close()` method passes that value back to the main application. If the user select the Cancel button, the `close()` method returns nothing:,

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\myComponents\MyAlertPopUpReturn.mxml -->
<s:SkinnablePopUpContainer xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Script>
        <![CDATA[
            import spark.events.IndexChangeEvent;
            // Event handler for the change event of the List control.
            protected function list1_changeHandler(event:IndexChangeEvent):void {
                // Close the SkinnablePopUpContainer.
                // Set the commit argument to true to indicate that the
                // data argument contians a vaild value.
                close(true, list1.selectedItem);
            }
        ]]>
    </fx:Script>
    <s:Panel title="My Alert Panel">
        <s:VGroup width="100%" horizontalAlign="center"
                  paddingTop="20" gap="20">

            <s:List id="list1" width="100%" height="100%"
                    change="list1_changeHandler(event);">
                <s:layout>
                    <s:VerticalLayout/>
                </s:layout>
                <s:dataProvider>
                    <s:ArrayCollection source="{['Add', 'Delete', 'Post', 'Bookmark']}"/>
                </s:dataProvider>
            </s:List>

            <s:Button label="Cancel" click="close();"/>
        </s:VGroup>
    </s:Panel>

</s:SkinnablePopUpContainer>
```

Shown below is the main application that uses this component:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkSkinnablePopUpContainerReturn.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            // Import the MyAlertPopUp class.
            import myComponents.MyAlertPopUpReturn;
            import spark.events.PopUpEvent;

            // Create and open the SkinnablePopUpContainer.
            protected function button1_clickHandler(event:MouseEvent):void {
                // Create an instance of MyAlertPopUp.
                var alertDB:MyAlertPopUpReturn = new MyAlertPopUpReturn();

                // Add an event handler for the close event to check for
                // any returned data.
                alertDB.addEventListener('close', alertDB_closeHandler);
                alertDB.open(this, true);
            }

            // Handle the close event from the SkinnablePopUpContainer.
            protected function alertDB_closeHandler(event:PopUpEvent):void {
                // If commit is false, do data is returned.
                if (!event.commit)
                    return;

                // Write the returned String to the TextArea control.
                myTA.text = event.data as String;
            }
        ]]>
    </fx:Script>

    <s:Button label="Open Alert" click="button1_clickHandler(event);"/>
    <s:TextArea id="myTA"/>
</s:Application>
```

This application uses the `click` event of the Button control to open the SkinnablePopUpContainer. The event handler for the `click` event creates an instance of the MyAlertPopUpReturn components, and then adds an event listener for the component's `close` event.

The event handler for the `close` event examines the `commit` property of the event object. If the `commit` property is `true`, the data returned from the MyAlertPopUpReturn component is written to the TextArea control.

The Spark TitleWindow container

A TitleWindow layout container is a Panel container that is optimized for use as a pop-up window. The container consists of a title bar, a caption and status area in the title bar, a border, and a content area for its children. Unlike the Panel container, it can display a close button. The TitleWindow container is designed to work as a pop-up window that users can drag around the screen the application window.

Modality

A pop-up TitleWindow container can be *modal*, which means that it takes all keyboard and mouse input until it is closed, or *nonmodal*, which means other windows can accept input while the pop-up window is still open.

Forms

One typical use for a TitleWindow container is to hold a form. When the user completes the form, you can close the TitleWindow container programmatically, or let the user request the application to close it by using the close icon (a box with an *x* inside it) in the upper-right corner of the window.

PopUpManager

Because you pop up a TitleWindow, you do not create it directly in MXML, as you do most controls. Instead you use the PopUpManager to open a TitleWindow container.

SkinnablePopUpContainer

Flex also defines the SkinnablePopUpContainer container. Unlike the TitleWindow container, the SkinnablePopUpContainer does not support dragging. It is a light-weight container that you use for simple pop ups. You can define a custom skin class to control the visual aspects of the SkinnablePopUpContainer, such as the transitions and effects that play when the container opens and closes. For more information, see "The Spark SkinnablePopUpContainer container" on page 437.

Using the PopUpManager to create a Spark TitleWindow container

To create and remove a pop-up TitleWindow container, you use methods of the PopUpManager. The PopUpManager is in the mx.managers package.

Creating and deleting Spark pop-up window

To create a pop-up window, use the PopUpManager `createPopUp()` method. The `createPopUp()` method has the following signature:

```
public static createPopUp(parent:DisplayObject, class:Class,
    modal:Boolean = false):IFlexDisplayObject
```

The method takes the following arguments.

Argument	Description
parent	A reference to a window to pop-up over.
class	A reference to the class of object you want to create. This is typically a custom MXML component that implements a Spark or MX TitleWindow container.
modal	(Optional) A Boolean value that indicates whether the window is modal, and takes all keyboard and mouse input until it is closed (`true`), or whether interaction is allowed with other controls while the window is displayed (`false`). The default value is `false`.

***Note:** Flex continues executing code in the parent even after you create a modal pop-up window.*

You use the `createPopUp()` method to create a pop-up window from a component definition. Typically, that means you have created an MXML component based on the TitleWindow container that defines your pop-up window. You can also create a pop-up window by passing an instance of a TitleWindow class or custom component to the PopUpManager `addPopUp()` method.

To remove a pop-up window, use the PopUpManager `removePopUp()` method. Pass the object created with the `createPopUp()` method or the `addPopUp()` method to the `removePopUp()` method.

Defining a custom Spark TitleWindow component

One of the most common ways of creating a TitleWindow container is to define it as a custom MXML component. Define the TitleWindow container, its event handlers, and all of its children in the custom component. Then, use the PopUpManager `createPopUp()` and `removePopUp()` methods to create and remove the TitleWindow container.

The following example code defines a custom MyLoginForm TitleWindow component that is used as a pop-up window:

```
<?xml version="1.0"?>
<!-- containers\spark\myComponents\MyLoginForm.mxml -->
<s:TitleWindow xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    close="handleCloseEvent();">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            import mx.managers.PopUpManager;
            // Handle the close button and Cancel button.
            private function handleCloseEvent():void {
                PopUpManager.removePopUp(this);
            }

            // Handle the OK button.
            private function processLogin():void {
                // Check credentials (not shown) then remove pop up.
                PopUpManager.removePopUp(this);
            }
        ]]>
    </fx:Script>
    <s:Form>
        <s:FormItem label="User Name">
            <s:TextInput id="username" width="100%"/>
        </s:FormItem>
        <s:FormItem label="Password">
            <s:TextInput id="password"
                displayAsPassword="true"
                width="100%"/>
        </s:FormItem>
    </s:Form>
    <s:HGroup>
        <s:Button label="OK"
            click="processLogin();" />
        <s:Button label="Cancel"
            click="handleCloseEvent();"/>
    </s:HGroup>
</s:TitleWindow>
```

This file, named MyLoginForm.mxml, defines a TitleWindow container by using the `<s:TitleWindow>` tag. The TitleWindow container defines a Form container with two TextInput controls for user name and password. It also defines two Button controls for submitting the form and for closing the TitleWindow container. This example does not include the code for verifying the user name and password in the `submitForm()` event listener.

In this example, you process the form data in an event listener of the MyLoginForm.mxml component. To make this component more reusable, you can define the event listeners in your main application. This lets you create a generic form that leaves the data handling to the application that uses the form.

Close icon

By default, the TitleWindow container displays a close icon (a small *x* in the upper-right corner of the TitleWindow title bar) to make it appear similar to dialog boxes in a GUI environment.

Close event

The TitleWindow broadcasts a `close` event when the user clicks the close icon. Flex does not close the window automatically. Create a handler for that event and close the TitleWindow from within that event handler. In the MyLoginForm.mxml component, you use the same event handler for the close and Cancel buttons. You can create a skin file for the TitleWindow to hide the close button, or set the visible property of the close button to `false`.

Using the PopUpManager.createPopUp() method to create the pop-up Spark TitleWindow

To create a pop-up window, you call the PopUpManager `createPopUp()` method and pass it the parent, the name of the class that creates the pop-up, and the modal Boolean value. The following main application code creates the TitleWindow container defined in the previous section:

```
<?xml version="1.0"?>
<!-- containers\spark\SparkMainMyLoginForm.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
            import mx.managers.PopUpManager;
            import spark.components.TitleWindow;
            import myComponents.MyLoginForm;
            // Open the pop-up window.
            private function showLogin():void {
                // Create a non-modal TitleWindow container.
                var helpWindow:TitleWindow=
                    PopUpManager.createPopUp(this, MyLoginForm, false) as TitleWindow;
                PopUpManager.centerPopUp(helpWindow);
            }
        ]]>
    </fx:Script>

    <s:VGroup width="300" height="300">
        <s:Button label="Login"
            click="showLogin();"/>
    </s:VGroup>
</s:Application>
```

In this example, when the user selects the Login button, the event listener for the `click` event uses the `createPopUp()` method to create a TitleWindow container, passing to it the name of the MyLoginForm.mxml file as the class name.

By casting the return value of the `createPopUp()` method to TitleWindow, you can manipulate the properties of the pop-up TitleWindow container, as the following example shows:

```
<?xml version="1.0"?>
<!-- containers\spark\SparkMainMyLoginFormCast.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
          import mx.managers.PopUpManager;
          import spark.components.TitleWindow;
          import myComponents.MyLoginForm;
          private function showLogin():void {
            // Create the TitleWindow container.
            var helpWindow:TitleWindow =
          PopUpManager.createPopUp(this, MyLoginForm, false) as TitleWindow;
            // Add title to the title bar.
            helpWindow.title="Enter Login Information";
            // Make title bar slightly transparent.
            helpWindow.setStyle("borderAlpha", 0.9);

            // Hide the close button.
            helpWindow.closeButton.visible = false;
          }
        ]]>
    </fx:Script>

    <s:VGroup width="300" height="300">
        <s:Button click="showLogin();" label="Login"/>
    </s:VGroup>
</s:Application>
```

Using the PopUpManager.addPopUp() method to create the pop-up Spark TitleWindow

You can use the `addPopUp()` method of the PopUpManager to create a pop-up window without defining a custom component. This method takes an instance of any class that implements IFlexDisplayObject. Because it takes a class instance, not a class, you can use ActionScript code in an `<fx:Script>` block to create the component instance to pop up, rather than as a separate custom component.

Using the `addPopUp()` method may be preferable to using the `createPopUp()` method if you have to pop up a simple dialog box that is not reused elsewhere in the application. However, it is not the best coding practice if the pop-up is complex, or if you want to create a component that can be used anywhere in the application.

The following example creates a pop-up with `addPopUp()` method and adds a Button control to that window that closes the window when you click it:

```
<?xml version="1.0"?>
<!-- containers\spark\MyPopUpButton.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    height="600" width="600" >
    <fx:Script>
        <![CDATA[
            import spark.components.TitleWindow;
            import flash.events.*;
            import mx.managers.PopUpManager;
            import spark.components.Button;
            import mx.core.IFlexDisplayObject;

            // The variable for the TitleWindow container
            public var myTitleWindow:TitleWindow = new TitleWindow();
            // Method to instantiate and display a TitleWindow container.
            // This is the initial Button control's click event handler.
            public function openWindow(event:MouseEvent):void {
                // Set the TitleWindow container properties.
                myTitleWindow = new TitleWindow();
                myTitleWindow.title = "My Window Title";
                myTitleWindow.width= 220;
                myTitleWindow.height= 150;
                // Call the method to add the Button control to the
                // TitleWindow container.
                populateWindow();
                // Use the PopUpManager to display the TitleWindow container.
                PopUpManager.addPopUp(myTitleWindow, this, true);
            }

            // The method to create and add the Button child control to the
            // TitleWindow container.
            public function populateWindow():void {
                var btn1:Button = new Button();
                btn1.label="close";
                btn1.addEventListener(MouseEvent.CLICK, closeTitleWindow);
                myTitleWindow.addElement(btn1);
            }

            // The method to close the TitleWindow container.
            public function closeTitleWindow(event:MouseEvent):void {
                PopUpManager.removePopUp(myTitleWindow);
            }
        ]]>
    </fx:Script>
    <s:Button label="Open Window" click="openWindow(event);"/>
</s:Application>
```

Using the mouseDown event to close the Spark TitleWindow

You can use the mouseDownOutside event to close the pop-up window when a user clicks the mouse outside the TitleWindow. To do this, you add an event listener to the TitleWindow instance for the mouseDownOutside event, as the following example shows:

```
<?xml version="1.0"?>
<!-- containers\spark\MainMyLoginFormMouseDown.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
            import mx.managers.PopUpManager;
            import spark.components.TitleWindow;
            import myComponents.MyLoginForm;
            import mx.events.FlexMouseEvent;
            private var helpWindow:TitleWindow;
            private function showLogin():void {
                // Create the TitleWindow container.
                helpWindow = PopUpManager.createPopUp(this,
                    MyLoginForm, false) as TitleWindow;
                helpWindow.addEventListener("mouseDownOutside", removeForm);
            }
            private function removeForm(event:FlexMouseEvent):void {
                PopUpManager.removePopUp(helpWindow);
            }
        ]]>
    </fx:Script>

    <s:VGroup width="300" height="300">
        <s:Button click="showLogin();" label="Login"/>
    </s:VGroup>
</s:Application>
```

You define the event listener in the main application, and then assign it to the pop-up window when you create it. This technique lets you use a generic pop-up window, defined by the component MyLoginForm.mxml, and then modify the behavior of the component by assigning event listeners to it from the main application.

Creating a modal pop-up window

The `createPopUp()` method takes an optional *modal* parameter. You can set this parameter to `true` to make the window modal. When a TitleWindow is modal, you cannot select any other component while the window is open. The default value of *modal* is `false`.

The following example creates a modal pop-up window:

```
var pop1:IFlexDisplayObject = PopUpManager.createPopUp(this, MyLoginForm, true);
```

Dragging the popup Spark TitleWindow

After you pop up the Spark TitleWindow container, you can drag it around the application window. To drag the TitleWindow, click and hold the mouse in the title bar area of the window, then move the mouse.

By default, you click in the title bar area of the TitleWindow container to drag it. That area is defined by the `moveArea` skin part. You can create a custom skin class to modify the move area.

Events during a move operation

The Tile Window dispatches the following events as part of a move operation:

Event	**Descriptions**
`windowMove`	Dispatched when you stop dragging the window. This event can be dispatched multiple times before the `windowMoveEnd` event if you stop dragging the window but do not release the mouse button.
`windowMoveEnd`	Dispatched when the user releases the mouse button to end the drag.
`windowMoveStart`	Dispatched when the user presses the mouse button while the pointer is in the move area to begin the drag. This event is cancelable.
`windowMoving`	Dispatched repeatedly as the user drags the window. This event is cancelable.

The event handlers for these events receive an object of type TitleWindowBoundsEvent. The TitleWindowBoundsEvent class defines the `beforeBounds` and `afterBounds` properties, of type Rectangle. You can use these properties to determine the position of the TitleWindow as it is dragged, as the following table shows:

Event	**beforeBounds**	**afterBounds**
`windowMove`	The previous bounds of the window.	The current bounds of the window.
`windowMoveEnd`	The starting bounds of the window.	The ending bounds of the window.
`windowMoveStart`	The starting bounds of the window.	null
`windowMoving`	The current bounds of the window.	The future bounds of the window if the window moves to the current cursor position.

The following example shows a TitleWindow component that displays each event in a TextArea control as it occurs:

```
<?xml version="1.0"?>
<!-- containers\spark\myComponents\MyLoginFormMoveEvents.mxml -->
<s:TitleWindow xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    width="300" height="300"
    close="handleCloseEvent();"
    windowMove="windowMoveHandler(event);"
    windowMoveEnd="windowMoveEndHandler(event);"
    windowMoveStart="windowMoveStartHandler(event);"
    windowMoving="windowMovingHandler(event);">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            import spark.events.TitleWindowBoundsEvent;
            import mx.managers.PopUpManager;
            // Handle the close button and Cancel button.
            private function handleCloseEvent():void {
                PopUpManager.removePopUp(this);
            }
            protected function windowMoveHandler(event:TitleWindowBoundsEvent):void
            {
                myTA.text += "windowMove event occurred" + "\n"
            }
            protected function windowMoveEndHandler(event:TitleWindowBoundsEvent):void {
                myTA.text += "windowMoveEnd event occurred" + "\n"
            }
            protected function windowMoveStartHandler(event:TitleWindowBoundsEvent):void {
                myTA.text += "windowMoveStart event occurred" + "\n"
            }
            protected function windowMovingHandler(event:TitleWindowBoundsEvent):void {
                myTA.text += "windowMoving event occurred" + "\n"
            }
        ]]>
    </fx:Script>
    <s:TextArea id="myTA"
        width="100%" height="100%"/>

    <s:HGroup>
        <s:Button label="Cancel"
            click="handleCloseEvent();"/>
        <s:Button label="Clear"
                  click="myTA.text='';"/>
    </s:HGroup>
</s:TitleWindow>
```

The following example uses this component. As you drag the TitleWindow container around the application, the event handlers write a string to the TextArea control:

```
<?xml version="1.0"?>
<!-- containers\spark\SparkMainMoveEvents.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
            import mx.managers.PopUpManager;
            import spark.components.TitleWindow;
            import myComponents.MyLoginFormMoveEvents;
            // Open the pop-up window.
            private function showLogin():void {
                // Create a non-modal TitleWindow container.
                var helpWindow:TitleWindow =
            PopUpManager.createPopUp(this, MyLoginFormMoveEvents, false) as TitleWindow;
                PopUpManager.centerPopUp(helpWindow);
            }
        ]]>
    </fx:Script>

    <s:VGroup width="300" height="300">
        <s:Button label="Login"
            click="showLogin();"/>
    </s:VGroup>
</s:Application>
```

You can disable dragging of the TitleWindow by setting the `visible` property of the `moveArea` skin part to `false`:

```
helpWindow.moveArea.visible = false;
```

Passing data to and from a Spark pop-up window

To make your pop-up window more flexible, you might want to pass data to it or return data from it. To do this, use the following guidelines:

- Create a custom component to be your pop-up. In most circumstances, this component is a TitleWindow container.
- Declare variables in your pop-up that you set in the application that creates the pop-up.
- Cast the pop-up to be the same type as your custom component.
- Pass a reference to that component to the pop-up window, if the pop-up window is to set a value on the application or one of the application's components.

For example, the following application populates a ComboBox in the pop-up window with an ArrayList defined in the main application.

```
<?xml version="1.0"?>
<!-- containers\spark\SparkMainArrayEntryForm.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayList;
            import mx.managers.PopUpManager;
            import myComponents.ArrayEntryForm;

            public function displayForm():void {
                /* ArrayList with data for the custom control ComboBox control. */
                var doctypes:ArrayList = new ArrayList(["*.as", "*.mxml", "*.swc"]);

                /* Create the pop-up and cast the
                   return value of the createPopUp()
                   method to the ArrayEntryForm custom component. */
                var pop1:ArrayEntryForm = ArrayEntryForm(
                    PopUpManager.createPopUp(this, ArrayEntryForm, true));

                /* Set TitleWindow properties. */
                pop1.title="Select File Type";

                /* Set properties of the ArrayEntryForm custom component. */
                pop1.targetComponent = ti1;
                pop1.myArray = doctypes;
                PopUpManager.centerPopUp(pop1);
            }
        ]]>
    </fx:Script>
    <s:TextInput id="ti1" text=""/>
    <s:Button id="b1" label="Select File Type"
        click="displayForm();"/>
</s:Application>
```

When creating the pop-up, the application casts the pop-up to be of type ArrayEntryForm, which is the name of the custom component that defines the pop-up window. If you do not do this, the application cannot access the properties that you create.

The application passes a reference to the TextInput component in the Application container to the pop-up window so that the pop-up can write its results back to the container. The application also passes the ArrayList of filename extensions for the pop-up ComboBox control's data provider, and sets the pop-up window's title. By setting these in the application, you can reuse the pop-up window in other parts of the application without modification, because it does not have to know the name of the component it is writing back to or the data that it is displaying, only that its data is in an Array and it is writing to a TextArea.

The following custom component, ArrayEntryForm.mxml, declares two variables. The first one is for the ArrayList that the parent application passes to the pop-up window. The second holds a reference to the parent application's TextInput control. The component uses that reference to update the parent application:

```
<?xml version="1.0"?>
<!-- containers\spark\myComponents\ArrayEntryForm.mxml -->
<s:TitleWindow xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    width="200" borderAlpha="1"
    close="removeMe();">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            import spark.components.TextInput;
            import mx.managers.PopUpManager;
            import mx.collections.ArrayList;

            // Variables whose values are set by the main application.
            // Data provider array for the component's ComboBox control.
            [Bindable]
            public var myArray:ArrayList;
            // A reference to the TextInput control
            // in which to put the result.
            public var targetComponent:TextInput;
            // OK button click event listener.
            // Sets the target component in the application to the
            // selected ComboBox item value.
            private function submitData():void {
                targetComponent.text = String(cb1.selectedItem);
                removeMe();
            }
            // Cancel button click event listener.
            private function removeMe():void {
                PopUpManager.removePopUp(this);
            }
        ]]>
    </fx:Script>
    <s:ComboBox id="cb1" dataProvider="{myArray}"/>
    <s:HGroup>
        <s:Button label="OK" click="submitData();"/>
        <s:Button label="Cancel" click="removeMe();"/>
    </s:HGroup>
</s:TitleWindow>
```

From within a pop-up custom component, you can also access properties of the parent application by using the `parentApplication` property. For example, if the application has a Button control named b1, you can get the label of that Button control, as the following example shows:

```
myLabel = parentApplication.b1.label;
```

This technique, however, uses a hard-coded value in the pop-up component for both the target component id in the parent and the property in the component.

Passing data using events

The following example modifies the example from the previous section to use event listeners defined in the main application to handle the passing of data back from the pop-up window to the main application. This example shows the ArrayEntryFormEvents.mxml file with no event listeners defined within it.

```
<?xml version="1.0"?>
<!-- containers\spark\myComponents\ArrayEntryFormEvents.mxml -->
<s:TitleWindow xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    width="200"
    borderAlpha="1">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            import mx.managers.PopUpManager;
            import mx.collections.ArrayList;

            // Variables whose values are set by the main application.
            // Data provider array for the component's ComboBox control.
            [Bindable]
            public var myArray:ArrayList;
        ]]>
    </fx:Script>
    <s:ComboBox id="cb1" dataProvider="{myArray}"/>
    <s:HGroup>
        <s:Button id="okButton" label="OK"/>
        <s:Button id="cancelButton" label="Cancel"/>
    </s:HGroup>
</s:TitleWindow>
```

The main application defines the event listeners and registers them with the controls defined within the pop-up window:

```
<?xml version="1.0"?>
<!-- containers\spark\SparkMainArrayEntryFormEvents.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayList;
            import mx.managers.PopUpManager;
            import myComponents.ArrayEntryFormEvents;

            public var pop1:ArrayEntryFormEvents;

            public function displayForm():void {
                /* ArrayList with data for the custom control ComboBox control. */
                var doctypes:ArrayList = new ArrayList(["*.as", "*.mxml", "*.swc"]);

                /* Create the pop-up and cast the return value
                   of the createPopUp() method to the ArrayEntryFormEvents custom
                   component. */
                pop1 = ArrayEntryFormEvents(
                PopUpManager.createPopUp(this, ArrayEntryFormEvents, true));
                /* Set TitleWindow properties. */
                pop1.title="Select File Type";

                /* Set the event listeners for
                   the ArrayEntryFormEvents component. */
                pop1.addEventListener("close", removeMe);
                pop1.cancelButton.addEventListener("click", removeMe);
                pop1.okButton.addEventListener("click", submitData);

                /* Set properties of the ArrayEntryFormEvents custom control. */
                pop1.myArray = doctypes;
                PopUpManager.centerPopUp(pop1);
            }

            /* OK button click event listener.
               Sets the target component in the application to the
               selected ComboBox item value. */
            private function submitData(event:Event):void {
                ti1.text = String(pop1.cb1.selectedItem);
                removeMe(event);
            }
            /* Cancel button click event listener. */
            private function removeMe(event:Event):void {
                PopUpManager.removePopUp(pop1);
            }
        ]]>
    </fx:Script>
    <s:VGroup>
        <s:TextInput id="ti1" text=""/>
    </s:VGroup>
    <s:Button id="b1" label="Select File Type" click="displayForm();"/>
</s:Application>
```

The Spark Form, Spark FormHeading, and Spark FormItem containers

The Spark Form is a highly customizable container that supports multiple form designs and helps you create richer form experiences. When designing forms, you sometimes have limited space to display all the form elements. Spark forms help you solve this problem by providing horizontal and stacked layouts, as well as multiple customized columns.

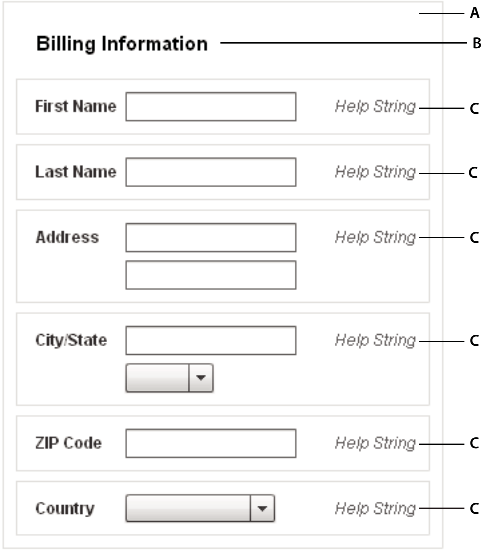
Spark Forms let you customize the appearance of your form through skinning.

Adobe Product Evangelist James Ward provides an overview of the Spark Form container in the video Overview of Spark Forms in Flex.

Creating a Spark Form

You use the `<s:Form>` tag to define a Spark Form. Specify an `id` value if you intend to refer to the entire form elsewhere in your MXML, either in another tag or in an ActionScript block.

To create a Spark Form, you typically use three different components: the Form container, FormHeading controls, and FormItem containers, as the following example shows:



Spark Form example
***A.** Form container* ***B.** FormHeading control* ***C.** FormItem containers*

For complete reference information, see Form, FormHeading, and FormItem in the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

For a video on creating a Spark Form, see www.adobe.com/go/learn_flexsparkformvideo_en

Creating a Spark FormHeading control

A Spark FormHeading control specifies an optional label for a group of FormItem containers. The label is aligned with the start of the FormItem label controls in the form. You can have multiple FormHeading controls in your form to designate multiple content areas. You can also use FormHeading controls with a blank `label` property to create vertical space in your form.

You use the `<s:FormHeading>` tag to define a FormHeading container. Specify an `id` value if you intend to refer to the heading elsewhere in your MXML, either in another tag or in an ActionScript block.

The following code example defines the FormHeading control for the Spark Form:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\layouts\spark\SparkFormHeadingSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:Form id="myForm" width="400" height="100">
        <s:FormHeading label="Spark Form Heading" />
        <!--Define FormItem containers here. -->
    </s:Form>
</s:Application>
```

For complete reference information, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Creating a Spark FormItem container

A Spark FormItem consists of the following parts:

- A single label

- A sequence label
- One or more child controls or containers, such as text input or button control
- Help content that provides a description of the form item or instructions for filling it out
- Required indicator to indicate if a form item has to be filled

By default, all the FormItem elements are arranged in a horizontal layout with the label placed on the left and the Help content on the right.

The following code example defines the Spark FormItem container for the Spark Form:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\layouts\spark\SparkFormItemSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:Form id="myForm" width="450" height="125">
        <s:FormHeading label="Spark Form Heading" />
        <s:FormItem label="Username:">
            <s:TextInput id="username" />
            <s:helpContent>
                <s:Label text="Enter your LDAP username" />
            </s:helpContent>
        </s:FormItem>
    </s:Form>
</s:Application>
```

For complete reference information, see Spark FormItem in the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Using sequence labels in a Spark FormItem control

You sometimes need to fill the form in a sequential order. Sequential labels help you design forms that define a visual order to the form items. When laying out form items in a Spark Form, you can define sequence labels using the `sequenceLabel` property.

The following code example uses sequence labels, incrementing the sequence number by one for each label:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\layouts\spark\SparkFormItemSequenceLabels.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:Form id="myForm" width="350" height="325">
        <!-- Reduce gap between form items. -->
        <s:layout>
            <s:FormLayout gap="-14"/>
        </s:layout>
        <s:Label fontSize="16" text="My Spark Form"/>
        <s:FormItem label="Address" sequenceLabel="1.">
            <s:TextInput width="100%"/>
            <s:TextInput width="100%"/>
            <s:TextInput width="100%"/>
        </s:FormItem>
        <s:FormItem label="City" sequenceLabel="2.">
            <s:TextInput width="100%"/>
        </s:FormItem>
        <s:FormItem label="State" sequenceLabel="3.">
            <s:TextInput width="100%"/>
        </s:FormItem>
        <s:FormItem label="ZipCode" sequenceLabel="4.">
            <s:TextInput width="100%"/>
        </s:FormItem>
    </s:Form>
</s:Application>
```

You can customize the appearance of sequence labels by styling the FormItem container's sequenceLabelDisplay skin part. Properties like label `color` and `fontWeight` are explicitly set in the default FormItemSkin. To change these properties, you can create a custom skin using MXML or ActionScript and override the default styles.

Defining Help content in a Spark FormItem control

Help content provides a description for the form item or instructions for filling out the form item. When you create a FormItem, you use the `helpContent` property to define the Help content for the FormItem.

In a BasicLayout Group container, the Help content is placed next to the FormItem input control, by default. If you have multiple items in your helpContent group, you can place the Help content in an HGroup container or a VGroup container. The HGroup container lays out Help content horizontally and the VGroup container lays out Help content vertically.

The following code example defines Help content for FormItems in a Spark Form:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\layouts\spark\SparkFormItemHelpContent.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    width="600">

    <s:Form id="form1" x="164" y="38">
        <!-- Reduce space between form items. -->
        <s:layout>
            <s:FormLayout gap="-14"/>
        </s:layout>
        <s:FormHeading label="Mailing Information"/>
        <s:FormItem label="Address">
            <s:helpContent>
                <s:Label text="(eg. 123 Main Street)"/>
            </s:helpContent>
            <s:TextInput/>
            <s:TextInput/>
        </s:FormItem>
        <s:FormItem label="City/State">
            <s:TextInput/>
        </s:FormItem>
        <s:FormItem label="Phone" fontFamily="Verdana" required="true">
            <s:helpContent>
                <s:VGroup>
                    <s:Label text="(xxx)-xxx-xxxx"/>
                    <s:Label text="Will appear in your profile"/>
                </s:VGroup>
            </s:helpContent>
            <s:TextInput/>
        </s:FormItem>
    </s:Form>
</s:Application>
```

You can customize the appearance of the Help content by styling the FormItem container's `helpContentGroup` skin part. Properties like `fontStyle` and `color` are explicitly set in the default FormItem skin. To change these properties, you can create a custom skin using MXML or ActionScript and override the default styles.

Spark Form and Spark FormItem skin classes

The Flex framework provides two sets of skin classes for the Spark Form and Spark FormItem controls:

The default skin classes define a horizontal layout of form items. The default skin classes include the following:

- FormHeadingSkin: A horizontal layout for a FormHeading.
- FormItemSkin: A horizontal layout for a FormItem with four columns and five skin parts. For more information, see "Using the required indicator for form items" on page 462.
- FormSkin: A four-column skin for the Form, where the columns are arranged horizontally in a single row.

The stacked skin classes define each form item with the label above the form control to use less horizontal space. The stacked skin classes include the following:

- StackedFormHeadingSkin: A stacked layout for a FormHeading
- StackedFormItemSkin: A stacked layout for a FormItem with four columns and five skin parts.
- StackedFormSkin: A three-column skin with two rows per item, and the label placed in the top row.

The following code example defines a Spark Form control using a StackedFormHeadingSkin, StackedFormItemSkin, and StackedFormSkin class:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkFormStackedSkinClasses.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    width="300">

    <fx:Style>
       @namespace s "library://ns.adobe.com/flex/spark";

       s|Form
           {
               skinClass: ClassReference("spark.skins.spark.StackedFormSkin");
           }
       s|FormHeading
           {
               skinClass: ClassReference("spark.skins.spark.StackedFormHeadingSkin");
           }
       s|FormItem
           {
               skinClass: ClassReference("spark.skins.spark.StackedFormItemSkin");
           }
    </fx:Style>

    <s:Form id="frm" width="300">
        <!-- Reduce gap between form items. -->
        <s:layout>
            <s:FormLayout gap="-14"/>
        </s:layout>
        <s:FormHeading label="STACKED SPARK FORM" backgroundColor="Gray" color="#FFFFFF"
width="300"/>
        <s:FormItem sequenceLabel="1." label="First name" required="true">
            <s:TextInput id="fName" maxChars="64" />
        </s:FormItem>
        <s:FormItem sequenceLabel="2." label="Last name">
            <s:TextInput id="lName" maxChars="64" />
        </s:FormItem>
        <s:FormItem sequenceLabel="3." label="Address">
            <s:TextInput id="AddressLine1" maxChars="32"/>
            <s:TextInput id="AddressLine2" maxChars="32"/>
            <s:TextInput id="AddressLine3" maxChars="32"/>
        </s:FormItem>
        <s:FormItem sequenceLabel="4." label="City">
            <s:TextInput id="City" maxChars="64" />
        </s:FormItem>
        <s:FormItem sequenceLabel="5." label="State">
            <s:TextInput id="State" maxChars="64" />
        </s:FormItem>
        <s:FormItem sequenceLabel="6." label="ZipCode" required="true">
            <s:TextInput id="ZipCode" maxChars="64" />
        </s:FormItem>
    </s:Form>
</s:Application>
```

Using the required indicator for form items

The `required` state indicates that you must enter the FormItem's content before submitting the form. The `required` state occurs when you set the FormItem's `required` property to true as follows:

```
<s:FormItem label="Username:" required="true">
    <s:TextInput id="username" />
</s:FormItem>
```

When you set the `required` property to `true`, an asterisk (*) is used to denote the field. A Spark FormItem lets you customize the appearance of the required fields through skinning. For example, a required field can have a light green background, a bold label, or a "(required)" text.

An error state highlights the input error in the form item. The `error` state occurs when the FormItem's content fails validation. For example, you can define a red border or a light red background to indicate an error state. For more information on including form validation in your Spark Form, see “Validating data in a Spark Form” on page 462.

Validating data in a Spark Form

You can include form validation in your Spark Form. You can add custom logic to validate the input controls to ensure that the required data is entered in a proper format. To do so, you create the proper validator or formatter controls, and associate them with their Form Item controls. When a user enters incorrect data in the Form Item, the Form Item skin uses a different state to represent the erroneous state of the Form Item.

The following code example shows a Spark Form where the phone entry TextInput control is bound to a PhoneFormatter. The TextInput control is bound to the PhoneFormatter such that the data entered is formatted to display, as required. The ZIP code text input is bound to a ZipCodeValidator for data validation, such that, on entering incorrect data, an appropriate error message appears.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkFormValidation.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Declarations>
        <mx:PhoneFormatter
            id="pnf"
            areaCode="-1"
            areaCodeFormat="(###)"
            formatString="(###) ###-####"
            validPatternChars="+()#-. "/>
        <mx:ZipCodeValidator
            id="zcv"
            source="{ti_zip}"
            property="text"/>
    </fx:Declarations>

    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;
            [Bindable]
            public var statesDP:ArrayCollection = new ArrayCollection
                    (["Arizona","California","Kansas","New Mexico","Texas","Wyoming"]);

            import mx.events.ValidationResultEvent;
            private var vResult:ValidationResultEvent;
            // Event handler to validate and format input.
            private function format():void {
                ti_phone.text = pnf.format(ti_phone.text);
            }
        ]]>
    </fx:Script>

    <s:Form width="500" height="600" backgroundColor="0xeeeeee">
        <s:Label fontSize="16" text="My Spark Form"/>
        <s:FormItem label="Address" sequenceLabel="1.">
            <s:TextInput width="100%"/>
            <s:TextInput width="100%"/>
            <s:TextInput width="100%"/>
            <s:helpContent>
                <s:Label text="(ex. 123 Main Street)" baseline="24" />
                <s:Button label="?" width="30" baseline="24" x="120"/>
            </s:helpContent>
        </s:FormItem>
        <s:FormItem label="City" sequenceLabel="2.">

        </s:FormItem>
        <s:FormItem label="State" sequenceLabel="3.">
            <s:ComboBox dataProvider="{statesDP}" width="100%"/>
        </s:FormItem>
        <s:FormItem label="ZipCode" sequenceLabel="4." required="true">
            <s:TextInput widthInChars="4" restrict="0123456789"/>
            <s:helpContent>
              <s:Label text="Will appear in your profile" left="0" right="0" baseline="24" />
            </s:helpContent>
        </s:FormItem>
        <s:FormItem id="phoneZipItem" label="Phone and Zip" sequenceLabel="5.">
            <s:TextInput id="ti_phone" width="100%" focusOut="format()"/>
            <s:TextInput id="ti_zip" widthInChars="4" restrict="0123456789"/>
            <s:helpContent>
                <s:Label text="(xxx)-xxx-xxxx" left="0" right="0" baseline="24" />
            </s:helpContent>
        </s:FormItem>
        <s:Label text="PhoneZip ErrorString : {phoneZipItem.elementErrorStrings}"/>
    </s:Form>
</s:Application>
```

Scrolling a Spark Form

The simplest way to add scrolling to a Spark Form is to wrap the Form in a Group container. Then wrap the Group container in a Scroller, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\layouts\spark\SparkFormScroll.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <s:Scroller width="300" height="200">
        <s:Group>
            <s:Form>
                <s:FormItem label="Label 1:" textAlign="right">
                    <s:layout>
                        <s:HorizontalLayout/>
                    </s:layout>
                    <s:TextInput width="30"/>
                    <s:TextInput width="30"/>
                    <s:TextInput width="30"/>
                    <s:TextInput width="30"/>
                </s:FormItem>

                <s:FormItem label="Longer Label 2:" textAlign="right">
                    <s:layout>
                        <s:HorizontalLayout/>
                    </s:layout>
                    <s:TextInput width="30"/>
                    <s:TextInput width="30"/>
                    <s:TextInput width="30"/>
                    <s:TextInput width="30"/>
                </s:FormItem>

                <s:FormItem label="Label 3:" textAlign="right">
                    <s:TextInput width="200"/>
                </s:FormItem>
                <s:FormItem label="Label 4:" textAlign="right">
                    <s:TextInput width="200"/>
                </s:FormItem>
            </s:Form>
        </s:Group>
    </s:Scroller>
</s:Application>
```

Use a Group container because the Form container does not implements the spark.core.IViewport interface that is required by all children of Scroller.

Changing the layout of FormItems in a Spark Form

FormLayout is the layout class for the FormSkin class and StackedFormSkin class. FormLayout provides a vertical layout for its child FormItem containers in the Form. Elements using FormItemLayout within a FormLayout are aligned along columns.

Note: *Only use the FormLayout class with the Form container. Do not use it to lay out the contents of any other container.*

You can change the layout of a Spark Form by setting properties such as `gap` and padding properties on the FormLayout tag. The following example reduces the vertical space between the FormItems and indents the form by 25 pixels:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\layouts\spark\SparkFormLayout.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    width="600">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <s:Form id="form1" x="164" y="38">
        <!-- Reduce space between form items and indent form 25 pixels. -->
        <s:layout>
            <s:FormLayout gap="-14" paddingLeft="25"/>
        </s:layout>
        <s:FormHeading label="Mailing Information (Custom spacing)"/>
        <s:FormItem label="Address">
            <s:TextInput prompt="Enter your address"/>
        </s:FormItem>
        <s:FormItem label="City/State">
            <s:TextInput prompt="Enter your city and state"/>
        </s:FormItem>
        <s:FormItem label="Phone" fontFamily="Verdana" required="true">
            <s:TextInput prompt="Enter your phone number"/>
        </s:FormItem>
    </s:Form>
    <s:Form id="form2" x="164" y="38">
        <!-- Reduce space between form items. -->
        <s:layout>
            <s:FormLayout gap="0" paddingLeft="0"/>
        </s:layout>
        <s:FormHeading label="Mailing Information (Default properties)"/>
        <s:FormItem label="Address">
            <s:TextInput prompt="Enter your address"/>
        </s:FormItem>
        <s:FormItem label="City/State">
            <s:TextInput prompt="Enter your city and state"/>
        </s:FormItem>
        <s:FormItem label="Phone" fontFamily="Verdana" required="true">
            <s:TextInput prompt="Enter your phone number"/>
        </s:FormItem>
    </s:Form>
</s:Application>
```

Using the FormItemLayout layout class

FormItemLayout is a grid layout for the FormItemSkin and StackedFormItemSkin classes. The FormItemLayout has a set of columns and rows, where each layout element can position its edges relative to each column and row.

The FormItemLayout class is necessary for the Form container to align the columns. Layout elements align to the specified columns and rows using constraints. For more information, see "Using constraint rows and columns with MX containers and the Spark FormLayout class" on page 387.

The Spark DataGroup and Spark SkinnableDataContainer containers

The Spark DataGroup and Spark SkinnableDataContainer containers take as children any components that implement the IVisualElement interface and are subclasses of DisplayObject. However, these containers are primarily used to take data items as children. Data items can be simple data items such String and Number objects, and more complicated data items such as Object and XMLNode objects.

An item renderer defines the visual representation of the data item in the container. The item renderer converts the data item into a format that can be displayed by the container. You must pass an item renderer to a DataGroup or SkinnableDataContainer container.

The main differences between the DataGroup and SkinnableDataContainer containers are:

- SkinnableDataContainer can be skinned. The DataGroup container is designed for simplicity and minimal overhead, and cannot be skinned.
- DataGroup can be a child of the Scroller control to support scroll bars. Create a skin for the SkinnableDataContainer to add scroll bars.

The default layout class of the DataGroup container is BasicLayout. The default layout class of the SkinnableDataContainer class is VerticalLayout. For complete reference information, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Creating a Spark DataGroup and Spark SkinnableDataContainer container

You use the `<s:DataGroup>` and `<s:SkinnableDataContainer>` tags to define a DataGroup and SkinnableDataContainer container. Specify an `id` value if you intend to refer to a component elsewhere in your MXML, either in another tag or in an ActionScript block.

The DataGroup and SkinnableDataContainer container are examples of data provider components. Data provider components require data for display or user interaction. To provide data, assign a collection which implements the IList interface, such as an ArrayList, ArrayCollection, or XMLListCollection object, to the container’s `dataProvider` property. For more information on using data providers, see “Data providers and collections” on page 898.

The `dataProvider` property takes an array of children, as the following example shows:

```
<s:DataGroup itemRenderer=...>
    <s:dataProvider>
        <mx:ArrayList>
            <fx:String>Dave Jones</fx:String>
            <fx:String>Mary Davis</fx:String>
            <fx:String>Debbie Cooper</fx:String>
        </mx:ArrayList>
    </s:dataProvider>
</s:DataGroup>
```

If you are using Flex Components as children of the container, you can specify them as the following example shows:

```
<s:DataGroup itemRenderer=...>
    <s:dataProvider>
        <mx:ArrayList>
            <s:Button/>
            <s:Button/>
            <s:Button/>
        </mx:ArrayList>
    </s:dataProvider>
</s:DataGroup>
```

Because dataProvider is the default property of the DataGroup and SkinnableDataContainer container, you do not have to specify a <s:dataProvider> child tag. Therefore, you can write the example as shown below:

```
<s:DataGroup itemRenderer=...>
    <mx:ArrayList>
        <fx:String>Dave Jones</fx:String>
        <fx:String>Mary Davis</fx:String>
        <fx:String>Debbie Cooper</fx:String>
    </mx:ArrayList>
</s:DataGroup>
```

You can mix different types of data items in a container, or mix data items and Flex components. For example, you might mix String, Object, and XML data in the same container. However, you must define an item renderer function to apply the correct item renderer to the child. For more information, see "Using an item renderer function with a Spark container" on page 481.

You can skin the SkinnableDataContainer in the same way that you skin the container. For an example of a skin, see "Creating a Spark SkinnableContainer container" on page 428.

Using a default item renderer with a Spark container

The DataGroup and SkinnableDataContainer containers require an item renderer to draw each container child on the screen. By default, the DataGroup and SkinnableDataContainer containers do not define an item renderer. You can configure the containers to use the item renderers provided by Flex, or define your own custom item renderer.

Flex ships with two item renderers: spark.skins.spark.

- spark.skins.spark.DefaultItemRenderer Converts its data item to a single String for display in a Spark Label control. It is useful when displaying a scalar data item, such as a String or a Number, that can be easily converted to a String.
- spark.skins.spark.DefaultComplexItemRenderer Displays a Flex component in a Group container. Each component is wrapped in its own Group container. Therefore, it is useful when the children of the container are visual elements, such as Flex components.

The following example uses the DefaultItemRenderer with a DataGroup container:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkDataGroupContainerDefaultRenderer.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:DataGroup itemRenderer="spark.skins.spark.DefaultItemRenderer">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <mx:ArrayList>
            <fx:String>Dave Jones</fx:String>
            <fx:String>Mary Davis</fx:String>
            <fx:String>Debbie Cooper</fx:String>
        </mx:ArrayList>
    </s:DataGroup>
</s:Application>
```

Each data item of the container is a String. Because you use the DefaultItemRenderer with the container, each String appears in the container in a Label control.

If the data item is of type Object or is a data type that is not easily converted to a String, then you either have to convert it to a String, or define a custom item renderer to display it. For more information, see “Passing data to a Spark item renderer” on page 474.

The following example shows a DataGroup container where all its children are Flex components. The DataGroup class uses the DefaultComplexItemRenderer to display each child:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkDataGroupContainerSimpleVisual.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:DataGroup itemRenderer="spark.skins.spark.DefaultComplexItemRenderer">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <mx:ArrayList>
            <s:Button/>
            <s:Button/>
            <s:Button/>
            <s:Button/>
        </mx:ArrayList>
    </s:DataGroup>
</s:Application>
```

Because you use the DefaultComplexItemRenderer with the container, each Button control appears in the container nested in its own Group container. By wrapping each control in a Group container, the item renderer can support selection highlighting for the individual children. However, if you do not want each control to appear in its own Group container, set the item renderer to `null`, as shown below:

```
<s:DataGroup itemRenderer="{null}">
```

***Note:** If you are only displaying visual elements in a DataGroup or SkinnableDataContainer container, you should instead use the Group or SkinnableContainer containers.*

You might be able to create your application by using just the DefaultItemRenderer and DefaultComplexItemRenderer classes. However, you typically define a custom item renderer if your data items are not simple values, or if you want more control over the appearance of your container children. For more information on creating a custom item renderer, see “Define a custom Spark item renderer” on page 470.

Adding and removing children at runtime

To modify the children of the DataGroup and SkinnableDataContainer containers at runtime, modify the `dataProvider` property. The following example uses event handlers to add and remove container children by calling the `addItem()` and `removeItemAt()` methods on the `dataProvider` property:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkDataGroupContainerAddRemoveChild.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[

            private function addDGChild():void {
                var newChild:String = "new child";
                myDG.dataProvider.addItem(newChild);

                addDG.enabled = false;
                removeDG.enabled = true;
            }

            private function removeDGChild():void {
                myDG.dataProvider.removeItemAt(3);

                addDG.enabled = true;
                removeDG.enabled = false;
            }
        ]]>
    </fx:Script>
    <s:DataGroup id="myDG"
        itemRenderer="spark.skins.spark.DefaultItemRenderer">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <mx:ArrayList>
            <fx:String>Dave Jones</fx:String>
            <fx:String>Mary Davis</fx:String>
            <fx:String>Debbie Cooper</fx:String>
        </mx:ArrayList>
    </s:DataGroup>

    <s:Button id="addDG" label="Add Child"
        click="addDGChild();"/>
    <s:Button id="removeDG" label="Remove Child"
        enabled="false"
        click="removeDGChild();"/>
</s:Application>
```

For more information on using data providers, see “Data providers and collections” on page 898.

Using virtualization with Spark DataGroup and SkinnableDataContainer

A DataGroup or SkinnableDataContainer container can represent any number of children. However, each child requires an instance of an item renderer. If the container has many children, you might notice performance degradation as you add more children to the container.

Instead of creating an item renderer for each child, you can configure the container to use a virtual layout. With virtual layout, the container reuses item renderers so that it only creates item renderers for the currently visible children of the container. As a child is moved off the screen, possible by scrolling the container, a new child being scrolled onto the screen can reuse its item renderer.

To configure a container to use virtual layout, set the `useVirtualLayout` property to `true` for the layout associated with the container. Only the DataGroup or SkinnableDataContainer with the VerticalLayout, HorizontalLayout, and TileLayout supports virtual layout.

***Note:** If you define an itemRendererFunction to determine the item renderer for each data item, Flex will not reuse item renderers. The itemRendererFunction must examine each data item and create the item renderers as necessary for the specific data item type. While Flex does not reuse item renderers, it only creates enough item renderers for the currently visible data items. For more information, see "Creating a recyclable item renderer for virtual layout" on page 484.*

There are a few differences between the way a layout class works when virtual layout is enabled and when it is disabled:

- A layout with virtual layout enabled does not support the layout's major axis percent size property. This axis corresponds to the `percentHeight` property for the VerticalLayout class, and the `percentWidth` property for the HorizontalLayout class.
- A container using a virtual layout that contains few children whose sizes vary widely can respond poorly to interactive scrolling using the scroll thumb. No performance degradation occurs when scrolling using the scroll arrows or by clicking in the scroll track. Responsiveness improves as the variation in size decreases or the number of children increases.

Use virtual layout when the cost of creating or measuring a DataGroup is prohibitive because of the number of data elements or the complexity of the item renderers.

For more information on creating item renderers, see "Define a custom Spark item renderer" on page 470.

Custom Spark item renderers

The Spark list-based controls, such as List and ComboBox, support custom item renderers. You can also use Spark item renderers with some MX controls, such as the MX DataGrid and MX Tree controls.

Define a custom Spark item renderer

Several Spark components represent lists of items. These list-based components, such as DataGroup, List, and DataGrid, let the application user scroll through the item list. Some components, such as List, also let you select one or more items from the list.

You define a custom item renderer to control the display of a data item in a list-based component. The appearance can include the font, background color, border, and any other visual aspects of the data item.

An item renderer also defines the appearance of a data item when the user interacts with it. For example, the item renderer can display the data item one way when the user hovers over the data item, and in a different way when the user selects the data item.

Many Spark components support both skins and item renderers. While the item renderer defines the appearance of the data item, the skin defines the complete visual appearance of the component. The skin can include borders, scroll bars, and any other aspects of the appearance of the component. For more information on skins, see "Spark Skinning" on page 1602.

Adobe engineer Balaji Sridhar explains creating item renderers in Using Flash Builder 4 to create Spark item renderers .

Item renderer architecture

Create an item renderer in MXML or ActionScript. The advantage to creating item renderers in MXML is that it requires the least amount of code because much of the item renderer functionality is built into the base class, ItemRenderer, that you use to define MXML item renderers.

ActionScript item renderers provide the best performance because they give you complete control over the implementation. In an ActionScript item renderer, you only implement the code necessary to support your application requirements. Create an ActionScript item renderer as a subclass of the spark.components.LabelItemRenderer class for mobile applications, and the mx.core.UIComponent class for desktop applications.

The Spark item renderer architecture is defined by interfaces. Regardless of how you create your item renderer, MXML or ActionScript, the item renderer typically implements two interfaces:

Item renderer interface	Implemented by	Use
IDataRenderer	Item renderer	Defines the `data` property used to pass information to an item renderer. At a minimum, an item renderer must implement IDataRenderer to display data.
IItemRenderer	Item renderer	Defines the APIs that a component must implement to create an item renderer that can communicate with a host component to support user interaction with the data item. User interactions include selection, dragging, and the caret indicator. For some components, such as the Spark List control, user interaction includes item selection.

The list-based components that uses the item renderer is called the host component, or item renderer owner. To function as a host component, the component must implement the IItemRendererOwner interface.

Host component interface	Implemented by	Use
IItemRendererOwner	Host component of an item renderer	Defines the methods used by the host component to pass data to the item renderer.

Custom item renderer example

To better understand how item renderers work, examine the implementation of a custom item renderer. Shown below is the code for a custom MXML item renderer for the SkinnableDataContainer container that changes the font of the data item when the user hovers over the data item:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\myComponents\MySimpleCustomItemRenderer.mxml -->
<s:ItemRenderer xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:states>
        <s:State name="normal"/>
        <s:State name="hovered"/>
    </s:states>

    <s:Label id="labelDisplay"
        verticalCenter="0"
        left="3" right="3" top="6" bottom="4"
        fontSize.hovered='14' fontStyle.hovered="italic"/>
</s:ItemRenderer>
```

The base class of this item renderer is the ItemRenderer class. The ItemRenderer class implements the IDataRenderer and IItemRenderer interfaces. It is also a subclass of the Group class, so it is itself a container. In the body of the item renderer, define the layout, view states, and child controls of the item renderer used to represent the data item.

The default layout of the ItemRenderer class is BasicLayout. In this example, since there is no specification for the `layout` property, the item renderer uses BasicLayout.

The item renderer can define view states. All view states are optional. In this example, you handle the normal and hovered view states. The normal state defines the appearance of the data item when there is no user interaction. The hovered view state defines the appearance when the user hovers the pointer over the data item.

This example uses the hovered view state to change the font when the user mouses over the data item. In this example, the custom item renderer displays the text in 14 point, italic font on mouse over. For more information on using view states in an item renderer, see "Defining item renderer view states for a Spark container" on page 488.

The Label control is centered vertically in the display area of the item renderer, and is constrained to be three pixels in from the left border, three pixels in from the right border, six pixels in from the top border, and four pixels in from the bottom border. You can use these same settings in your custom item renderers to mimic the look of the default Flex item renderer, or change them as necessary for your application.

The `id` of the Label control in the item renderer is `labelDisplay`. This is a specially named component in an item renderer. Flex writes the String representation of the data item to the component named `labelDisplay`. Flex also uses the `labelDisplay` component to determine the value of the `baselinePosition` property in the host component.

The following application uses this custom item renderer:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkDataGroupContainerSimpleIR.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:SkinnableDataContainer
        itemRenderer="myComponents.MySimpleCustomItemRenderer">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <mx:ArrayList>
            <fx:String>Bill Smith</fx:String>
            <fx:String>Dave Jones</fx:String>
            <fx:String>Mary Davis</fx:String>
            <fx:String>Debbie Cooper</fx:String>
        </mx:ArrayList>
    </s:SkinnableDataContainer>
</s:Application>
```

Differences between mobile and desktop item renderers

An item renderer is often designed to appear differently in a mobile application than in a desktop application. Therefore, while it is possible, you typically do not use the same item renderer in a mobile application and in a desktop application.

For example, the differences between an item renderer for a mobile and a desktop application include the following:

- The size of a mobile item renderer tends to be larger than for a desktop item renderer.
- An item renderer for the selected item on in a mobile application usually indicates selection with a checkmark or other icon. For a desktop application, item renderers usually show selection by changing the `backgroundColor` style.
- The caret in a mobile application is usually indicated by changing the `backgroundColor` style. For a desktop application, the caret is usually indicated by drawing a border around the item.

The way you create item renderers can also depend on whether the application is for a desktop application or for a mobile application. You define item renderers in two ways:

- MXML

  Use MXML to define item renderers for desktop applications. MXML item renderers are simple to implement, but do not provide the highest performance often necessary for mobile applications. You typically create an MXML item renderer as a subclass of the spark.components.ItemRenderer class.

  For a mobile application, if your component hosting the item renderer displays only has a few data items or does not support scrolling, you might be able to use an MXML item renderer.

- ActionScript

  Use ActionScript for item renderers for applications that require the highest performance. For item renderers used in mobile applications, or for item renderers to use in both mobile and desktop applications, create them in ActionScript. For a mobile project, you typically create ActionScript item renderers as a subclass of the spark.components.LabelItemRenderer class.

Blogger Nahuel Foronda created a series of articles on Mobile ItemRenderer in ActionScript.

Blogger Rich Tretola created a cookbook entry on Creating a List with an ItemRenderer for a mobile application.

Interacting with a mobile and desktop item renderer

The mx.core.UIComponent class defines the `interactionMode` style property that you use to configure components for the type of input used in the application. For the Halo and Spark themes, the default value is `mouse` to indicate that the mouse is the primary input device. For the Mobile theme, the default value is `touch` to indicate the primary input is the touch screen.

One important difference between item renderers for desktop and for mobile applications is the way you interact with the application. For desktop applications, you use a mouse to interact with the application. You can use the mouse to:

- Move the mouse pointer over a data item. This is referred to as hovering over the item.
- Select the item by clicking on it. Many Spark components let the user select multiple data items by using the Shift and Control keys in combination with the mouse.
- Display a caret item. The caret item is the data item that currently has focus. The caret item can be the currently selected data item, or it can be a different item.
- Drag and drop data items when enabled by the Spark control.

When you interact with an application on a mobile device, you often use a touch screen or a five-way navigation control, not a mouse. With a mobile application, the data items in a list-based control do not enter the hovered state, and you typically do not have to support drag and drop. Therefore, when implementing an item renderer for mobile applications, you do not have to worry about supporting those situations.

MXML item renderers define view states. View states provide MXML item renderers with a simple mechanism for handling the different states of the data item. In ActionScript item renderers, you do not use view states. Instead, you handle user interaction in the body of your item renderer.

Differences between down and selected item renderers in a mobile application

For mobile applications, an item renderer must distinguish between an item being in the down state and the item being in the selected state. An item is down when the user presses down on the item. An item is selected when the user releases their finger after pressing down on the item.

***Note:** In a desktop application, one where `interactionMode` is `mouse`, selection occurs on the `mouseDown` event.*

When a user presses down on an item, the item renderer does not immediately enter the down state. Instead, the item renderer waits for the duration of time specified by the `touchDelay` property. The default delay duration specified by the `touchDelay` property is 100 ms.

This delay ensures that the user did not intend to initiate a scroll operation. If the item renderer immediately went to the down state, and the user intended to scroll, the item renderer would flicker from the normal state to the down state, and then back to the normal state. For more information on initiating a scroll operation in a mobile application, see Use scroll bars in a mobile application.

Working with item renderers

Passing data to a Spark item renderer

The host component of the item renderer is called the item renderer's owner. The host component passes information to the item renderer by using the properties defined by the IDataRenderer and IItemRenderer interfaces.

The following table describes the properties of the IDataRenderer and IItemRenderer interfaces:

Item renderer property	Type	Description	Interface
`data`	Object	The data item to render or edit as defined in the data provider of the host component.	IDataRenderer
`dragging`	Boolean	Contains `true` if the item renderer is being dragged. Mobile applications do not support drag and drop. Therefore, for an item renderer used only in a mobile application, you can define this property with a setter/getter that always returns `false`. To use the item renderer in a desktop application that supports drag and drop, you must implement it.	IItemRenderer
`itemIndex`	int	The index of the item in the data provider of the host component of the item renderer.	IItemRenderer
`label`	String	A String representation of the data item to display in the item renderer.	IItemRenderer
`selected`	Boolean	Contains `true` if the item renderer can show itself as selected. Many Spark components, such as the DataGroup and SkinnableDataContainers support item renderers, but do not support the selection of a data item. Other Spark components,. such as List, ComboBox, and DataGrid, support the selection of a data item.	IItemRenderer
`showsCaret`	Boolean	Contains `true` if the item renderer can show itself as focused.	IItemRenderer

Your item renderer might also implement the `hovered` property. The hovered property is not defined by an interface but is implemented by many Flex item renderers. The following table describes the `hovered` property:

Item renderer property	Type	Description	Interface
`hovered`	Boolean	Contains `true` when the user hovers over the list item. Typically, the item renderer listens for the `rollOver` and `rollOut` events to set `hovered` and to update the display of the item renderer accordingly. Mobile applications do not support hovered. For an item renderer used in a mobile application, you are not required to implement the hovered property. To use the item renderer in a desktop application, you must implement it. The predefined mobile item renderers supplied with Flex implement the hovered property so that you can use the item renderer in a mobile and desktop application.	None

The UIComponent class, the base class for all Flex components including item renderers, defines the `owner` property. The `owner` property contains a reference to the component that hosts the item renderer. For example, the SkinnableDataContainer can be the owner of an item renderer. From within the item renderer, you can access the host component by using the `owner` property.

The host component of an item renderer must implement the IItemRendererOwner interface. That interface defines the following methods to write information to the item renderer:

Host component method	Description	Interface
`itemToLabel()`	Converts the data item to a String representation. Host components can override this method to customize the String conversion.	IItemRendererOwner
`updateRenderer()`	Write the data item as a String to the `label` property. Updates the `owner` property with a reference to the host component. The last thing this method does is set the `data` property of the item renderer. Host components can override this method to write additional information to the item renderer.	IItemRendererOwner

Before you create a custom item renderer, decide how to pass the data item to the item renderer. In some situations, you want the host component to perform any processing on the data item before it passes it to the item renderer. If so, override the `itemToLabel()` and `updateRenderer()` methods in the host component. The item renderer then accesses the data by using the `label` property.

Instead of the host component processing the data item, the item renderer can perform the processing. If you want the item renderer to process the data item, use `IDataRenderer.data` property to pass it. The item renderer then accesses the `data` property and performs any processing on the data item before displaying it.

For an example that overrides the `itemToLabel()` and `updateRenderer()` methods, see "Passing data using the IItemRenderer.label property" on page 476. For an example that overrides the `data` property, see "Passing data using the IIDataRenderer.data property" on page 479.

Passing data using the IItemRenderer.label property

If the data item is a String, or a value that can easily be converted to a String, you can use the `IItemRenderer.label` property to pass it to the item renderer. If the data item is in a format that must be converted to a String representation, override the `IItemRendererOwner.itemToLabel()` method in the host component to customize the conversion.

***Note:** The example item renderers in this section are written in MXML. For examples written in ActionScript, see "Create a Spark item renderer in ActionScript" on page 495.*

In the following example, the children of the SkinnableDataContainer container are Strings specifying different colors:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkDataContainerColor.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:MyComps="myComponents.*">
    <s:SkinnableDataContainer
        itemRenderer="myComponents.MySimpleColorRenderer">
        <mx:ArrayList>
            <fx:String>red</fx:String>
            <fx:String>green</fx:String>
            <fx:String>blue</fx:String>
        </mx:ArrayList>
    </s:SkinnableDataContainer>
</s:Application>
```

This example uses a custom item renderer named MySimpleColorRenderer, defined in the file MySimpleColorRenderer.mxml, that shows the String text in a background of the matching color. Shown below is the MXML item renderer:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\myComponents\MySimpleColorRenderer.mxml -->
<s:ItemRenderer xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    autoDrawBackground="false">

    <fx:Script>
        <![CDATA[

            // Property to hold the RGB color value.
            [Bindable]
            public var myColor:uint;

            // Write String to labelDisplay component.
            override public function set label(value:String):void
            {
                super.label = value;
                labelDisplay.text = label;

                // Determine the RGB color value from the data item.
                if (label == "red")
                    myColor = 0xFF0000;
                if (label == "green")
                    myColor = 0x00FF00;
                if (label == "blue")
                    myColor = 0x0000FF;
            }
        ]]>
    </fx:Script>

    <!-- Set the background color to the RGB color value.-->
    <s:Rect width="100%" height="100%" alpha="0.5">
        <s:fill>
            <s:SolidColor color="{myColor}" />
        </s:fill>
    </s:Rect>
    <!-- Display the color name -->
    <s:Label id="labelDisplay"/>
</s:ItemRenderer>
```

In this example, the item renderer overrides the `label` property to write the color to the Label control, and set the fill color of the Rect component.

This item renderer displays the data with no visual changes based on state. Therefore, it sets the `ItemRenderer.autoDrawBackground` property to `false`. This item renderer is useful for displaying data in the container when it does not have any user interaction. For an example of an item renderer that changes its display based on user interaction, see “Controlling the background color using the autoDrawBackground property” on page 487.

If you want to modify the String passed to the `label` property, you can override the `itemToLabel()` method in the host component. The `itemToLabel()` method has the following signature:

```
itemToLabel(item:Object):String
```

The method takes a single argument representing the data item. It returns a String representation of the data item for display in the item renderer.

In the following example, each data item is represented by an Object containing three fields. The custom SkinnableDataContainer container, called MyDataGroup, overrides the `itemToLabel()` method to format the Object as a String before passing the String to the item renderer. The example then uses the DefaultItemRenderer to display the text:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkDataGroupContainerOverride.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:MyComps="myComponents.*">

    <!-- Define a custom DataGroup container to override the itemToLabel() method. -->
    <MyComps:MyDataGroup itemRenderer="spark.skins.spark.DefaultItemRenderer">
        <MyComps:layout>
            <s:VerticalLayout/>
        </MyComps:layout>

        <mx:ArrayList>
            <fx:Object firstName="Bill" lastName="Smith" companyID="11233"/>
            <fx:Object firstName="Dave" lastName="Jones" companyID="13455"/>
            <fx:Object firstName="Mary" lastName="Davis" companyID="11543"/>
            <fx:Object firstName="Debbie" lastName="Cooper" companyID="14266"/>
        </mx:ArrayList>
    </MyComps:MyDataGroup>
</s:Application>
```

The MyDataGroup.mxml file defines the custom SkinnableDataContainer container that overrides the `itemToLabel()` method:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\myComponents\MyDataGroup.mxml -->
<s:SkinnableDataContainer xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            // Override to return the Object as a formatted String.
            override public function itemToLabel(item:Object):String {
                var tempString:String;
                if (item == null)
                    return " ";
                tempString = item.firstName + " " + item.lastName
                    + " " + ", ID: " + item.companyID;
                return tempString;
            }
        ]]>
    </fx:Script>
</s:SkinnableDataContainer>
```

Passing data using the IIDataRenderer.data property

Rather than processing the data in the host component, you can let the item renderer perform all the processing of the data item for display. In this situation, use the `ItemRenderer.data` property to pass the data item to the item renderer. This technique lets you define a set of item renderers that display the same data in different ways depending on your application requirements.

***Note:** The example item renderers in this section are written in MXML. For examples written in ActionScript, see "Create a Spark item renderer in ActionScript" on page 495.*

In the next example, each data item is represented by an Object that defines three fields:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkDataGroupContainerSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:SkinnableDataContainer
        itemRenderer="myComponents.MySimpleItemRenderer">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <mx:ArrayList>
            <fx:Object firstName="Bill" lastName="Smith" companyID="11233"/>
            <fx:Object firstName="Dave" lastName="Jones" companyID="13455"/>
            <fx:Object firstName="Mary" lastName="Davis" companyID="11543"/>
            <fx:Object firstName="Debbie" lastName="Cooper" companyID="14266"/>
        </mx:ArrayList>
    </s:SkinnableDataContainer>
</s:Application>
```

The SkinnableDataContainer uses a custom item renderer named MySimpleItemRenderer.mxml. The custom item renderer displays the firstName and lastName fields in a single Label control, and display the companyID in a second Label control:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\myComponents\MySimpleItemRenderer.mxml -->
<s:ItemRenderer xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:HGroup verticalCenter="0" left="2" right="2" top="2" bottom="2">
        <s:Label text="{data.lastName}, {data.firstName}"/>
        <s:Label text="{data.companyID}"/>
    </s:HGroup>
</s:ItemRenderer>
```

The `data` property contains an Object passed from the DataGroup container. The Object represents the data item in its original form. The renderer uses data binding to populate the controls in the item renderer from the `data` property. The two Label controls are defined in a Group container so that they can be layed out horizontally.

Rather than using data binding, you can override the `data` property in the item renderer. Within the override, you can modify the data or perform other processing, then set properties in the renderer. The following example shows an alternative implementation of MySimpleItemRenderer.mxml that overrides the `data` property:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\myComponents\MySimpleItemRendererDataOverride.mxml -->
<s:ItemRenderer xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[

            override public function set data(value:Object):void {
                super.data = value;

                // Check to see if the data property is null.
                if (value== null)
                    return;
                // If the data property is not null,
                // set the Label controls appropriately.
                nameLabel.text = value.firstName + ', ' + value.lastName;
                compLabel.text = value.companyID;
            }
        ]]>
    </fx:Script>
    <s:HGroup verticalCenter="0" left="2" right="2" top="2" bottom="2">
        <s:Label id="nameLabel"/>
        <s:Label id="compLabel"/>
    </s:HGroup>
</s:ItemRenderer>
```

Controlling the background display of an item renderer

An item renderer controls the background display of the data item in the host component. Typically, an item renderer changes the background display of the data item to reflect user interaction. For example, an item renderer can use a transparent background when there is no user interaction with the data item. It could draw a blue background when the data item is selected, and a different background when the user hovers over the data item.

Flex defines the following CSS styles to define background colors for the three common user interactions:

Interaction	Style	Value for Spark theme	Value for Mobile theme
none	`contentBackgroundColor`	0xFFFFFF (white)	0x464646 (dark grey)
hovered	`rollOverColor`	0xCEDBEF (light blue)	0xCEDBEF (light blue/grey)
selected	`selectionColor`	0xA8C6EE (dark blue)	0xB2B2B2 (light grey)

These colors are defined in the default.css file for the spark.swc and mobilecomponents.swc file. If you want your item renderer to mimic the color setting of Flex, use these same colors for setting the background color of your custom item renderers.

You can use these same styles in a custom item renderer to mimic the default background colors used by Flex component. Or, you can define your item renderers to use different colors and backgrounds.

If you define an MXML item renderer, you typically create it as a subclass of the ItemRenderer class. The ItemRenderer class defines the default background color for all types of user interactions. By default the item renderer draws a transparent background around the item when there is not user interaction. It draws a light-blue background around an item when you hover over it. For more information, see “Controlling the background color using the autoDrawBackground property” on page 487.

If you define an item renderer in ActionScript, you define the background colors of the data item. You can choose to implement your item renderer to use the predefined CSS styles, or define your own.

In your main application, you can redefine the CSS styles for the background colors. The following applications sets the `rollOverColor` style of the application to green:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkDataGroupContainerSimpleIRStyled.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Style>
        @namespace s "library://ns.adobe.com/flex/spark";
        s|ItemRenderer { rollOverColor : green }
    </fx:Style>

    <s:SkinnableDataContainer
        itemRenderer="myComponents.MySimpleCustomItemRenderer">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <mx:ArrayList>
            <fx:String>Bill Smith</fx:String>
            <fx:String>Dave Jones</fx:String>
            <fx:String>Mary Davis</fx:String>
            <fx:String>Debbie Cooper</fx:String>
        </mx:ArrayList>
    </s:SkinnableDataContainer>
</s:Application>
```

Using an item renderer function with a Spark container

In some applications, you display different types of data items in a single container. In this scenario, each type of data item needs its own item renderer. Or, you mix data items and Flex components in a container. To mix data items and Flex components, define different item renderers for the data items and the Flex components.

You can use an item renderer function to examine each data item to determine which item renderer to use. The `DataGroup.itemRendererFunction` and `SkinnableDataContainer.itemRendererFunction` property takes a function with the following signature:

```
function itemRendererFunction(item:Object):ClassFactory
```

Where `item` is the data item, and the return value is the item renderer. If the child is a Flex component, return DefaultComplexItemRenderer to display the child in a Group container. Alternatively, return `null` to display the child with no renderer.

The following example defines an item renderer function to return one item renderer for data items defined as Object, and another item renderer for data items defined as String:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkDataGroupContainerFunction.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[

            import myComponents.MySimpleItemRendererFunction;
            import spark.skins.spark.DefaultItemRenderer;

            private function selectRenderer(item:Object):ClassFactory {
                var classFactory:ClassFactory;
                if (item is String) {
                    // If the item is a String, use DefaultItemRenderer.
                    classFactory = new ClassFactory(DefaultItemRenderer);
                }
                else {
                    // If the item is an Object, use MySimpleItemRendererFunction.
                    classFactory = new ClassFactory(MySimpleItemRendererFunction);
                }
                return classFactory;
            }
        ]]>
    </fx:Script>
    <s:DataGroup itemRendererFunction="selectRenderer">
        <s:layout>
            <s:TileLayout requestedColumnCount="3"/>
        </s:layout>
        <mx:ArrayList>
            <fx:Object firstName="Bill" lastName="Smith" companyID="11233"/>
            <fx:String>617-555-1212</fx:String>
            <fx:String>Newton</fx:String>
            <fx:Object firstName="Dave" lastName="Jones" companyID="13455"/>
            <fx:String>617-555-5555</fx:String>
            <fx:String>Newton</fx:String>
            <fx:Object firstName="Mary" lastName="Davis" companyID="11543"/>
            <fx:String>617-555-6666</fx:String>
            <fx:String>Newton</fx:String>
        </mx:ArrayList>
    </s:DataGroup>
</s:Application>
```

You also use item renderer function when mixing data items and Flex components in the container. Flex components implement the IVisualElement interface, and therefore do not need an item renderer to draw them on the screen. In your item renderer function, you can determine if the data item corresponds to a Flex component. If so, the item renderer function returns the DefaultComplexItemRenderer, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkDataGroupContainerFunctionVisual.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
            import mx.core.IVisualElement;

            import myComponents.MySimpleItemRendererEmployee;
            import spark.skins.spark.DefaultComplexItemRenderer;

            private function selectRenderer(item:Object):ClassFactory {
                var classFactory:ClassFactory;
                if(item is IVisualElement){
                    // If the item is a Flex component, use DefaultComplexItemRenderer.
                    classFactory = new ClassFactory(DefaultComplexItemRenderer);
                }
                else if (item is Object){
                    // If the item is an Object, use MySimpleItemRendererFunction.
                    classFactory = new ClassFactory(MySimpleItemRendererEmployee);
                }
                return classFactory;
            }
        ]]>
    </fx:Script>
    <s:DataGroup itemRendererFunction="selectRenderer">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <mx:ArrayList>
            <fx:Object firstName="Bill" lastName="Smith" companyID="11233"/>
            <fx:Object firstName="Dave" lastName="Jones" companyID="13455"/>
            <fx:Object firstName="Mary" lastName="Davis" companyID="11543"/>
            <fx:Object firstName="Debbie" lastName="Cooper" companyID="14266"/>
            <s:Button label="Add Employee"/>
        </mx:ArrayList>
    </s:DataGroup>
</s:Application>
```

Spark item renderer precedence

The DataGroup and SkinnableDataContainer containers use the follow rules to determine the item renderer for a child:

1 If the `itemRendererFunction` property is defined, call the associated function to obtain the item renderer. If the function returns `null`, go to rule 2.

2 If the `itemRenderer` property is defined, use the specified item renderer to display the item.

3 If the item is implements mx.core.IVisualElement and is of type flash.display.DisplayObject, use it directly.

4 Dispatch a runtime error if no item renderer found.

Creating a recyclable item renderer for virtual layout

With virtual layout disabled, the DataGroup and SkinnableDataContainer containers create one instance of the item renderer for each child. With virtual layout enabled, the container only creates enough item renderers to display its currently visible children. Virtual layout greatly reduces the overhead required to use the DataGroup and SkinnableDataContainer containers.

With virtual layout enabled, when a child is moved off the visible area of the container, its item renderer is recycled. When the item renderer is reused, its `data` property is set to the data item representing the new child. Therefore, if a recycled item renderer performs any actions based on the value of the `data` property, it must first check that the property is not `null`.

When the item renderer is reassigned, Flex also calls the `updateRenderer()` method of the item renderer owner. This method must set the `owner` and `label` properties on the item renderer. Subclasses of SkinnableDataContainer, can use the `updateRenderer()` method to set additional properties on the item renderer.

Because a container can reuse an item renderer, ensure that you fully define its state. For example, you use a CheckBox control in an item renderer to display a `true` (checked) or `false` (unchecked) value based on the current value of the `data` property. A common mistake is to assume that the CheckBox control is always in its default state of unchecked and only inspect the data property for a value of `true`.

However, remember that the CheckBox can be recycled and had previously been checked. Therefore, inspect the `data` property for a value of `false`, and explicitly uncheck the control if it is checked, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\myComponents\MySimpleItemRendererCB.mxml -->
<s:ItemRenderer xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    dataChange="setMgr();">

    <fx:Script>
        <![CDATA[
            private function setMgr():void {
                // Check to see if the data property is null.
                if (data == null)
                    return;
                // If the data property is not null,
                // set the CheckBox control appropriately..
                if (data.manager == "yes") {
                    mgr.selected = true;
                }
                else {
                    mgr.selected = false;
                }
            }
        ]]>
    </fx:Script>
    <s:HGroup verticalCenter="0" left="2" right="2" top="2" bottom="2">
        <s:Label text="{data.lastName}, {data.firstName}"/>
        <s:Label text="{data.companyID}"/>
        <s:CheckBox id="mgr"/>
    </s:HGroup>
</s:ItemRenderer>
```

Use the `dataChange` event of the ItemRenderer class to detect the change to its `data` property. This event is dispatched whenever the `data` property changes. Alternatively, you can override the `data` property.

Alternatively, you can override the `ItemRenderer.data` property itself, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\myComponents\MySimpleItemRendererCBData.mxml -->
<s:ItemRenderer xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <fx:Script>
        <![CDATA[

            override public function set data(value:Object):void {
                super.data = value;
                // Check to see if the data property is null.
                if (value== null)
                    return;
                // If the data property is not null,
                // set the CheckBox control appropriately..
                if (value.manager == "yes") {
                    mgr.selected = true;
                }
                else {
                    mgr.selected = false;
                }
            }
        ]]>
    </fx:Script>
    <s:HGroup verticalCenter="0" left="2" right="2" top="2" bottom="2">
        <s:Label text="{data.lastName}, {data.firstName}"/>
        <s:Label text="{data.companyID}"/>
        <s:CheckBox id="mgr"/>
    </s:HGroup>
</s:ItemRenderer>
```

Defining a typical item for determining the size of an item renderer

When using virtual layout with the DataGroup and SkinnableDataContainer containers, you can pass to the container a data item that defines a typical data item. The container then uses the typical data item, and the associated item renderer, to determine the default size of the child. By defining the typical item, the container does not have to size each child as it is drawn on the screen.

If you do not specify the data item, by default the control uses the first item in the data provider as the typical data item.

Use the `typicalItem` property of the container to specify the data item, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkDataGroupContainerTypicalItem.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            [Bindable]
            public var typicalObj:Object = {
                    firstName:"Long first name",
                    lastName:"Even longer last name",
                    companyID:"123456",
                    manager:"yes"
            };
        ]]>
    </fx:Script>

    <s:Scroller>
        <s:DataGroup itemRenderer="myComponents.MySimpleItemRendererCB"
            height="100"
            typicalItem="{typicalObj}" >
            <s:layout>
                <s:VerticalLayout useVirtualLayout="true"/>
            </s:layout>
            <mx:ArrayList>
                <fx:Object firstName="Bill" lastName="Smith"
                    companyID="11233" manager="yes"/>
                <fx:Object firstName="Dave" lastName="Jones"
                    companyID="13455" manager="no"/>
                <fx:Object firstName="Mary" lastName="Davis"
                    companyID="11543" manager="yes"/>
                <fx:Object firstName="Debbie" lastName="Cooper"
                    companyID="14266" manager="no"/>
                <fx:Object firstName="Bob" lastName="Martins"
                    companyID="11233" manager="yes"/>
                <fx:Object firstName="Jack" lastName="Jones"
                    companyID="13455" manager="no"/>
                <fx:Object firstName="Sam" lastName="Johnson"
                    companyID="11543" manager="yes"/>
                <fx:Object firstName="Tom" lastName="Fitz"
                    companyID="14266" manager="no"/>
                <fx:Object firstName="Dave" lastName="Mead"
                    companyID="11233" manager="yes"/>
                <fx:Object firstName="Dave" lastName="Jones"
                    companyID="13455" manager="no"/>
                <fx:Object firstName="Mary" lastName="Davis"
                    companyID="11543" manager="yes"/>
                <fx:Object firstName="Debbie" lastName="Cooper"
                    companyID="14266" manager="no"/>
            </mx:ArrayList>
        </s:DataGroup>
    </s:Scroller>
</s:Application>
```

In this example, you define typicalObj, an Object that represents a data item with a long value for the firstName and lastName fields. You then pass typicalObj to the `typicalItem` property of the container. The container uses that data item, and the associated item renderer, to determine the size of the children.

Specifying a value for the `typicalItem` property passes that value, and the associated item renderer, to the `typicalLayoutElement` property of the layout of the container. For more information on the `typicalLayoutElement` property, see "Set the row height or column width of a layout" on page 423.

Create a Spark item renderer in MXML

MXML item renderers require the least amount of code to create. Typically, you create an MXML item renderer as a subclass of the ItemRenderer class.

Controlling the background color using the autoDrawBackground property

To completely control the background color of an item renderer, set the `ItemRenderer.autoDrawBackground` property to `false`. When you set that property to `false`, your item renderer is responsible for displaying the background colors for all user interactions.

The following custom item renderer alternates the background color between white and green for the items in a SkinnableDataContainer:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\myComponents\MyAlternatingItemRenderer.mxml -->
<s:ItemRenderer xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    autoDrawBackground="false">

    <fx:Script>
        <![CDATA[

            // Make the default background color white.
            [Bindable]
            public var myBGColor:int = 0xFFFFFF;

            // Override the itemIndex set function to draw a
            // white background behind even number items,
            // and a green background behind odd numbered items.
            override public function set itemIndex(value:int):void {
                if ((value%2) == 0) {
                    myBGColor= 0xFFFFFF;
                }
                if ((value%2) == 1) {
                    myBGColor= 0xCCFF66;
                }
            }
        ]]>
    </fx:Script>
    <s:states>
        <s:State name="normal"/>
        <s:State name="hovered"/>
    </s:states>
    <s:Rect id="myRect"
        left="0" right="0" top="0" bottom="0"
        alpha="1.0">
        <s:stroke>
            <s:SolidColorStroke
                color="0xA8C6EE"
                weight="1"/>
        </s:stroke>
        <s:fill>
            <!-- Bind the myBGColor property to the fill color. -->
            <s:SolidColor
                color="{myBGColor}"/>
        </s:fill>
    </s:Rect>

    <s:Label id="labelDisplay"
        verticalCenter="0"
        left="3" right="3" top="6" bottom="4"
        fontSize.hovered='14' fontStyle.hovered="italic"/>
</s:ItemRenderer>
```

This example overrides the `itemIndex` property of the ItemRenderer class. The `itemIndex` property contains the index of the data item in the data provider of the host component. In the override, set the background color to green for odd-numbered items, and to white for even-numbered items.

The following application uses this item renderer:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkDataGroupContainerAlternatingIR.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:SkinnableDataContainer
        itemRenderer="myComponents.MyAlternatingItemRenderer">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <mx:ArrayList>
            <fx:String>Bill Smith</fx:String>
            <fx:String>Dave Jones</fx:String>
            <fx:String>Mary Davis</fx:String>
            <fx:String>Debbie Cooper</fx:String>
        </mx:ArrayList>
    </s:SkinnableDataContainer>
</s:Application>
```

Defining item renderer view states for a Spark container

Item renderers support optional view states. You typically use view states in MXML item renderers to control the appearance of a data item based on user interaction with the item. The ItemRenderer class supports all views states so that you can use those item renderers with list-based classes.

Flex defines the following view states that you can support in your item renderers.

- normal The data item has no user interaction.
- hovered The mouse is over the data item.
- selected The data item is selected.

- dragging The data item is being dragged.
- normalAndShowCaret The data item is in the normal state, and it has focus in the item list.
- hoveredAndShowCaret The data item is in the hovered state, and it has focus in the item list.
- selectedAndShowCaret The data item is in the normal state, and it has focus in the item list.

When the user interacts with a control in a way that changes the view state of the item renderer, Flex first determines if the renderer defines that view state. If the item renderer supports the view state, Flex sets the item renderer to use that view state. If the item renderer does not supports the view state, Flex does nothing.

The selected, normalAndShowCaret, hoveredAndShowCaret, and selectedAndShowCaret view states are supported by the list-based components. The list-based components are subclasses of the spark.components.supportClasses.ListBase class. The DataGroup and SkinnableDataContainer containers do not implement these view states.

The view states supported by your item renderers, and the action performed by a change to each view state, are determined by your application requirements. For example, you can alter the display of the data renderer based on the view state, show different data, or do nothing. Your item renderer can also define additional view states.

In the next example, you define a SkinnableDataContainer to display an Object with four fields: firstName, lastName, companyID, and phone:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkDataGroupContainerSimpleStates.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:SkinnableDataContainer itemRenderer="myComponents.MySimpleItemRendererWithStates">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <mx:ArrayList>
            <fx:Object firstName="Bill" lastName="Smith"
                companyID="11233" phone="617-555-1212"/>
            <fx:Object firstName="Dave" lastName="Jones"
                companyID="13455" phone="617-555-1213"/>
            <fx:Object firstName="Mary" lastName="Davis"
                companyID="11543" phone="617-555-1214"/>
            <fx:Object firstName="Debbie" lastName="Cooper"
                companyID="14266" phone="617-555-1215"/>
        </mx:ArrayList>
    </s:SkinnableDataContainer>
</s:Application>
```

The following item renderer displays the text of the Label controls in bold, blue font for the hover state:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\myComponents\MySimpleItemRendererWithStates.mxml -->
<s:ItemRenderer xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    autoDrawBackground="false">
    <s:states>
        <s:State name="normal"/>
        <s:State name="hovered"/>
    </s:states>

    <s:HGroup verticalCenter="0" horizontalCenter="0">
        <s:Label text="{data.lastName}, {data.firstName}"
            color.hovered="blue"
            fontWeight.hovered="bold"/>
        <s:Label text="{data.companyID}"
            color.hovered="blue"
            fontWeight.hovered="bold"/>
        <s:Label text="{data.phone}"
            color.hovered="blue"
            fontWeight.hovered="bold"/>
    </s:HGroup>
</s:ItemRenderer>
```

Because a SkinnableDataContainer does not support the selected view state, the item renderer does not define any settings for the selected state.

You can also include a transition in an item renderer. A transition plays whenever you change a view state. The following item renderer uses a transition to display the company ID and telephone number of the employee on mouse over:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\myComponents\MySimpleItemRendererWithTrans.mxml -->
<s:ItemRenderer xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    autoDrawBackground="false">
    <s:states>
        <s:State name="normal"/>
        <s:State name="hovered"/>
    </s:states>
    <s:transitions>
        <s:Transition fromState="normal">
            <s:Sequence>
                <s:Resize target="{this}" />
                <mx:SetPropertyAction targets="{[cID, empPhone]}"
                    name="visible" value="true" />
             </s:Sequence>
        </s:Transition>
        <s:Transition toState="normal">
            <s:Sequence>
                <mx:SetPropertyAction targets="{[cID, empPhone]}"
                    name="visible" value="false" />
                <s:Resize target="{this}" />
            </s:Sequence>
        </s:Transition>
    </s:transitions>
    <s:VGroup verticalCenter="0" horizontalCenter="0">
        <s:Label text="{data.lastName}, {data.firstName}"
            color.hovered="blue"
            fontWeight.hovered="bold"/>
        <s:Label id="cID"
            includeIn="hovered"
            includeInLayout.hovered="true"
            includeInLayout.normal="false"
            text="{data.companyID}"/>
        <s:Label id="empPhone"
            includeIn="hovered"
            includeInLayout.hovered="true"
            includeInLayout.normal="false"
            text="{data.phone}"/>
    </s:VGroup>
</s:ItemRenderer>
```

The following application uses this item renderer:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkDataGroupContainerSimpleStatesTransition.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:SkinnableDataContainer itemRenderer="myComponents.MySimpleItemRendererWithTrans">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <mx:ArrayList>
            <fx:Object firstName="Bill" lastName="Smith"
                companyID="11233" phone="617-555-1212"/>
            <fx:Object firstName="Dave" lastName="Jones"
                companyID="13455" phone="617-555-1213"/>
            <fx:Object firstName="Mary" lastName="Davis"
                companyID="11543" phone="617-555-1214"/>
            <fx:Object firstName="Debbie" lastName="Cooper"
                companyID="14266" phone="617-555-1215"/>
        </mx:ArrayList>
    </s:SkinnableDataContainer>
</s:Application>
```

For more information on view states, see “View states” on page 1847. For more information on transitions, see “Transitions” on page 1870.

Defining an inline item renderer for a Spark container

The examples of item renderers shown above are all defined in an MXML file. That makes the item renderer highly reusable because you can reference it from multiple containers.

You can also define inline item renderers in the MXML definition of a component. By using an inline item renderer, your code can all be defined in a single file. However, it is not easy to reuse an inline item renderer.

The following example uses an inline item renderer with the SkinnableDataContainer container:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkDataGroupContainerInline.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:SkinnableDataContainer>
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <mx:ArrayList>
            <fx:Object firstName="Bill" lastName="Smith" companyID="11233"/>
            <fx:Object firstName="Dave" lastName="Jones" companyID="13455"/>
            <fx:Object firstName="Mary" lastName="Davis" companyID="11543"/>
            <fx:Object firstName="Debbie" lastName="Cooper" companyID="14266"/>
        </mx:ArrayList>
        <s:itemRenderer>
            <fx:Component>
                <s:ItemRenderer>
                    <s:Group verticalCenter="0" left="2" right="2" top="2" bottom="2">
                        <s:layout>
                            <s:HorizontalLayout/>
                        </s:layout>
                        <s:Label text="{data.lastName}, {data.firstName}"/>
                        <s:Label text="{data.companyID}"/>
                    </s:Group>
                </s:ItemRenderer>
            </fx:Component>
        </s:itemRenderer>
    </s:SkinnableDataContainer>
</s:Application>
```

Notice that you define the item renderer inline by using the `itemRenderer` property of the DataGroup container. The first child tag of the `itemRenderer` property is always the `<fx:Component>` tag. Inside the `<fx:Component>` tag is the same code as was in the MySimpleItemRenderer.mxml file shown above.

Items allowed in an inline component

There is only one restriction on what you can and cannot do in an inline item renderer. You cannot create an empty `<fx:Component></fx:Component>` tag. For example, you can combine effect and style definitions in an inline item renderer along with your rendering logic.

You can include the following items in an inline item renderer:

- Binding tags
- Effect tags
- Metadata tags
- Model tags
- Scripts tags
- Service tags
- State tags
- Style tags
- XML tags

- id attributes, except for the top-most component

Using the Component tag

The <fx:Component> tag defines a new scope in an MXML file, where the local scope of the item renderer is defined by the MXML code block delimited by the <fx:Component> and </fx:Component> tags. To access elements outside the local scope of the item renderer, you prefix the element name with the outerDocument keyword.

For example, you define one variable named localVar in the scope of the main application. You define another variable with the same name in the scope of the item renderer. From within the item renderer, you access the application's localVar by prefixing it with outerDocument keyword, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkDataGroupContainerInlineScope.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
            // Variable in the Application scope.
            [Bindable]
            public var localVar:String="Application scope";
        ]]>
    </fx:Script>
    <s:SkinnableDataContainer>
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <mx:ArrayList>
            <fx:Object firstName="Bill" lastName="Smith" companyID="11233"/>
            <fx:Object firstName="Dave" lastName="Jones" companyID="13455"/>
            <fx:Object firstName="Mary" lastName="Davis" companyID="11543"/>
            <fx:Object firstName="Debbie" lastName="Cooper" companyID="14266"/>
        </mx:ArrayList>
        <s:itemRenderer>
            <fx:Component>
                <s:ItemRenderer>
                    <fx:Script>
```

```
                        <![CDATA[
                            // Variable in the Renderer scope.
                            [Bindable]
                            public var localVar:String="Renderer scope";
                        ]]>
                    </fx:Script>
                    <s:Group verticalCenter="0" left="2" right="2" top="2" bottom="2">
                        <s:layout>
                            <s:HorizontalLayout/>
                        </s:layout>
                        <s:Label text="{data.lastName}, {data.firstName}"/>
                        <s:Label text="{data.companyID}"/>
                        <s:Label text="{'Renderer localVar = ' + localVar}"/>
                       <s:Label text="{'Application localVar = ' + outerDocument.localVar}"/>
                    </s:Group>
                </s:ItemRenderer>
            </fx:Component>
        </s:itemRenderer>
    </s:SkinnableDataContainer>
</s:Application>
```

Creating a reusable inline item renderer

Rather than defining an inline item renderer in the definition of a component, you can define a reusable inline item renderer for use in multiple locations in your application.

To create a reusable inline item renderer, specify the `className` property of the `<fx:Component>` tag. By naming the class, you define a way to reference the item renderer, and the elements of the item renderer.

The following example uses the `<fx:Component>` tag to define an inline item renderer for two containers:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkDataGroupContainerInlineReuse.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Declarations>
        <fx:Component id="inlineRenderer" className="myIR">
            <s:ItemRenderer>
                <s:Group verticalCenter="0" horizontalCenter="0">
                    <s:layout>
                        <s:HorizontalLayout/>
                    </s:layout>
                    <s:Label text="{data.lastName}, {data.firstName}"/>
                    <s:Label text="{data.companyID}"/>
                </s:Group>
            </s:ItemRenderer>
        </fx:Component>
    </fx:Declarations>
    <s:SkinnableDataContainer itemRenderer="myIR">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <mx:ArrayList>
            <fx:Object firstName="Bill" lastName="Smith" companyID="11233"/>
            <fx:Object firstName="Dave" lastName="Jones" companyID="13455"/>
            <fx:Object firstName="Mary" lastName="Davis" companyID="11543"/>
            <fx:Object firstName="Debbie" lastName="Cooper" companyID="14266"/>
        </mx:ArrayList>
    </s:SkinnableDataContainer>
    <s:SkinnableDataContainer itemRenderer="myIR">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <mx:ArrayList>
            <fx:Object firstName="Jim" lastName="Sullivan" companyID="11233"/>
            <fx:Object firstName="Joan" lastName="Connors" companyID="13455"/>
            <fx:Object firstName="Jack" lastName="Wilson" companyID="11543"/>
            <fx:Object firstName="Jeff" lastName="Lodge" companyID="14266"/>
        </mx:ArrayList>
    </s:SkinnableDataContainer>
</s:Application>
```

In this example, you use data binding to specify the renderer as the value of the `itemRenderer` property for the two containers.

Create a Spark item renderer in ActionScript

To ensure that your application achieves the highest performance, implement item renderers in ActionScript. Typically, you create item renderers in ActionScript only for mobile applications, but you can create them for desktop application as well.

The item renderer typically implements two interfaces:

Item renderer interface	Implemented by	Use
IDataRenderer	Item renderer	Defines the `data` property used to pass information to an item renderer. At a minimum, an item renderer must implement IDataRenderer to display data.
IItemRenderer	Item renderer	Defines the APIs that a component must implement to create an item renderer that can communicate with a host component to support user interaction with the data item. User interactions include selection, dragging, and the caret indicator. For some components, such as the Spark List control, user interaction includes item selection.

Create an ActionScript item renderer in one of the following ways:

- Create an ActionScript subclass from an existing item renderer class, such as spark.components.LabelItemRenderer, spark.components.IconItemRenderer, or spark.components.supportClasses.ItemRenderer. The existing item renderer classes already implement all necessary interfaces.

  For the highest performance in a mobile application, create a subclass of spark.components.LabelItemRenderer. In your subclass, you can control the background display and the layout of the data items.

  If you want to use the built-in Flex layout mechanism, and are not as concerned with performance, create a subclass of spark.components.supportClasses.ItemRenderer.

  For more information, see "Create an ActionScript item renderer as a subclass of the LabelItemRenderer class" on page 497.

  For more information on using LabelItemRenderer and IconItemRenderer, see "Using a mobile item renderer with a Spark list-based control" on page 524.

- Create an ActionScript subclass of the mx.core.UIComponent class.

  By implementing an item renderer as a subclass of the UIComponent class, you can obtain the best performance because you only have to implement the logic necessary to support your application. However, basing an item renderer on UIComponent requires the most effort. To be used as an item renderer, your subclass must implement the mx.core.IDataRenderer and spark.components.IItemRenderer interfaces.

For example implementations of item renderers written in ActionScript, view the source code for the spark.components.LabelItemRenderer, spark.components.IconItemRenderer, and spark.components.supportClasses.ItemRenderer classes.

Creating item renderers in ActionScript

To define an item renderer in ActionScript, override the necessary methods from the parent class, and call any necessary invalidation methods from within your overrides. For general information on this process, see "Create advanced Spark visual components in ActionScript" on page 2451.

The methods that you have to override in your class depend on the parent class of the item renderer. You optionally can override one or more of the following protected methods of the parent class:

Method	Description
`commitProperties()`	Commits any changes to component properties, either to make the changes occur at the same time or to ensure that properties are set in a specific order. For more information, see "Implementing the commitProperties() method for MX components" on page 2483.
`createChildren()`	Creates any child components of the component. For example, the ComboBox control contains a TextInput control and a Button control as child components. For more information, see "Implementing the createChildren() method for MX components" on page 2482.

Method	**Description**
`measure()`	Sets the default size and default minimum size of the component. For more information, see "Implementing the measure() method for MX components" on page 2485.
`styleChanged()`	Detects changes to style properties. For more information, see "Overriding the styleChanged() method" on page 2502.
`updateDisplayList()`	Sizes and positions the children of the component on the screen based on all previous property and style settings, and draws any skins or graphic elements used by the component. The parent container for the component determines the size of the component itself. ***Note:** You typically only have to implement this method when you use the mx.core.UIComponent class as the base class of your item renderer. You do not have to implement it when creating a subclass of the LabelItemRenderer class. Override* `LabelItemRenderer.drawBackground()` *and* `LabelItemRenderer.layoutContent()` *instead.* For more information, see "Implementing the updateDisplayList() method for MX components" on page 2489.

If the parent class is the LabelItemRenderer, you typically override one or both of the following methods:

Method	**Description**
`drawBackground()`	Defines the background display of the item renderer.
`layoutContents()`	Lays out the children of the item renderer.

Flex uses an invalidation mechanism to synchronize modifications to components. Flex implements the invalidation mechanism as a set of methods that you call to signal that something about the component has changed and requires Flex to call the component's `commitProperties()`, `measure()`, or `updateDisplayList()` methods.

The following table describes the invalidation methods:

Invalidation method	**Description**
`invalidateProperties()`	Marks a component so that its `commitProperties()` method gets called during the next screen update.
`invalidateSize()`	Marks a component so that its `measure()` method gets called during the next screen update.
`invalidateDisplayList()`	Marks a component so that its `updateDisplayList()` methods get called during the next screen update.

When a component calls an invalidation method, it signals to Flex that the component must be updated. When multiple components call invalidation methods, Flex coordinates the updates so that they all occur together during the next screen update. For more information on these methods, see "About the invalidation methods for MX components" on page 2476.

Create an ActionScript item renderer as a subclass of the LabelItemRenderer class

The following example shows a view component for a mobile application:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\mobile\views\ListColor.mxml -->
<s:View xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    title="Colors">
    <s:layout>
        <s:VerticalLayout paddingTop="10"/>
    </s:layout>

    <s:Label text="Favorites"/>
    <s:SkinnableDataContainer
        itemRenderer="myComponents.MySimpleColorRenderer">
        <mx:ArrayList>
            <fx:String>red</fx:String>
            <fx:String>green</fx:String>
            <fx:String>blue</fx:String>
        </mx:ArrayList>
    </s:SkinnableDataContainer>
</s:View>
```

In this example, the SkinnableDataContainer contains three data items corresponding to three colors. In this example, you define an item renderer in the file MySimpleColorRenderer.as. Your custom item renderer displays the text of the data item and changes the background color of the data item to match the text.

Because this is a mobile application, for optimal performance create the item renderer as a subclass of the LabelItemRenderer class. This example does not change the way the data item is layed out in the container, only its background color. Therefore, you only override the `LabelItemRenderer.drawBackground()` method, and not the `LabelItemRenderer.layoutContent()` method.

The MySimpleColorRenderer.as item renderer is shown below:

```
package myComponents
{
    // containers\mobile\myComponents\MySimpleColorRenderer .as
    import spark.components.LabelItemRenderer;

    public class MySimpleColorRenderer extends LabelItemRenderer
    {
        public function MySimpleColorRenderer() {
            super();
        }

        // Use the value of the myColor property to draw
        // the background color of the item in the list.
        override protected function drawBackground(unscaledWidth:Number,
unscaledHeight:Number):void {
            // Define a var to hold the color.
            var myColor:uint;
            // Determine the RGB color value from the label property.
            if (data == "red")
                myColor = 0xFF0000;
            if (data == "green")
                myColor = 0x00FF00;
            if (data == "blue")
                myColor = 0x0000FF;
            graphics.beginFill(myColor, 1);
            graphics.drawRect(0, 0, unscaledWidth, unscaledHeight);

        }
    }
}
```

This item renderer accesses the `LabelItemRenderer.data` property in the override of the `drawbackground()` method to determine the background color of the item. The `label` property contains the String value to display in the item renderer.

Override the LabelItemRenderer.layoutComponents() method in an item renderer

By default, the LabelItemRenderer class uses a single spark.components.supportClasses.StyleableTextField control to display a String. The name of the StyleableTextField control in the item renderer is `labelDisplay`.

In the next example, you define an item renderer to display multiple fields of a data item in separate StyleableTextField controls in the item renderer. This example uses the predefined `labelDisplay` control to display the first and last name fields of the data item. It then adds a second StyleableTextField control to display the company ID field.

Shown below is the view component for the mobile application:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\mobile\views\EmployeeMainViewIR.mxml -->
<s:View xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    title="Employees View Main">
    <s:layout>
        <s:VerticalLayout paddingTop="10"/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            public function myLabelFunction(item:Object):String {
                return item.lastName + ', ' + item.firstName;;
            }
        ]]>
    </fx:Script>

    <s:Label text="Select an employee name"/>
    <s:List id="myList"
        width="100%" height="100%"
        itemRenderer="myComponents.MyGroupItemRenderer"
        labelFunction="myLabelFunction">
        <s:ArrayCollection>
            <fx:Object firstName="Bill" lastName="Smith" companyID="11233"/>
            <fx:Object firstName="Dave" lastName="Jones" companyID="13455"/>
            <fx:Object firstName="Mary" lastName="Davis" companyID="11543"/>
            <fx:Object firstName="Debbie" lastName="Cooper" companyID="14266"/>
        </s:ArrayCollection>
    </s:List>
</s:View>
```

The List control uses the `itemRenderer` property to specify the name of the custom item renderer as MyGroupItemRenderer.as. In MyGroupItemRenderer.as, you:

- Define the StyleableTextField control named compLabelDisplay.
- Override the protected `createChildren()` method to create the compLabelDisplay control.
- Override the protected `styleChanged()` method to propagate and style changes to the compLabelDisplay control.
- Override the `data` property to initialize the compLabelDisplay control. The `data` property contains the original Object representing the data item in the List control.
- Override the `measure()` method to calculate the size of the labelDsiplay and compLabelDisplay controls.
- Override the `layoutContents()` method to size and position the labelDisplay and compLabelDisplay controls. The override uses the padding styles to calculate the availale space for the components.

Shown below is the definition of MyGroupItemRenderer, the item renderer:

```
package myComponents
{
    // containers\mobile\myComponents\MyGroupItemRenderer.as
    import spark.components.LabelItemRenderer;
    import spark.components.supportClasses.StyleableTextField;
    public class MyGroupItemRenderer extends LabelItemRenderer
    {
        public function MyGroupItemRenderer(){
            super();
        }

        // Define the StyleableTextField control used
        // to display the company ID.
        public var compLabelDisplay:StyleableTextField;

        // The distance between the label and the company ID.
        public var verticalGap:Number = 10;

        // Override createChildren() to create the StyleableTextField control.
        override protected function createChildren():void {
            super.createChildren();

            // Make sure it does not already exist.
            if (!compLabelDisplay) {
                compLabelDisplay = new StyleableTextField();

                // Specify The object that provides styles for the control.
                // This property must be set for the control to pick up
                // the correct styles.
                compLabelDisplay.styleName = this;

                // Set basic attributes of the control.
                compLabelDisplay.editable = false;
                compLabelDisplay.selectable = false;
                compLabelDisplay.multiline = false;
                compLabelDisplay.wordWrap = false;

                // Add the control as a child of the item renderer.
                addChild(compLabelDisplay);
            }
        }

        // Override styleChanged() to proopgate style changes to compLabelDisplay.
        override public function styleChanged(styleName:String):void {
            super.styleChanged(styleName);

            // Pass any style changes to compLabelDisplay.
            if (compLabelDisplay)
                compLabelDisplay.styleChanged(styleName);
        }

        // Override the data property to initialize compLabelDisplay.
        // The label function in the view specifies the String
        // displayed in labelDisplay.
        override public function set data(value:Object):void {
            super.data = value;
            compLabelDisplay.text = String(value.companyID);
        }

        // Override measure() to calculate the size required by the item renderer.
        override protected function measure():void {
            // Measure the labelDisplay by calling super.measure()
            super.measure();
            // Then consider the compLabelDisplay if it exists.
            if (compLabelDisplay)
            {
             var horizontalPadding:Number = getStyle("paddingLeft") + getStyle("paddingRight");
              var verticalPadding:Number = getStyle("paddingTop") + getStyle("paddingBottom");

                // Commit the styles changes to compLabelDisplay.
                // This method must be called before the text is displayed,
                // and any time the styles have changed.
                // This method does nothing if the styles have already been committed.
                compLabelDisplay.commitStyles();
                measuredWidth =  Math.max(getElementPreferredWidth(labelDisplay),
getElementPreferredWidth(compLabelDisplay))
                measuredWidth += horizontalPadding;

                measuredHeight =  getElementPreferredHeight(labelDisplay);
                measuredHeight += getElementPreferredHeight(compLabelDisplay);
                measuredHeight += verticalPadding + verticalGap;
            }
        }

        // Override layoutContents() to lay out the item renderer.
        override protected function layoutContents(unscaledWidth:Number,
unscaledHeight:Number):void {
            // Because you are handling the layout of both the
            // predefined labelDisplay component and the new
            // compLabelDisplay component, you do not have to call
            // super.layoutContents().

            // Make sure labelDisplay and compLabelDisplay exist.
            if (!labelDisplay)
                return;
            if (!compLabelDisplay)
                return;

            // Get the padding from the associated styles.
            var paddingLeft:Number = getStyle("paddingLeft");
            var paddingRight:Number = getStyle("paddingRight");
            var paddingTop:Number = getStyle("paddingTop");
            var paddingBottom:Number = getStyle("paddingBottom");

            // Calculate the available space for the component.
            var viewWidth:Number  = unscaledWidth - paddingLeft - paddingRight;
            var viewHeight:Number = unscaledHeight - paddingTop - paddingBottom;

            // Calcualte the size of the labelDisplay component.
            var labelWidth:Number = Math.max(viewWidth, 0);
            var labelHeight:Number = 0;

            if (label != "") {
                labelDisplay.commitStyles();

                // Reset text if it was truncated before.
                if (labelDisplay.isTruncated)
                    labelDisplay.text = label;

                labelHeight = getElementPreferredHeight(labelDisplay);
            }

            // Set the size and position of the labelDisplay component.
            setElementSize(labelDisplay, labelWidth, labelHeight);
            setElementPosition(labelDisplay, paddingLeft, paddingTop);

            // Attempt to truncate the text now that we have its official width
            labelDisplay.truncateToFit();

            // Size and position the compLabelDisplay component.
            var compLabelWidth:Number = Math.max(viewWidth, 0);
            var compLabelHeight:Number = 0;

            compLabelDisplay.commitStyles();
            compLabelHeight = getElementPreferredHeight(compLabelDisplay);

            setElementSize(compLabelDisplay, compLabelWidth, compLabelHeight);
            setElementPosition(compLabelDisplay, paddingLeft, paddingTop + labelHeight + 
verticalGap);
        }
    }
}
```

Using a Spark item renderer with an MX control

Many MX list-based controls, such as the DataGrid, AdvancedDataGrid, and Tree, support item renderers. These three MX list-based controls also support item editors. Item editors let you create a custom view of data during the editing process. The item editor returns the new data back to the control so that the control can update its data provider.

Flash Builder has built-in support for creating Spark item renderers. To support the use of Flash Builder for creating item editors and item editors for MX controls, Flex defines the mx.controls.listClasses.MXItemRenderer class as a subclass of the Spark spark.components.supportClasses.ItemRenderer class. You can use the MXItemRenderer class to create item renderers and item editors for the MX DataGrid and Tree classes.

***Note:** Many MX controls, such as the MX List and MX TileList controls, support item renderers or item editors. However, Flex provides the Spark List and Spark TileLayout class as replacements for the MX List and MX TileList controls. Always use the Spark components, when possible, in your application. There is no Spark equivalent for the MX DataGrid, MX AdvancedDataGrid, and MX Tree controls. Therefore, only those MX controls support the MXItemRenderer class.*

About MX item renderers and item editors

The MXItemRenderer class simplifies the development of item renderers and editors in Flash Builder. By basing item renderers and item editors on the MXItemRenderer class, your MX controls can take advantage of all of the features of the ItemRenderer class, including Flash Builder support.

All of the functionality of MX item renderers and item editors is supported by the MXItemRenderer class. Therefore, you should be familiar with the architecture of MX item renderers and editors before you create them based on the MXItemRenderer class.

See the following documentation for basic information on MX item renderers:

- “About MX item renderers” on page 1006
- “Creating MX item renderers and item editor components” on page 1033
- “About the MX cell editing process” on page 1048
- “About the MX cell editing process” on page 1048
- “Using item renderers with the AdvancedDataGrid control” on page 1442
- “Returning data from an MX item editor” on page 1049
- “Using MX cell editing events” on page 1057
- “MX item editor examples” on page 1062

Using the MXItemRenderer class

You base a Spark item renderer or item editor for an MX control on the MXItemRenderer class. While you can base an item renderer or editor on the MXItemRenderer class itself, you typically create them based on one of the following subclasses of MXItemRenderer:

- MXDataGridItemRenderer   The base class for a Spark item renderer or editor for the MX DataGrid control.
- MXAdvancedDataGridItemRenderer   The base class for a Spark item renderer or editor for the MX AdvancedDataGrid control.
- MXTreeItemRenderer   The base class for a Spark item renderer or editor for the MX Tree control.

Creating a Spark item renderer for an MX DataGrid control

The following application shows an MX DataGrid control that uses a custom item renderer:

```
<?xml version="1.0"?>
<!-- itemRenderers\sparkmx\SparkMainDGImageRenderer.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    width="650">

    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;

            [Bindable]
            private var initDG:ArrayCollection = new ArrayCollection([
                {Artist:'Pavement', Album:'Slanted and Enchanted',
                    Price:11.99, Cover: '../assets/slanted.jpg'},
                {Artist:'Pavement', Album:'Brighten the Corners',
                    Price:11.99, Cover: '../assets/brighten.jpg'}
            ]);
        ]]>
    </fx:Script>
    <mx:DataGrid id="myGrid" height="400" width="600"
        dataProvider="{initDG}">
        <mx:columns>
            <mx:DataGridColumn dataField="Artist"/>
            <mx:DataGridColumn dataField="Album"/>
            <mx:DataGridColumn dataField="Cover"
                itemRenderer="myComponents.RendererDGImage"/>
            <mx:DataGridColumn dataField="Price"/>
        </mx:columns>
    </mx:DataGrid>
</s:Application>
```

In this example, you use the custom item renderer to display the album cover for each album listed in the DataGrid control. The Cover field of the data provider of the DataGrid contains the path to the JPG file for the cover.

Shown below is the definition of the RendererDGImage.mxml file that defines the item renderer:

```
<?xml version="1.0"?>
<!-- itemRenderers\sparkmx\myComponents\RendererDGImage.mxml -->
<s:MXDataGridItemRenderer xmlns:fx="http://ns.adobe.com/mxml/2009"
        xmlns:s="library://ns.adobe.com/flex/spark"
        xmlns:mx="library://ns.adobe.com/flex/mx">
        <mx:Image id="albumImage" height="175" source="{data.Cover}"/>
</s:MXDataGridItemRenderer>
```

Notice that this item renderer is based on the MXDataGridItemRenderer class. The item renderer uses the Image control to display the album cover.

The next example also displays the album name and cover image, but uses a single column of the DataGrid to display both fields:

```
<?xml version="1.0"?>
<!-- itemRenderers\sparkm\SparkMainDGTitleRenderer.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    width="650">

    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;

            [Bindable]
            private var initDG:ArrayCollection = new ArrayCollection([
                {Artist:'Pavement', Album:'Slanted and Enchanted',
                    Price:11.99, Cover: '../../assets/slanted.jpg'},
                {Artist:'Pavement', Album:'Brighten the Corners',
                    Price:11.99, Cover: '../../assets/brighten.jpg'}
            ]);
        ]]>
    </fx:Script>
    <mx:DataGrid id="myGrid" width="600"
        dataProvider="{initDG}"
        variableRowHeight="true">
        <mx:columns>
            <mx:DataGridColumn dataField="Artist" />
            <mx:DataGridColumn dataField="Album"
                itemRenderer="myComponents.RendererDGTitleImage" />
            <mx:DataGridColumn dataField="Price"  />
        </mx:columns>
    </mx:DataGrid>
</s:Application>
```

The RendererDGTitleImage.mxml file implements the render. It uses a Spark Label control and the MX Image control to display the album name and cover image in a single cell:

```
<?xml version="1.0"?>
<!-- itemRenderers\sparkmx\myComponents\RendererDGTitleImage.mxml -->
<s:MXDataGridItemRenderer xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:HorizontalLayout verticalAlign="middle"
            paddingLeft="5" paddingRight="5"/>
    </s:layout>
    <s:Label id="albumName"
        width="100%"
        text="{data.Album}"/>
    <mx:Image id="albumImage"
        source="{data.Cover}"/>
</s:MXDataGridItemRenderer>
```

Creating a Spark item renderer for an MX AdvancedDataGrid control

The following application uses the AdvancedDataGrid control:

```
<?xml version="1.0"?>
<!-- itemrenderers/sparkmx/SparkHierarchicalADGSimpleRenderer.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
              import mx.collections.ArrayCollection;

              include "SimpleHierarchicalData.as";
        ]]>
    </fx:Script>
    <mx:AdvancedDataGrid width="100%" height="100%">
        <mx:dataProvider>
            <mx:HierarchicalData source="{dpHierarchy}"/>
        </mx:dataProvider>
        <mx:columns>
            <mx:AdvancedDataGridColumn dataField="Region"/>
            <mx:AdvancedDataGridColumn dataField="Territory_Rep"
                headerText="Territory Rep"/>
            <mx:AdvancedDataGridColumn dataField="Actual"/>
            <mx:AdvancedDataGridColumn dataField="Estimate"/>
            <mx:AdvancedDataGridColumn id="diffCol"
                headerText="Difference"/>
        </mx:columns>
        <mx:rendererProviders>
            <mx:AdvancedDataGridRendererProvider column="{diffCol}"
                depth="3" renderer="myComponents.SummaryRenderer"/>
        </mx:rendererProviders>
    </mx:AdvancedDataGrid>
</s:Application>
```

This application uses the custom item renderer defined in the file SummaryRenderer.mxml to display the value of the Difference column. The value is determined by the difference between the Estimate and Actual columns. If the territory representative exceeded sales estimate, the cell appears in green. If the territory representative did not exceed the estimate, the cell appears in red.

The SummaryRenderer.mxml also includes a CurrencyFormatter to format the value in dollars. The SummaryRenderer.mxml is shown below:

```
<?xml version="1.0"?>
<!-- itemrenderers/sparkmx/myComponents/SummaryRenderer.mxml -->
<s:MXAdvancedDataGridItemRenderer xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    textAlign="center">

    <fx:Script>
        <![CDATA[
            override public function set data(value:Object):void
            {
                // Calculate the difference.
                var diff:Number =
                    Number(value["Actual"]) - Number(value["Estimate"]);
                if (diff < 0)
                {
                    // If Estimate was greater than Actual,
                    // display results in red.
                    setStyle("color", "red");
                    myLabel.text = "Undersold by " + usdFormatter.format(diff);
                }
                else
                {
                    // If Estimate was less than Actual,
                    // display results in green.
                    setStyle("color", "green");
                    myLabel.text = "Exceeded estimate by " + usdFormatter.format(diff);
                }
            }
        ]]>
    </fx:Script>
    <fx:Declarations>
        <mx:CurrencyFormatter id="usdFormatter" precision="2"
            currencySymbol="$" decimalSeparatorFrom="."
            decimalSeparatorTo="." useNegativeSign="true"
            useThousandsSeparator="true" alignSymbol="left"/>
    </fx:Declarations>
    <s:Label id="myLabel"/>
</s:MXAdvancedDataGridItemRenderer>
```

Creating a Spark item renderer for an MX Tree control

The following application uses an MX Tree control to display XML data:

```
<?xml version="1.0" encoding="iso-8859-1"?>
<!-- itemRenderers\tree\SparkMainTreeItemRenderer.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    initialize="initCollections();">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[

            import mx.collections.*;

            public var xmlBalanced:XMLList =
                <>
                    <node label="Containers">
                        <node label="DividedBoxClasses">
                            <node label="BoxDivider" data="BoxDivider.as"/>
                        </node>
                        <node label="GridClasses">
                            <node label="GridRow" data="GridRow.as"/>
                            <node label="GridItem" data="GridItem.as"/>
                            <node label="Other File" data="Other.as"/>
                        </node>
                    </node>
                    <node label="Data">
                        <node label="Messages">
                            <node label="DataMessage"
                                data="DataMessage.as"/>
                            <node label="SequenceMessage"
                                data="SequenceMessage.as"/>
                        </node>
                        <node label="Events">
                            <node label="ConflictEvents"
                                data="ConflictEvent.as"/>
                            <node label="CommitFaultEvent"
                                data="CommitFaultEvent.as"/>
                        </node>
                    </node>
                </>;

            [Bindable]
            public var xlcBalanced:XMLListCollection;

            private function initCollections():void {
                xlcBalanced = new XMLListCollection(xmlBalanced);
            }
        ]]>
    </fx:Script>
    <mx:Text width="400"
        text="The nodes with children are in bold red text, with the number of children in 
parenthesis.)"/>
    <mx:Tree id="compBalanced"
        width="400" height="500"
        dataProvider="{xlcBalanced}"
        labelField="@label"
        itemRenderer="myComponents.MyTreeItemRenderer"/>
</s:Application>
```

This application uses the item renderer defined by the MyTreeItemRenderer.mxml file to display the parent nodes in a red, bold font. It also shows the number of child nodes for each parent in parenthesis. Shown below is the definition of MyTreeItemRenderer.mxml:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- itemRenderers\sparkmx\myComponents\MyTreeItemRenderer.mxml -->
<s:MXTreeItemRenderer xmlns:fx="http://ns.adobe.com/mxml/2009" 
    xmlns:s="library://ns.adobe.com/flex/spark" 
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Script>
        <![CDATA[
            import mx.controls.treeClasses.*;
            import mx.collections.*;

            // Override the set method for the data property
            // to set the font color and style of each node.
            override public function set data(value:Object):void {
                super.data = value;
                if(treeListData.hasChildren)
                {
                    setStyle("color", 0xff0000);
                    setStyle("fontWeight", 'bold');
                    var tmp:XMLList = 
                        new XMLList(treeListData.item);
                    var myStr:int = tmp[0].children().length();
                    labelDisplay.text =  treeListData.label + 
                        "(" + myStr + ")";
                }
                else
                {
                    setStyle("color", 0x000000);
                    setStyle("fontWeight", 'normal');
                    labelDisplay.text =  treeListData.label;
                }
            }
        ]]>
    </fx:Script>

    <s:HGroup left="0" right="0" verticalCenter="0">
        <s:Rect id="indentationSpacer"
            width="{treeListData.indent}" height="22"
            alpha="0">
            <s:fill>
                <s:SolidColor color="0xFFFFFF" />
            </s:fill>
        </s:Rect>
        <s:Group id="disclosureGroup">
            <s:BitmapImage source="{treeListData.disclosureIcon}"
                width="16" height="16"
                visible="{treeListData.hasChildren}" />
        </s:Group>
        <s:BitmapImage source="{treeListData.icon}"
            width="16" height="16"/>
        <s:Label id="labelDisplay" />
    </s:HGroup>
</s:MXTreeItemRenderer>
```

The item renderer uses the `treeListData` property of the MXTreeItemRenderer class to determine the information about the tree node. The `treeListData` property is of type TreeListData. TreeListData defines information such as the depth of the node in the tree, any icon associated with the node, and the data object of the node from the tree's data provider.

This item renderer overrides the `ItemRenderer.data` property to control the display of the tree nodes. The override first determines if the node is a parent node and, if so, sets the text display to use a bold, red font. It then adds the number of children to the display of the node.

The second part of the item renderer defines the appearance of the node in the Tree control. In this example, you use a Rect control to define a white background for the node. The item renderer uses two BitmapImage controls to define the appearance of any icons. The Label control defines the appearance of the text displayed by the node.

Creating a Spark item editor for an MX DataGrid control

An MX DataGrid, AdvancedDataGrid, or Tree control displays an item editor when the `editable` property of the control is set to `true`. The item editor appears when the user releases the mouse button while over a cell, tabs to the cell, or in another way attempts to edit the cell. By default, the `editable` property is `false`.

When creating an item editor for an MX DataGrid or Tree control, the item editor usually returns a single value corresponding to the new value in the control's data provider. For example, the following item renderer returns a single value named myRetValue:

```
<?xml version="1.0"?>
<!-- itemRenderers\sparkmx\myComponents\NSEditor.mxml -->
<s:MXDataGridItemRenderer xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Script>
        <![CDATA[
            public var myRetVal:int = 0;
        ]]>
    </fx:Script>

    <!-- Use the valueCommit event when the user selects the
         cell but does not change the value. -->
    <s:NumericStepper id="myNS"
        value="{data.quant}"
        stepSize="1"
        maximum="50"
        change="myRetVal=myNS.value;"
        valueCommit="myRetVal=myNS.value;"/>
</s:MXDataGridItemRenderer>
```

This item editor contains a single NumericStepper control. When the item editor is open, the NumericStepper appears in the DataGrid control. The user can then use the NumericStepper to edit the value of the cell.

The user ends the editing session by removing focus from the cell. Flex then commits the new value in the DataGrid control. The following application uses this item editor:

```
<?xml version="1.0"?>
<!-- itemRenderers\sparkmx\SparkMainNSEditor.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;

            [Bindable]
            private var myDP:ArrayCollection = new ArrayCollection([
                {label1:"Order #2314", quant:3, Sent:true},
                {label1:"Order #2315", quant:3, Sent:false}
            ]);
        ]]>
    </fx:Script>
    <mx:DataGrid id="myDG" dataProvider="{myDP}"
            variableRowHeight="true"
            editable="true" >
        <mx:columns>
            <mx:DataGridColumn dataField="label1"
                headerText="Order #"/>
            <mx:DataGridColumn dataField="quant"
                itemEditor="myComponents.NSEditor"
                editorDataField="myRetVal"/>
        </mx:columns >
    </mx:DataGrid>
</s:Application>
```

Notice in the main application that the DataGridColumn uses the `itemEditor` property to specify the name of the item editor. It uses the `editorDataField` property to specify the name of the property of the item editor that contains the return value.

Creating an inline Spark item editor for an MX DataGrid control

An MX DataGrid, AdvancedDataGrid, or Tree control can use an inline item renderer or editor. The following example uses a Spark DropDownList control as the item editor for a column of an MX DataGrid control:

```
<?xml version="1.0"?>
<!-- itemRenderers\sparkmx\SparkDGInlineRenderer.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    width="650">

    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;

            [Bindable]
            private var initDG:ArrayCollection = new ArrayCollection([
                {Artist:'Pavement', Album:'Slanted and Enchanted',
                    Price:11.99, Cover: '../assets/slanted.jpg', Rating:'none'},
                {Artist:'Pavement', Album:'Brighten the Corners',
                    Price:11.99, Cover: '../assets/brighten.jpg', Rating:'none'}
            ]);
        ]]>
    </fx:Script>
    <mx:DataGrid id="myGrid" height="400" width="600"
        dataProvider="{initDG}" editable="true">
        <mx:columns>
            <mx:DataGridColumn dataField="Artist"/>
            <mx:DataGridColumn dataField="Album"/>
            <mx:DataGridColumn dataField="Rating" editorDataField="rating">
                <mx:itemEditor>
                    <fx:Component>
                        <s:MXDataGridItemRenderer focusEnabled="true" height="22" >
                            <fx:Script>
                                <![CDATA[
                                    import mx.collections.ArrayList;
                                    public function get rating():String {
                                        return  dd.selectedItem;
                                    }
                                ]]>
                            </fx:Script>
                            <s:DropDownList id="dd" top="5" left="5"
                                selectedItem="{data.Rating}"
                                initialize="dd.dataProvider =
                                    new ArrayList(['none', 'no good', 'good', 'great'])"/>
                        </s:MXDataGridItemRenderer>
                    </fx:Component>
                </mx:itemEditor>
            </mx:DataGridColumn>
            <mx:DataGridColumn dataField="Cover"
                itemRenderer="myComponents.RendererDGImage"/>
            <mx:DataGridColumn dataField="Price"/>
        </mx:columns>
    </mx:DataGrid>
</s:Application>
```

This example adds a Rating column to the DataGrid. The user clicks in a cell of the Rating column to open the item editor. When the user removes focus from the cell, the value of the DropDownList is copied to the data provider of the DataGrid.

Spark list-based controls

The Spark list-based controls are designed to display data items in different visual formats and layouts.

Using Spark list-based controls

The Spark list-based controls include the following:

- ButtonBar
- ComboBox
- DataGrid
- DropDownList
- List
- TabBar

The Spark list-based controls are all subclasses of the SkinnableDataContainer and ListBase classes. The SkinnableDataContainer class is designed to display data items by using item renderers. Data items can be simple data types, such as String and Number objects, or more complex data types such as Object and XMLNode objects.

The ListBase class is a subclass of the SkinnableDataContainer class. The ListBase class adds support for item selection in the list of data items, and for controlling the text displayed in the list. The ButtonBar, ComboBox, DropDownList, List, and TabBar controls add additional functionality to the ListBase class.

For more information on SkinnableDataContainer, and on creating item renderers, see “The Spark DataGroup and Spark SkinnableDataContainer containers” on page 466.

"Sorting and matching" on page 2062

Defining the children of a list-based control

The list-based controls are examples of data provider components. Data provider components require data for display or user interaction. To provide data, assign a collection which implements the IList interface, such as an ArrayList, ArrayCollection, or XMLListCollection object, to the control's `dataProvider` property. For more information on using data providers, see "Data providers and collections" on page 898.

Data items can be simple data items such as String and Number objects, and more complicated data items such as Object and XMLNode objects. The following example shows a List control that displays data items represented by String data:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- dpcontrols\sparkdpcontrols\SparkListSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:List>
        <s:dataProvider>
            <mx:ArrayCollection>
                <fx:String>Flash</fx:String>
                <fx:String>Director</fx:String>
                <fx:String>Dreamweaver</fx:String>
                <fx:String>ColdFusion</fx:String>
            </mx:ArrayCollection>
         </s:dataProvider>
    </s:List>
</s:Application>
```

For simple data items, such as Strings and Numbers, the controls display the entire data item as a String. For more complicated data items, such as Objects, you can control the text displayed in the control based on the data item. For more information, see "Controlling the text displayed for each data item" on page 516.

Because `dataProvider` is the default property of the list-based controls, you do not have to specify a `<s:dataProvider>` child tag. Therefore, you can write the example as shown below:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- dpcontrols\sparkdpcontrols\SparkListSimpleNoDP.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:List>
        <mx:ArrayCollection>
            <fx:String>Flash</fx:String>
            <fx:String>Director</fx:String>
            <fx:String>Dreamweaver</fx:String>
            <fx:String>ColdFusion</fx:String>
        </mx:ArrayCollection>
    </s:List>
</s:Application>
```

Controlling the text displayed for each data item

The following example shows a List control where each data item is represented by an Object with three fields:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- dpcontrols\sparkdpcontrols\SparkListSimpleObjects.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:List id="myList"
        labelField="firstName">
        <mx:ArrayCollection>
            <fx:Object firstName="Bill" lastName="Smith" companyID="11233"/>
            <fx:Object firstName="Dave" lastName="Jones" companyID="13455"/>
            <fx:Object firstName="Mary" lastName="Davis" companyID="11543"/>
            <fx:Object firstName="Debbie" lastName="Cooper" companyID="14266"/>
        </mx:ArrayCollection>
    </s:List>
</s:Application>
```

When the data items contains multiple fields, you must configure the control to display the correct String. In the previous example, you use the `labelField` property to specify to display the firstName field in the control.

You can use several different mechanisms for controlling the String displayed by the control:

- Use the `labelFunction` property

  The `labelFunction` property lets you define a function that returns a String for display by the control. By default, the `labelFunction` property takes precedence over the `labelField` property.

- Use the `labelField` property

  The `labelField` property specifies the field of the data item to display in the control.

- Override the `itemToLabel()` method

  Override the `itemToLabel()` method to convert the data item to a String that is then passed to an item renderer. This method is defined on the SkinnableDataContainer class.

By default, `itemToLabel()` prioritizes `labelFunction` over `labelField`. If you override `itemToLabel()`, you can implement it however you like. Your implementation can then choose to use or ignore `labelField` and `labelFunction`. For an example that overrides this method, see "Passing data using the IItemRenderer.label property" on page 476.

When you use the `labelFunction` property, you define a function that calculates the String to display. Typically, the String is derived from the fields of the data item. The label function must have the following signature:

```
labelFunction(item:Object):String
```

The *`item`* parameter contains the data item. The function must return a String.

The following example uses a label function to concatenate the firstName and lastName fields of each data item for display by the control:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- dpcontrols\sparkdpcontrols\SparkListSimpleObjectsLF.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            public function myLabelFunc(item:Object):String {
                return item.firstName + " " + item.lastName;
            }
        ]]>
    </fx:Script>
    <s:List id="myList"
        labelFunction="myLabelFunc">
        <mx:ArrayCollection>
            <fx:Object firstName="Bill" lastName="Smith" companyID="11233"/>
            <fx:Object firstName="Dave" lastName="Jones" companyID="13455"/>
            <fx:Object firstName="Mary" lastName="Davis" companyID="11543"/>
            <fx:Object firstName="Debbie" lastName="Cooper" companyID="14266"/>
        </mx:ArrayCollection>
    </s:List>
</s:Application>
```

Modifying the children of a list-based control

A list-based control creates list items based on the value of its `dataProvider` property. Typically, the control creates one list item for each data item. For example, the List control creates one list item for each data item, and the ButtonBar control creates one button for each data item.

Use the `addItem()` and `removeItem()` methods to manipulate the `dataProvider` property. A ButtonBar control automatically adds or removes children based on changes to the `dataProvider` property, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- dpcontrols\sparkdpcontrols\SparkBBarSimpleModDP.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            // Add data item, and button, to the ButtonBar.
            private function addFlexToDP():void {
                myBB.dataProvider.addItem("Flex");
                addFlex.enabled=false;
                removeFlex.enabled=true;
            }
            // Remove data item, and button, from the ButtonBar.
            private function removeFlexToDP():void {
                myBB.dataProvider.removeItemAt(4);
                addFlex.enabled=true;
                removeFlex.enabled=false;
            }
        ]]>
    </fx:Script>
    <s:ButtonBar id="myBB">
        <mx:ArrayCollection>
            <fx:String>Flash</fx:String>
            <fx:String>Director</fx:String>
            <fx:String>Dreamweaver</fx:String>
            <fx:String>ColdFusion</fx:String>
        </mx:ArrayCollection>
    </s:ButtonBar>

    <s:Button id="addFlex" label="Add Flex"
        click="addFlexToDP();"/>
    <s:Button id="removeFlex" label="Remove Flex"
        enabled="false"
        click="removeFlexToDP();"/>
</s:Application>
```

Setting the layout

The list-based controls support the `layout` property to let you control the layout of the data items. For example, the default layout of the List control is VerticalLayout. You can use any of the Flex layout classes with the list-based controls, and any custom layouts that you create.

***Note:** The Spark list-based controls do not support the BasicLayout class. Do not use BasicLayout with the Spark list-based controls.*

The following example overrides that layout to use TileLayout:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- dpcontrols\sparkdpcontrols\SparkListLayout.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <s:List width="200">
        <s:layout>
            <s:TileLayout/>
        </s:layout>
        <mx:ArrayCollection>
            <fx:String>Flex</fx:String>
            <fx:String>Flash Builder</fx:String>
            <fx:String>Flash</fx:String>
            <fx:String>Director</fx:String>
            <fx:String>Dreamweaver</fx:String>
            <fx:String>ColdFusion</fx:String>
            <fx:String>Illustrator</fx:String>
        </mx:ArrayCollection>
    </s:List>
</s:Application>
```

For more information on Spark layouts, see “About Spark layouts” on page 420.

Working with list events

The list-based classes all support the following events:

- `caretChange` Dispatched after the focus has changed from one data item to another. For more information, see “Working with the caret item” on page 521.
- `change` Dispatched after the currently selected data item changes to another data item. This event is dispatched when the user interacts with the control.

  When you change the value of the `selectedIndex` or `selectedItem` properties programmatically, the control does not dispatch the `change` event. It dispatches the `valueCommit` event instead.

  For more information, see “Working with the selected item” on page 519.
- `changing` Dispatched before the currently selected data item changes. This event is dispatched when the user interacts with the control.

  Calling the `preventDefault()` method in the event handler prevents the selection from changing. This event is useful when you want to perform processing on the currently selected item before selection moves to a new data item, or to prevent an item from being selected.

  When you change the value of the `selectedIndex` or `selectedItem` properties programmatically, it does not dispatch the `changing` event. It dispatches the `valueCommit` event instead.

The event object for all events is spark.events.IndexChangeEvent.

Working with the selected item

The ListBase class adds support for item selection in the list of data items, and for controlling the text displayed in the list. Several properties of the ListBase class handle the selection of a data item in the control. These properties include the following:

- `requireSelection` Specifies that a data item must always be selected. The default is `false`. If `true`, then the first data item is selected by default until the user selects a list item, or until you set the `selectedIndex` property.

- `selectedIndex` The index of the currently selected data item. The index of items in the list-based controls is zero-based, which means that values are 0, 1, 2, ... , *n* - 1, where *n* is the total number of items. If `requireSelection` is `false`, you can also set `selectedIndex` to -1 to deselect all data items.
- `selectedItem` The object from the data provider corresponding to the currently selected data item.

You often use these properties in event handlers, as the following example shows for the `change` event. In this example, the List control displays the firstName field of each data item. When you select a data item in the control, the event handler for the `change` event displays the index and the lastName field of the data item in TextArea controls.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- dpcontrols\sparkdpcontrols\SparkListSelected.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    height="450">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            import spark.events.IndexChangeEvent;
            protected function selectionChangedHandler(event:IndexChangeEvent):void
            {
                var currentIndx:int = event.currentTarget.selectedIndex;
                var currentDataItem:Object = event.currentTarget.selectedItem;
                selIndex.text = String(currentIndx);
                selLName.text = String(currentDataItem.lastName);
            }
        ]]>
    </fx:Script>

    <s:List id="myList"
        labelField="firstName"
        change="selectionChangedHandler(event)">
        <mx:ArrayCollection>
            <fx:Object firstName="Bill" lastName="Smith" companyID="11233"/>
            <fx:Object firstName="Dave" lastName="Jones" companyID="13455"/>
            <fx:Object firstName="Mary" lastName="Davis" companyID="11543"/>
            <fx:Object firstName="Debbie" lastName="Cooper" companyID="14266"/>
        </mx:ArrayCollection>
    </s:List>

    <s:Label text="Selected index:"/>
    <s:TextArea id="selIndex" height="50"/>
    <s:Label text="Selected Last Name:"/>
    <s:TextArea id="selLName" height="50"/>

</s:Application>
```

The `currentTarget` property of the object passed to the event handler contains a reference to the List control. Therefore, the `currentTarget.selectedIndex` field contains the index of the selected item, and the `currentTarget.selectedItem` field contains a copy of the selected item.

Working with the caret item

The selected item is the item in the control selected by clicking on the item, or by using the arrow keys. For more information about determining the selected item, see "Working with the selected item" on page 519.

The caret item is the data item that currently has focus. The caret item can be the currently selected data item, or it can be a different item.

You use the `caretIndex` property to determine the index of the data item that currently has focus. The index is zero-based, which means that values are 0, 1, 2, ... , *n* - 1, where *n* is the total number of items.

The following example displays the `selectedIndex` and the `caretIndex` properties for a List control:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- dpcontrols\sparkdpcontrols\SparkListCaret.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout paddingTop="5" paddingLeft="5"/>
    </s:layout>
    <s:Label text="The selected item is: {myList.selectedIndex}" />
    <s:Label text="The caret item is: {myList.caretIndex}" />
    <s:List id="myList">
        <s:dataProvider>
            <s:ArrayCollection>
                <fx:String>One</fx:String>
                <fx:String>Two</fx:String>
                <fx:String>Three</fx:String>
                <fx:String>Four</fx:String>
                <fx:String>Five</fx:String>
                <fx:String>Six</fx:String>
                <fx:String>Seven</fx:String>
                <fx:String>Eight</fx:String>
                <fx:String>Nine</fx:String>
                <fx:String>Ten</fx:String>
            </s:ArrayCollection>
        </s:dataProvider>
    </s:List>
</s:Application>
```

To see the difference between the `selectedIndex` and the `caretIndex` properties:

1 Select an item in the List control by clicking on it. Notice that because the item is both selected and in focus that the `selectedIndex` and the `caretIndex` properties have the same value.

2 Use the Up Arrow and Down Arrow keys to move the selected item. Notice that because the item is both selected and in focus that the `selectedIndex` and the `caretIndex` properties have the same value.

3 With an item selected:

- (On Windows) Hold down the Control key, and then use the Up Arrow and Down Arrow keys to move the caret index.
- (On OSX) Hold down the Command key, and then use the Up Arrow and Down Arrow keys to move the caret index.

Notice that the List control displays a blue box around the data item at the caret index, but the index of the selected item does not change. The data item at the caret index has focus, but is not selected. Press the Space key to select the data item at the caret index.

The list-based controls dispatch the `caretChange` event when the caret item changes.

Working with item renderers

Because the list-based classes are subclasses of the SkinnableDataContainer class, they require an item renderer to display the data items. The SkinnableDataContainer class does not define a default item renderer. However, the list-based classes all define a default item render as the following table shows:

Control	**Default item renderer**
ButtonBar	ButtonBarButton
ComboBox	DefaultItemRenderer
DropDownList	DefaultItemRenderer
List	DefaultItemRenderer
TabBar	ButtonBarButton with TabBarButtonSkin as the skin

You can override the default item renderer. For more information, see "Using an item renderer function with a Spark container" on page 481.

Using virtualization with list-based controls

A list-based control can represent any number of children. However, each child requires an instance of an item renderer. If the container has many children, you can notice performance degradation as you add more children to the container.

Instead of creating an item renderer for each child, you can use the `useVirtualLayout` property to configure the control to use a virtual layout. With virtual layout enabled, the control reuses item renderers so that it only creates item renderers for the currently visible children of the container. As a child is moved off the screen, possible by scrolling the container, a new child being scrolled onto the screen can reuse its item renderer.

The layout class associated with a component determines if the component supports virtual layout. Typically, you use the component's skin class to specify the layout class. By default, the skins for the Spark list-based classes have the `useVirtualLayout` property to `true` to enable virtual layout.

However, the default skins of some components use layouts that do not support the `useVirtualLayout` property. The TabBar and ButtonBar components use the ButtonBarHorizontalLayout which does not support the `useVirtualLayout` property or virtual layout.

For more information on virtualization, see "Using virtualization with Spark DataGroup and SkinnableDataContainer" on page 469.

Supporting view states in an item renderer for a list-based control

The Spark list-based controls support view states that you can use in a custom item renderer. Support for these view states is not required. If the host component attempts to set the item renderer to a view state that is not defined in the renderer, then the item renderer uses the normal view state.

Flex defines the following view states for item renderers.

- normal   The data item has no user interaction.
- hovered   The mouse is over the data item.
- selected   The data item is selected.
- dragging   The data item is being dragged.

- normalAndShowCaret The data item is in the normal state, and it has focus in the item list.
- hoveredAndShowCaret The data item is in the hovered state, and it has focus in the item list.
- selectedAndShowCaret The data item is in the selected state, and it has focus in the item list.

The default item renderers, including DefaultItemRenderer and DefaultComplexItemRenderer, support all of these view states.

The list-based controls add the ability to select a data item. Therefore, one of the view states corresponds to the data item being selected. The item renderer can use the selected view state to modify the appearance of the item when selected.

Several view states are associated with the caret index. The caret index identifies the data item that has focus. That item does not have to be the selected item,

The following example shows a simple item renderer for the List class that supports the selected view state. In this example, the item renderer shows the selected item in red with a black border:

```
<?xml version="1.0" encoding="utf-8"?>
<s:ItemRenderer xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[

            override public function set label(value:String):void {
                super.label = value;
                labelDisplay.text = label;
            }
        ]]>
    </fx:Script>
    <s:states>
        <s:State name="normal"/>
        <s:State name="hovered"/>
        <s:State name="selected"/>
    </s:states>

    <s:Rect left="0" right="0" top="0" bottom="0">
        <s:stroke.selected>
            <s:SolidColorStroke
                color="0x000000"
                weight="1"/>
        </s:stroke.selected>
        <s:fill>
            <s:SolidColor
                color.normal="0xFFFFFF"
                color.hovered="0xCEDBEF"
                color.selected="0x00FF00"/>
        </s:fill>
    </s:Rect>
    <s:Label id="labelDisplay"
        fontWeight.selected="bold"
        verticalCenter="0"
        left="3" right="3"
        top="6" bottom="4"/>
</s:ItemRenderer>
```

This item renderer does not define all possible view states. If the host component attempts to set it to any undefined view state, the item renderer uses the normal state.

The following application uses this item renderer:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- dpcontrols\sparkdpcontrols\SparkListIR.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:List itemRenderer="myComponents.ListSelectedIR">
        <s:dataProvider>
            <mx:ArrayCollection>
                <fx:String>Flash</fx:String>
                <fx:String>Director</fx:String>
                <fx:String>Dreamweaver</fx:String>
                <fx:String>ColdFusion</fx:String>
            </mx:ArrayCollection>
         </s:dataProvider>
    </s:List>
</s:Application>
```

Using a mobile item renderer with a Spark list-based control

Flex provides two item renderers that you can use with Spark list-based controls in mobile applications. These item renderers, spark.components.LabelItemRenderer and spark.components.IconItemRenderer, are written in ActionScript to provide the highest level of performance required by mobile applications.

The default theme for mobile applications built in Flex is the Mobile theme. When you use the Mobile theme, Flex automatically uses the LabelItemRenderer for the Flex list-based controls. Like the DefaultItemRenderer, the LabelItemRenderer displays a single text field for each data item.

You can use the IconItemRenderer in a mobile application. The IconItemRenderer displays two text fields, one above the other, and two icons for every data item.

The following example shows a List control defined in the view of a mobile application. In this example, the List control uses the IconItemRenderer to display the first name, last name, and an icon for every data item in the list:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\mobile\views\ContactsMobileIconIR.mxml -->
<s:View xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    title="Contacts View Main">
    <s:layout>
        <s:VerticalLayout paddingTop="10"/>
    </s:layout>

    <fx:Style>
        @namespace s "library://ns.adobe.com/flex/spark";
        .myFontStyle {
            fontSize: 15;
            color: #9933FF;
        }
    </fx:Style>

    <s:Label text="Select a contact name"/>
    <s:List id="myList"
        width="100%" height="100%"
        labelField="firstName">
        <s:itemRenderer>
            <fx:Component>
                <s:IconItemRenderer messageStyleName="myFontStyle" fontSize="25"
                    labelField="firstName"
                    messageField="lastName"
                    decorator="@Embed(source='../assets/logo_small.jpg')"/>
            </fx:Component>
        </s:itemRenderer>
        <s:ArrayCollection>
         <fx:Object firstName="Dave" lastName="Duncam" company="Adobe" phone="413-555-1212"/>
          <fx:Object firstName="Sally" lastName="Smith" company="Acme" phone="617-555-1491"/>
          <fx:Object firstName="Jim" lastName="Jackson" company="Beta" phone="413-555-2345"/>
          <fx:Object firstName="Mary" lastName="Moore" company="Gamma" phone="617-555-1899"/>
        </s:ArrayCollection>
    </s:List>
</s:View>
```

Spark List control

The Spark List control displays a list of data items. Its functionality is very similar to that of the SELECT form element in HTML. The user can select one or more items from the list. The List control automatically displays horizontal and vertical scroll bar when the list items do not fit the size of the control.

The List control is a subclass of the SkinnableDataContainer container. Therefore, you can set the layout of the List control, apply a skin to it, and define a custom item renderer. For more information on the SkinnableDataContainer container, see “The Spark DataGroup and Spark SkinnableDataContainer containers” on page 466. To define a look and feel of items displayed in the List control, read more about “Define a custom Spark item renderer” on page 470.

Creating a Spark List control

You use the `<s:List>` tag to define a Spark List control. Specify an `id` value if you intend to refer to a component elsewhere in your MXML, either in another tag or in an ActionScript block.

You specify the data for the List control by using the `dataProvider` property of the control. However, because `dataProvider` is the List control's default property, you do not have to specify a `<s:dataProvider>` child tag of the `<s:List>` tag, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- dpcontrols\sparkdpcontrols\SparkListSimpleNoDP.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:List>
        <mx:ArrayCollection>
            <fx:String>Flash</fx:String>
            <fx:String>Director</fx:String>
            <fx:String>Dreamweaver</fx:String>
            <fx:String>ColdFusion</fx:String>
        </mx:ArrayCollection>
    </s:List>
</s:Application>
```

The default skin for the List control, ListSkin, defines scroll bars by including a Scroller component in the skin class. You can reference the Scroller component from the List by using the `List.scroller` skin part. Therefore, if the data items do not fit in the size of the control, Flex automatically display scroll bars, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- dpcontrols\sparkdpcontrols\SparkListSimpleScroll.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:List height="100">
        <s:dataProvider>
            <mx:ArrayCollection>
                <fx:String>Flex</fx:String>
                <fx:String>Flash Builder</fx:String>
                <fx:String>Flash</fx:String>
                <fx:String>Director</fx:String>
                <fx:String>Dreamweaver</fx:String>
                <fx:String>ColdFusion</fx:String>
                <fx:String>Illustrator</fx:String>
                <fx:String>PhotoShop</fx:String>
            </mx:ArrayCollection>
        </s:dataProvider>
    </s:List>
</s:Application>
```

Using the styles of the Spark List control

The List control defines several styles that you can use to modify the appearance of the control. You can use styles to make some visual changes to the control, but you create a skin for total control over the display.

The following example uses the `alternatingItemColors` and `rollOverColor` styles with the List control. The `alternatingItemColors` styles defines an Array with two entries, #66FFFF for light blue and #33CCCC for a blue-gray. Therefore, the rows of the List control alternate between these two colors. If you specify a three-color array, the rows alternate among the three colors, and so on.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- dpcontrols\spark\SparkListSimpleStyles.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:List
        alternatingItemColors="[#66FFFF, #33CCCC]"
        rollOverColor="#CC6600">
        <s:dataProvider>
            <mx:ArrayCollection>
                <fx:String>Flex</fx:String>
                <fx:String>Flash Builder</fx:String>
                <fx:String>Flash</fx:String>
                <fx:String>Director</fx:String>
                <fx:String>Dreamweaver</fx:String>
                <fx:String>ColdFusion</fx:String>
            </mx:ArrayCollection>
         </s:dataProvider>
    </s:List>
</s:Application>
```

Handling multiple selection in the Spark List control

The List control lets you select multiple items in the control. To enable multiple selection, set the `allowMultipleSelection` property to `true`. The default value is `false`.

After enabling multiple selection, select the first data item in the List by clicking on it. Then hold down the Control key to select additional items. If the item is currently deselected, clicking on it while holding down the Control key selects it. If the item is already selected, clicking on it while holding down the Control key deselects it.

You can also use the Shift key to select a range of data items. To select a range, select the first data item in the List by clicking on it. Then hold down the Shift key to select one additional item. The List control selects all data items between the two data items.

The List control defines two Vector properties that you use with multiple selection: `selectedIndices` and `selectedItems`. The `selectedIndices` Vector is of type int, and the `selectedItems` Vector is of type Object. These Vectors contain a list of the selected indices and selected data items in the reverse order in which they were selected. That means the first element in each Vector corresponds to the last item selected. The length of each Vector is the same as the number of selected items in the control. If your list contains 100 data items, these Vectors can be up to 100 elements long.

The following example enables multiple selection for the List control. It displays the index of all selected items in one TextArea control, and the data item itself in a second TextArea control:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- dpcontrols\sparkdpcontrols\SparkListSimpleMultipleSelection.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    height="450">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import spark.events.IndexChangeEvent;

            private function myChangedHandler(event:IndexChangeEvent):void {

                var selIndices:Vector.<int> = event.currentTarget.selectedIndices;
                var selItems:Vector.<Object> = event.currentTarget.selectedItems;
                var numItems:Number = selIndices.length;

                selIndicesTA.text = "";
                selItemsTA.text = "";

                for (var i:Number = 0; i<numItems; i++)
                {
                    selIndicesTA.text = selIndicesTA.text + selIndices[i] + "\n";
                    selItemsTA.text = selItemsTA.text + selItems[i] + "\n";
                }
            }
        ]]>
    </fx:Script>
    <s:List allowMultipleSelection="true"
        change="myChangedHandler(event);">
        <mx:ArrayCollection>
            <fx:String>Flex</fx:String>
            <fx:String>Flash Builder</fx:String>
            <fx:String>Flash</fx:String>
            <fx:String>Director</fx:String>
            <fx:String>Dreamweaver</fx:String>
            <fx:String>ColdFusion</fx:String>
        </mx:ArrayCollection>
    </s:List>

    <s:Label text="Selected indices"/>
    <s:TextArea id="selIndicesTA" height="75"/>
    <s:Label text="Selected items"/>
    <s:TextArea id="selItemsTA" height="75"/>
</s:Application>
```

Selecting multiple items does not dispatch the `changing` event. It only dispatches the `change` event.

Spark List control user interaction

The user clicks individual data items to select them, and holds down the Control and Shift keys while clicking to select multiple items. You must set the `allowMultipleSelection` property to `true` to allow multiple selection.

A List control shows the number of data items that fit in the display. Paging down through the data items displayed by a 10-line List control shows records 0-9, 10-19, 20-29, and so on.

The List control has the following default keyboard navigation features:

Key	Action
Up Arrow	Moves selection up one item. Hold down the Control key (Windows) or Command key (OSX) to only move focus, but not change the selected item.
Down Arrow	Moves selection down one item. Hold down the Control key (Windows) or Command key (OSX) to only move focus, but not change the selected item.
Left Arrow	Moves selection one column to the left, if you are using HorizontalLayout or TileLayout only. Hold down the Control key (Windows) or Command key (OSX) to only move focus, but not change the selected item.
Right Arrow	Moves selection one column to the right, if you are using HorizontalLayout or TileLayout only. Hold down the Control key (Windows) or Command key (OSX) to only move focus, but not change the selected item.
Page Up	Moves selection up one page.
Page Down	Moves selection down one page.
Home	Moves selection to the top of the list.
End	Moves selection to the bottom of the list.
Alphanumeric keys	Jumps to the next item with a label that begins with the character typed.
Control	Toggle key. Allows for multiple (noncontiguous) selection and deselection. Works with key presses, click selection, and drag selection.
Shift	Contiguous selection key. Allows for contiguous selections. Works with key presses, click selection, and drag selection.

Spark ButtonBar and TabBar controls

The Spark ButtonBar control defines a horizontal row of related buttons with a common appearance. The controls define a single event, the `itemClick` event, that is dispatched when any button in the control is selected.

The buttons maintain their state, either selected or deselected. Only one button in the ButtonBar control can be in the selected state. That means when you select a button in a ButtonBar control, the button stays in the selected state until you select a different button.

The TabBar control is similar to the ButtonBar control, except that is displays a horizontal row of tabs instead of buttons.

Adobe Engineer Joan Lafferty creates a custom skin for the Spark ButtonBar control in Adding toolTips to a Spark ButtonBar.

Creating a Spark ButtonBar control

You create a Spark ButtonBar control in MXML by using the `<s:ButtonBar>` tag. Specify an `id` value if you intend to refer to a component elsewhere in your MXML, either in another tag or in an ActionScript block.

You specify the data for the ButtonBar control by using the `dataProvider` property of the control. However, because `dataProvider` is the ButtonBar control's default property, you do not have to specify a `<s:dataProvider>` child tag of the `<s:ButtonBar>` tag, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- dpcontrols\sparkdpcontrols\SparkBBarSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout paddingLeft="20" paddingTop="20"/>
    </s:layout>
    <s:ButtonBar>
        <mx:ArrayCollection>
            <fx:String>Flash</fx:String>
            <fx:String>Director</fx:String>
            <fx:String>Dreamweaver</fx:String>
            <fx:String>ColdFusion</fx:String>
        </mx:ArrayCollection>
    </s:ButtonBar>
</s:Application>
```

This example creates a row of four Button controls.

Creating a Spark TabBar control

You create a Spark TabBar control in MXML by using the `<s:TabBar>` tag. Specify an `id` value if you intend to refer to a component elsewhere in your MXML, either in another tag or in an ActionScript block.

You specify the data for the TabBar control by using the `dataProvider` property of the control. However, because `dataProvider` is the TabBar control's default property, you do not have to specify a `<s:dataProvider>` child tag of the `<s:TabBar>` tag, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- dpcontrols\sparkdpcontrols\SparkTabBarSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout paddingLeft="20" paddingTop="20"/>
    </s:layout>
    <s:TabBar>
        <mx:ArrayCollection>
            <fx:String>Flash</fx:String>
            <fx:String>Director</fx:String>
            <fx:String>Dreamweaver</fx:String>
            <fx:String>ColdFusion</fx:String>
        </mx:ArrayCollection>
    </s:TabBar>
</s:Application>
```

This example creates a row of four tabs.

Using the Spark ButtonBar and TabBar controls with an MX ViewStack container

You can use the Spark ButtonBar and TabBar controls to set the active child of a ViewStack container, as the following example shows:

```
<?xml version="1.0"?>
<!-- containers\navigators\VSSparkButtonBar.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:VGroup>
        <!-- Create a Spark ButtonBar control to navigate
            the ViewStack container. -->
        <s:ButtonBar dataProvider="{myViewStack}"/>
        <!-- Define the ViewStack and the three child containers. -->
        <mx:ViewStack id="myViewStack"
            borderStyle="solid"
            width="100%">

            <s:NavigatorContent id="search" label="Search">
                <s:Label text="Search Screen"/>
            </s:NavigatorContent>
            <s:NavigatorContent id="custInfo" label="Customer Info">
                <s:Label text="Customer Info"/>
            </s:NavigatorContent>
            <s:NavigatorContent id="accountInfo" label="Account Info">
                <s:Label text="Account Info"/>
            </s:NavigatorContent>
        </mx:ViewStack>
    </s:VGroup>
</s:Application>
```

For more information on the ViewStack control, see the “MX ViewStack navigator container” on page 630.

Using skins and styles with the Spark ButtonBar and TabBar controls

The default skin class for the ButtonBar control, spark.skins.spark.ButtonBarSkin, references three skin classes to define the buttons:

- spark.skins.spark.ButtonBarFirstButtonSkin The skin for the first button.
- spark.skins.spark.ButtonBarMiddleButtonSkin The skin for the middle buttons.
- spark.skins.spark.ButtonBarLastButtonSkin The skin for the last button.

The individual button skins define the buttons to be instances of the ButtonBarButton control. You can define custom skin classes for the ButtonBar control. Your custom skin classes can then use any control to represent each data item, not just the ButtonBarButton control.

The tabs on a TabBar control are all drawn in the same way. Therefore, the default skin class for the TabBar control, spark.skins.spark.TabBarSkin, references only a single skin class to draw the tabs: spark.skins.spark.TabBarButtonSkin.

You can also set styles to control the appearance of the buttons and tabs. The following example uses styles on the ButtonBar and ButtonBarButton controls to define the appearance of the individual buttons:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- dpcontrols\sparkdpcontrols\SparkBBStyled.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout paddingLeft="20" paddingTop="20"/>
    </s:layout>

    <fx:Style>
        @namespace s "library://ns.adobe.com/flex/spark";
        s|ButtonBar s|ButtonBarButton:upAndSelected,
        s|ButtonBar s|ButtonBarButton:overAndSelected,
        s|ButtonBar s|ButtonBarButton:downAndSelected,
        s|ButtonBar s|ButtonBarButton:disabledAndSelected {
            chromeColor: #663366;
            color: #9999CC;
        }
        s|ButtonBar {
            chromeColor: #9999CC;
            color: #663366;
        }
    </fx:Style>

    <s:ButtonBar
        requireSelection="true"
        width="320">
        <mx:ArrayCollection>
            <fx:String>Flash</fx:String>
            <fx:String>Director</fx:String>
            <fx:String>Dreamweaver</fx:String>
            <fx:String>ColdFusion</fx:String>
        </mx:ArrayCollection>
    </s:ButtonBar>
</s:Application>
```

In this example, you use CSS descendant selectors to style the ButtonBarButton controls of the ButtonBar, and to set styles directly on the ButtonBar control. The styles of the ButtonBarButton controls define the appearance of the controls for different view states of the ButtonBarButton control.

For more information on using descendant selectors, see “Using Cascading Style Sheets” on page 1504.

Handling Spark ButtonBar and TabBar events

The ButtonBar and TabBar controls dispatches a `change` event when you select a button or tab. The event object passed to the event listener is of type IndexChangeEvent. Access properties of the event object to determine the index of the selected button or tab, and other information. The index of the first button or tab is 0. For more information about the event object, see the description of the ItemClickEvent class in the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

The ButtonBar control in the following example defines an event listener, named `changeHandler()`, for the `change` event:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- dpcontrols\sparkdpcontrols\SparkBBarEvent.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            import spark.events.IndexChangeEvent;

            private function changeHandler(event:IndexChangeEvent):void {
                myTA.text="Selected button index: " +
                String(event.newIndex) + "\n" +
                "Selected button label: " +
                event.target.selectedItem;
            }
        ]]>
    </fx:Script>

    <s:ButtonBar
        change="changeHandler(event);">
        <mx:ArrayCollection>
            <fx:String>Flash</fx:String>
            <fx:String>Director</fx:String>
            <fx:String>Dreamweaver</fx:String>
            <fx:String>ColdFusion</fx:String>
        </mx:ArrayCollection>
    </s:ButtonBar>

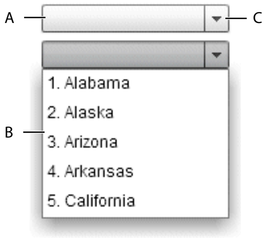
    <s:TextArea id="myTA" width="250" height="100"/>
</s:Application>
```

In this example, the click handler displays the index and label of the selected button in a TextArea control in response to an `change` event.

Spark DropDownList control

The DropDownList control pops up a list when the user selects the anchor. When the user selects an item from the drop-down list, the data item appears in the prompt area of the control.

The following image shows the DropDownList control:



***A.** Prompt in a closed DropDownList* ***B.** Drop-down list in an open DropDownList* ***C.** Anchor in a closed DropDownList*

Unlike the ComboBox control, the DropDownList control is not editable.

Peter DeHaan has several examples of using the Spark DropDownList on flexexamples.com.

StackOverflow shows how to adjust the height of an open DropDownList with a custom skin, and how to bind the data field to XML.

When the drop-down list is closed, clicking the anchor button opens it.

When the drop-down list is open:

- Clicking the anchor button closes the drop-down list and commits the currently selected data item.
- Clicking outside the drop-down list closes the drop-down list and commits the currently selected data item.
- Clicking on a data item selects that item and closes the drop-down list.
- If the `requireSelection` property is `false`, clicking on a data item while pressing the Control key deselects the item and closes the drop-down list.

For a complete list of keyboard command for the DropDownList control, see “Spark DropDownList control user interaction” on page 536.

For complete reference information, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Create a Spark DropDownList control

You define a DropDownList control in MXML by using the `<s:DropDownList>` tag. Specify an `id` value if you intend to refer to a component elsewhere in your MXML application, either in another tag or in an ActionScript block.

You specify the data for the DropDownList control by using the `dataProvider` property. However, because `dataProvider` is the DropDownList control’s default property, you do not have to specify a `<s:dataProvider>` child tag of the `<s:DropDownList>` tag, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- dpcontrols\sparkdpcontrols\SparkDDSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:DropDownList width="140">
        <mx:ArrayCollection>
            <fx:String>Alabama</fx:String>
            <fx:String>Alaska</fx:String>
            <fx:String>Arizona</fx:String>
            <fx:String>Arkansas</fx:String>
            <fx:String>California</fx:String>
        </mx:ArrayCollection>
    </s:DropDownList>
</s:Application>
```

Set the prompt in the Spark DropDownList control

By default, the prompt area is empty when the control first loads. Selecting a data item in the drop-down list sets the prompt to the data item.

Use the `prompt` property to define the text to display when the DropDownList loads, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- dpcontrols\sparkdpcontrols\SparkDDSimplePrompt.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout paddingLeft="10"
            paddingTop="10"/>
    </s:layout>
    <s:DropDownList width="140"
        prompt="Select a state">
        <mx:ArrayCollection>
            <fx:String>Alabama</fx:String>
            <fx:String>Alaska</fx:String>
            <fx:String>Arizona</fx:String>
            <fx:String>Arkansas</fx:String>
            <fx:String>California</fx:String>
        </mx:ArrayCollection>
    </s:DropDownList>
</s:Application>
```

If you set the `requireSelection` property to `true`, the control ignores the `prompt` property. Instead, it sets the prompt area and the `selectedIndex` property to the first data item in the control.

Alternatively, you can set the `selectedIndex` property to any data item. The prompt area displays the data item specified by the `selectedIndex` property. In the following example, you set the `selectedIndex` property to 4 to select California by default when the application starts:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- dpcontrols\sparkdpcontrols\SparkDDSimpleSetSelectedIndex.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout paddingLeft="10"
            paddingTop="10"/>
    </s:layout>
    <s:DropDownList width="140"
        selectedIndex="4">
        <mx:ArrayCollection>
            <fx:String>Alabama</fx:String>
            <fx:String>Alaska</fx:String>
            <fx:String>Arizona</fx:String>
            <fx:String>Arkansas</fx:String>
            <fx:String>California</fx:String>
        </mx:ArrayCollection>
    </s:DropDownList>
</s:Application>
```

Handle Spark DropDownList events

The DropDownList control inherits the events of the ListBase class, and adds the following events:

- `close` Dispatched when the drop-down list closes for any reason.
- `open` Dispatched when the drop-down list opens for any reason.

Spark DropDownList control user interaction

A page in the DropDownList control is defined as the number of data items that fit in the drop-down list. Paging down through the data displayed by a six-line control shows records 0-5, 6-11, 12-17, and so on.

Keyboard navigation when DropDownList is closed

The DropDownList control has the following keyboard navigation features when the drop-down list is closed:

Key	Action
Alphanumeric keys	Displays the closest match in the item list. The DropDownList does not open.
Up Arrow	Moves selection up one item.
Down Arrow	Moves selection down one item.
Control + Down Arrow	Opens the drop-down list.
Page Up	Moves the selection up one page. If the `selectedIndex` is currently -1, do nothing.
Page Down	Moves the selection down one page. If you are at the end of the list, do nothing.
Home	Moves selection to the top of the drop-down list.
End	Moves selection to the bottom of the drop-down list.

Keyboard navigation when DropDownList is open

The DropDownList control has the following keyboard navigation features when the drop-down list is open:

Key	Action
Alphanumeric keys	Scrolls to and highlights the closest match in the item list.
Up Arrow	Moves selection up one item but does not commit the selection until the drop-down list closes.
Down Arrow	Moves selection down one item but does not commit the selection until the drop-down list closes.
Control + Up Arrow	Closes the drop-down list and commits the selection.
Escape	Closes the drop-down list but do not commit the selection.
Page Up	Moves the selection to the top of the data items currently displayed but does not commit the selection until the drop-down list closes.
Page Down	Moves the selection to the bottom of the data items currently displayed but does not commit the selection until the drop-down list closes.
Home	If `selectedIndex` = -1, do not change the currently selected data item. Otherwise, moves selection to the first data item in the drop-down list. Does not commit the selection until the drop-down list closes.
End	Moves selection to the last data item in the drop-down list. Does not commit the selection until the drop-down list closes.

Spark ComboBox control

The ComboBox control is a child class of the DropDownListBase control. Like the DropDownList control, when the user selects an item from the drop-down list in the ComboBox control, the data item appears in the prompt area of the control.

Differences between ComboBox and DropDownList

One difference between the controls is that the prompt area of the ComboBox control is implemented by using the TextInput control, instead of the Label control for the DropDownList control. Therefore, a user can edit the prompt area of the ComboBox control to enter a value that is not one of the predefined options; the values in the DropDownList cannot be edited.

For example, the DropDownList control only lets the user select from a list of predefined items in the control. The ComboBox control lets the user either select a predefined item, or enter a new item into the prompt area. When the user enters a new item, the `selectedIndex` property is set to -3. Your application can recognize that a new item has been entered and, optionally, add it to the list of items in the control.

Searching

The ComboBox control also searches the item list as the user enters characters into the prompt area. As the user enters characters, the drop-down area of the control opens. It then and scrolls to and highlights the closest match in the item list.

Create a Spark ComboBox control

You define a ComboBox control in MXML by using the `<s:ComboBox>` tag. Specify an `id` value if you intend to refer to a component elsewhere in your MXML application, either in another tag or in an ActionScript block.

You specify the data for the ComboBox control by using the `dataProvider` property. However, because `dataProvider` is the ComboBox control's default property, you do not have to specify a `<s:dataProvider>` child tag of the `<s:ComboBox>` tag, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- dpcontrols\sparkdpcontrols\SparkCBSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout paddingTop="5" paddingLeft="5"/>
    </s:layout>
    <s:Label text="The selected index is: {myCB.selectedIndex}"/>
    <s:Label text="The selected item is: {myCB.selectedItem}"/>
    <s:ComboBox id="myCB" width="140" prompt="Select a Color">
        <s:dataProvider>
            <mx:ArrayList>
                <fx:String>Red</fx:String>
                <fx:String>Orange</fx:String>
                <fx:String>Yellow</fx:String>
                <fx:String>Blue</fx:String>
                <fx:String>Green</fx:String>
            </mx:ArrayList>
        </s:dataProvider>
    </s:ComboBox>
</s:Application>
```

This example demonstrates the following functionality of the ComboBox control:

- When you select an item in the drop-don list, the item appears in the prompt area of the control. The `ComboBox.selectedIndex` property contains the index of the selected item in the data provider of the control. The `ComboBox.selectedItem` property contains the selected data item.
- As you enter characters in the prompt area, it scrolls to and highlights the closest match in the item list.

You can control the matching algorithm by creating a custom callback function. You then specify that function as the value of the `ComboBox.itemMatchingFunction` property. The callback function returns a Vector.<int> that contains the index of each item in the data provider that matches the input. To disable matching, create a callback function that returns an empty Vector.<int>.

- If you enter a value in the prompt area that does not match an item in the list, and commit the item, the index of the selected item is -3. This value is determined by the `ComboBox.CUSTOM_SELECTED_ITEM` constant.

  Commit a new item by pressing the Enter or Tab key while the cursor is in the prompt area.

Handle events for the Spark ComboBox control

You commonly use the following events with the ComboBox control:

- The ComboBox control dispatches the `changing` event after each character is entered in the prompt area.
- The ComboBox control dispatches the `change` event when the user selects an existing item in the drop-down list, or enters a new item in the prompt area.

You can also add event listeners to the `textInput` skin part of the ComboBox control to handle events on the TextInput control. For example, the following line adds an event handler for the `change` event to the `textInput` skin part of the ComboBox named myCB:

```
myCB.textInput.addEventListener('change', myChangeHandler);
```

Process new data items entered into the Spark ComboBox control

When using the ComboBox control, you must decide on how your application handles new values entered into the prompt are of the control. For example, your application can recognize the new value and perform some action, it can provide user feedback with a list of allowed values, and it can add the item to the current list of data items.

The following actions occur when the user enters a value into the prompt area of the control, and the value is not found in the current list of data items:

- The ComboBox control dispatches the `change` event when the user commits the change, typically by pressing the Enter or Tab key.
- The `ComboBox.selectedIndex` property is set to `ComboBox.CUSTOM_SELECTED_ITEM`. The default value of this constant is -3.
- The ComboBox control calls the function defined by the `ComboBox.labelToItemFunction` property to convert the new value to the same data type as the data items in the data provider.

  If your data items are simple data types, such as String or int, then you can use the default function defined by the `labelToItemFunction` property. If your data items are Objects, then you typically have to write your own function.
- The converted value returned by the function specified by the `ComboBox.labelToItemFunction` property is written to the `ComboBox.selectedItem` property.

The following example uses the `change` event to recognize that a new item was entered into the prompt, and adds it to the data provider of the control:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- dpcontrols\sparkdpcontrols\SparkCBAddItem.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout paddingTop="5" paddingLeft="5"/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import spark.events.IndexChangeEvent;

            // Event handler to determine if the selected item is new.
            protected function myCB_changeHandler(event:IndexChangeEvent):void
            {
                // Determine if the index specifies a new data item.
                if(myCB.selectedIndex == spark.components.ComboBox.CUSTOM_SELECTED_ITEM)
                    // Add the new item to the data provider.
                    myCB.dataProvider.addItem(myCB.selectedItem);
            }
        ]]>
    </fx:Script>

    <s:Label text="The selected index is: {myCB.selectedIndex}"/>
    <s:Label text="The selected item is: {myCB.selectedItem}"/>
    <s:ComboBox id="myCB" width="140" change="myCB_changeHandler(event);">
        <s:dataProvider>
            <mx:ArrayList>
                <fx:String>Red</fx:String>
                <fx:String>Orange</fx:String>
                <fx:String>Yellow</fx:String>
                <fx:String>Blue</fx:String>
                <fx:String>Green</fx:String>
            </mx:ArrayList>
        </s:dataProvider>
    </s:ComboBox>
</s:Application>
```

In this example, the ComboBox control initially defines five colors. The user can either select one of the predefined colors, or enter a new one in the prompt area. When the user commits the new item, by pressing the Enter or Tab key, the application uses the `change` even to add the new item to the data provider.

The ComboBox in the previous example used simple String data for its data items. That means the application can use the default function defined by the `ComboBox.labelToItemFunction` property to convert new values to the same data type as the data items in the data provider.

However, your ComboBox control can use more complicated data items. In that case, you write a custom function to convert new data items to the format required by the data provider, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- dpcontrols\sparkdpcontrols\SparkCBAddItemObj.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout paddingTop="5" paddingLeft="5"/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import spark.events.IndexChangeEvent;

            // Define a custom function for the labelFunction property
            // to display an Object in the ComboBox control.
            public function myLabelFunc(item:Object):String {
                return item.firstName + " " + item.lastName;
            }

            // Define a custom function for the labelToItemFunction property
            // to convert the new value to an Object of the correct format
            // for storage in the data provider of the control.
            public function myLabelToItemFunc(value:String):Object {
                var tempObj:Object = new Object();
                var spaceChar:int = value.indexOf(' ');
                tempObj.firstName = value.substr(0, spaceChar);
                tempObj.lastName = value.substr(spaceChar+1, value.length);
                return tempObj;
            }

            // Event handler to determine if the selected item is new.
            protected function myCB_changeHandler(event:IndexChangeEvent):void
            {
                // Determine if the index specifies a new data item.
                if(myCB.selectedIndex == spark.components.ComboBox.CUSTOM_SELECTED_ITEM)
                    // Add the new item to the data provider.
                    myCB.dataProvider.addItem(myCB.selectedItem);
            }
        ]]>
    </fx:Script>

    <s:Label text="The selected index is: {myCB.selectedIndex}"/>
    <s:Label text="The selected item is: {myCB.selectedItem.firstName + ' '
             + myCB.selectedItem.lastName}"/>
    <s:ComboBox id="myCB" width="140"
        labelFunction="myLabelFunc"
        labelToItemFunction="myLabelToItemFunc"
        change="myCB_changeHandler(event);">
        <s:dataProvider>
            <mx:ArrayList>
                <fx:Object firstName="Steve" lastName="Smith"/>
                <fx:Object firstName="John" lastName="Jones"/>
                <fx:Object firstName="Mary" lastName="Moore"/>
            </mx:ArrayList>
        </s:dataProvider>
    </s:ComboBox>
</s:Application>
```

In this example, the data items are represented by Objects. Each Object contains two fields: `firstName` and `lastName`.

This example adds two new functions. The first, `myLabelFunction()`, converts the Objects in the data provider of the control to a String for display by the ComboBox control. Use the `labelFunction` property to assign this function to the ComboBox control. For more information, see "Controlling the text displayed for each data item" on page 516.

The second function, `myLabelToItemFunc()`, converts a new data item into the format required by the data provider of the control. Use the `labelToItemFunction` property to assign this function to the ComboBox control. The ComboBox control writes the value returned by the function to the `selectedItem` property.

The signature of the function specified to the `labelToItemFunction` property is shown below:

```
function funcName(value:String):Object {}
```

The value passed to the function is the String entered into the prompt area of the control. The function returns an Object written to the `selectedItem` property.

Spark ComboBox control user interaction

A page in the ComboBox control is defined as the number of data items that fit in the drop-down list. Paging down through the data displayed by a six-line control shows records 0-5, 6-11, 12-17, and so on.

Keyboard navigation when ComboBox is closed

The ComboBox control has the following keyboard navigation features when the drop-down list is closed:

Key	Action
Alphanumeric keys	Opens the drop-down list. The drop-down list it scrolls to and highlights the closest match in the item list.
Enter	Commit the highlighted data item, if one is highlighted. If no data item is highlighted, commit the value of the prompt area.
Up Arrow	Moves selection up one item.
Down Arrow	Moves selection down one item.
Control + Down Arrow	Opens the drop-down list.
Page Up	Moves the selection up one page. If the `selectedIndex` is currently -1, do nothing.
Page Down	Moves the selection down one page. If you are at the end of the list, do nothing.
Home	Moves selection to the top of the drop-down list.
End	Moves selection to the bottom of the drop-down list.

Keyboard navigation when ComboBox is open

The ComboBox control has the following keyboard navigation features when the drop-down list is open:

Key	Action
Alphanumeric keys	Scrolls to and highlights the closest match in the item list.
Enter	Close the drop-down list. Commit the highlighted data item, if one is highlighted. If no data item is highlighted, commit the value of the prompt area.
Up Arrow	Moves selection up one item but does not commit the selection until the drop-down list closes.
Down Arrow	Moves selection down one item but does not commit the selection until the drop-down list closes.
Control + Up Arrow	Closes the drop-down list and commits the selection.

Key	Action
Escape	Closes the drop-down list but do not commit the selection.
Page Up	Moves the selection to the top of the data items currently displayed but does not commit the selection until the drop-down list closes.
Page Down	Moves the selection to the bottom of the data items currently displayed but does not commit the selection until the drop-down list closes.
Home	If `selectedIndex` = -1, do not change the currently selected data item. Otherwise, moves selection to the first data item in the drop-down list. Does not commit the selection until the drop-down list closes.
End	Moves selection to the last data item in the drop-down list. Does not commit the selection until the drop-down list closes.

Mouse navigation when ComboBox is closed

The ComboBox control has the following mouse navigation features when the drop-down list is closed:

Mouse action	Action
Click in the prompt area	Puts focus in the prompt area. If it was not previously in focus, then all of text in the prompt area is selected.
Click in open button	Opens the drop-down list, removes the focus ring from the ComboBox control, removes focus from the prompt area, and highlights the closest match to the input string.

Mouse navigation when ComboBox is open

The ComboBox control has the following mouse navigation features when the drop-down list is open:

Mouse action	Action
Click in the prompt area	Puts focus in the prompt area. If it was not previously in focus, then all of text in the prompt area is selected.
Click in open button	Closes the drop-down list and commit the selection. Removes focus from the ComboBox and control and from the prompt area.

Use prompt text with the Spark ComboBox control

The Spark ComboBox control supports adding prompt text. Prompt text appears in the prompt area of the control when no item is selected. Prompt text disappears when you focus on the control. When you remove focus without selecting an item, the prompt text reappears.

You set prompt text on a ComboBox control by using the `prompt` property. This property can be bound to the value of another property or it can be static text.

The following example displays prompt when the application first starts. When you focus on the ComboBox control, the prompt text disappears. If you click the Reset button, the value of the ComboBox's `selectedIndex` property is reset to -1, and the prompt text reappears.

```
<?xml version="1.0"?>
<!-- dpcontrols/sparkdpcontrols/SparkCBPrompt.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <fx:Script>
    <![CDATA[
        [Bindable]
        private var promptText:String = "Choose Game";

        /* When you set selectedIndex to -1 and remove focus, the prompt text reappears. */
        private function resetCB():void {
            myComboBox.selectedIndex = -1;
        }
      ]]>
  </fx:Script>

    <s:VGroup>
        <s:ComboBox id="myComboBox" prompt="{promptText}">
            <s:dataProvider>
                <s:ArrayList>
                    <fx:String>Durche die Wuste</fx:String>
                    <fx:String>Samurai</fx:String>
                    <fx:String>Traumfabrik</fx:String>
                </s:ArrayList>
            </s:dataProvider>
        </s:ComboBox>
        <s:Button label="Reset" click="resetCB()"/>
    </s:VGroup>
</s:Application>
```

The prompt text is defined by the TextInput subcontrol of the ComboBox control. It cannot include any HTML markup, but can be styled using CSS. To style the prompt text, use the `normalWithPrompt` (for the normal state) and `disabledWithPrompt` (for the disabled state) pseudo selectors on a TextInput or SkinnableTextBase class in your CSS, as the following example shows:

```
<?xml version="1.0"?>
<!-- dpcontrols/sparkdpcontrols/SparkCBPromptStyles.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Style>
        @namespace s "library://ns.adobe.com/flex/spark";
        s|TextInput:normalWithPrompt {
            color: #FF3366;
            fontStyle: italic;
        }
        s|TextInput:disabledWithPrompt {
            color: #CCFFFF;
            fontStyle: italic;
        }
    </fx:Style>
  <fx:Script>
    <![CDATA[
        [Bindable]
        private var promptText:String = "Choose Game";

        /* When you set selectedIndex to -1 and remove focus, the prompt text reappears. */
        private function resetCB():void {
            myComboBox.selectedIndex = -1;
        }
      ]]>
  </fx:Script>

    <s:VGroup>
        <s:ComboBox id="myComboBox" prompt="{promptText}">
            <s:dataProvider>
                <s:ArrayList>
                    <fx:String>Durche die Wuste</fx:String>
                    <fx:String>Samurai</fx:String>
                    <fx:String>Traumfabrik</fx:String>
                </s:ArrayList>
            </s:dataProvider>
        </s:ComboBox>
        <s:Button label="Reset" click="resetCB()"/>
    </s:VGroup>
</s:Application>
```

Additional information

The flepstudio.org blog shows how to load an external XML file into a ComboBox.

Flex4Fun has an example that adds icons to the ComboBox itemRender and another example that adds icons without creating a custom itemRenderer.

Sensaran’s Weblog has an example that adds an editable ComboBox to a DataGrid.

Spark DataGrid and Grid controls

The Spark DataGrid control displays a row of column headings above a scrollable grid. The grid consists of a collection of individual cells arranged in rows and columns. The DataGrid control is designed to support smooth scrolling through a large number of rows and columns.

The Spark DataGrid control is implemented as a skinnable wrapper around the Spark Grid control. The Grid control defines the columns of the data grid, and much of the functionality of the DataGrid control itself.

The DataGrid skin is responsible for laying out the grid, the column headers, and the scroller. The skin also configures the graphic elements used to render visual elements used as indicators, separators, and backgrounds. The DataGrid skin defines a default item renderer used to display the contents of each cell.

***Note:** Because the DataGrid control is implemented as a wrapper on the Grid control, they share much of the same functionality. Therefore, many of the examples below are for the DataGrid control, but can be easily modified to apply to the Grid control.*

The Spark DataGrid control provides the following features:

- Interactive column width resizing
- Control of column visibility
- Cell and row selection
- Single item and multiple item selection modes
- Customizable column headers
- Cell editing
- Column sorting
- Custom item renderers and item editors
- Custom skins to control all aspects of the appearance of the DataGrid control

Adobe Product Evangelist James Ward provides an overview of the Spark DataGrid control in the video Overview of Spark DataGrid in Flex.

Adobe Senior Computer Scientist Alex Harui creates a custom skin for the Spark DataGrid control in Spark DataGrid Footers, and shares his sample code for the Spark DataGrid with HierarchicalCollection and GroupingCollection.

Browse Flex Cookbook entries for the Spark DataGrid for new sample applications for the Spark DataGrid control.

Creating a Spark DataGrid control

You use the `<s:DataGrid>` tag to define a Spark DataGrid control in MXML. Specify an `id` value if you intend to refer to a component elsewhere in your MXML, either in another tag or in an ActionScript block.

The DataGrid control uses a list-based data provider to supply the data to display. The data provider consists of a list of objects called *items*. Each item corresponds to one row of the DataGrid control. Each grid column typically corresponds to one property of each row item. For more information, see “Data providers and collections” on page 898.

You can specify data in several different ways. In the simplest case, use the `<s:ArrayList>` and `<fx:Object>` tags to define the entries. Each Object defines a row of the DataGrid control. The properties of each Object define the column entries for the row, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- dpcontrols\sparkdpcontrols\SparkDGSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:DataGrid>
        <s:dataProvider>
            <s:ArrayList>
                <fx:Object>
                    <fx:Artist>Pavement</fx:Artist>
                    <fx:Price>11.99</fx:Price>
                    <fx:Album>Slanted and Enchanted</fx:Album>
                </fx:Object>
                <fx:Object>
                    <fx:Price>11.99</fx:Price>
                    <fx:Artist>Pavement</fx:Artist>
                    <fx:Album>Brighten the Corners</fx:Album>
                </fx:Object>
            </s:ArrayList>
        </s:dataProvider>
    </s:DataGrid>
</s:Application>
```

***Note:** You do not have to specify the `dataProvider` tag in MXML because `dataProvider` is the default property of the DataGrid control.*

By default, each column displays one property from each data provider item. Each column heading displays the name of the associated property in the data provider item.

The index of rows in the DataGrid control is zero-based, meaning values are 0, 1, 2, ... , *n* - 1, where *n* is the total number of items in the data provider. Column indexes are also zero-based. Therefore, if you select the first cell in the second row, the row index is 1 and the column index is 0.

Passing data to a DataGrid control

Specify the data provider for the DataGrid control by using the `dataProvider` property. The data type of the `dataProvider` property is IList. That lets you use an ArrayList, ArrayCollection, or any other class that implements IList as the data provider.

ArrayList is a lightweight implementation of IList that is useful if you do not support row sorting in the DataGrid control. To support row sorting, use a class that implements the ICollectionView interface, such as ListCollectionView. Typically, you use a subclass of ListCollectionView, such as ArrayCollection or XMLListCollection, as the data provider to support row sorting.

Each row in the data grid corresponds to one item in the data provider. Data provider items can define their properties in differing orders. By default, the order of the columns corresponds to the order of the properties as defined in the first item in the data provider.

If a data provider item omits a property or a value for a property, the DataGrid control displays an empty cell in the corresponding column for that row.

Flex lets you populate a DataGrid control from an ActionScript variable definition or from a Flex data model. The following example populates a DataGrid control by using a variable:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- dpcontrols\sparkdpcontrols\SparkDGPassedData.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    initialize="initData();">

    <fx:Script>
        <![CDATA[
            import mx.collections.*;
            private var dgArray:Array = [
                {Artist:'Pavement', Album:'Slanted and Enchanted', Price:11.99},
                {Artist:'Pavement', Album:'Brighten the Corners', Price:11.99}];

            [Bindable]
            public var initDG:ArrayCollection;

            // Initialize initDG variable from the Array.
            public function initData():void {
                initDG = new ArrayCollection(dgArray);
            }
        ]]>
    </fx:Script>

    <s:DataGrid id="myGrid"
        width="350" height="200"
        dataProvider="{initDG}"/>
</s:Application>
```

In this example, you bind the variable `initDG` to the `<s:dataProvider>` property.

The following example populates the DataGrid control from XML data. In this example, you define the XML data by using the XMLList class. You then create an XMLListCollection object from the XMLList:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- dpcontrols\sparkdpcontrols\SparkDGXMLData.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    width="500">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Declarations>
        <fx:XMLList id="employees">
            <employee>
                <name>Joanne Wall</name>
                <phone>555-219-2012</phone>
                <email>jwall@fictitious.com</email>
                <active>true</active>
            </employee>
            <employee>
                <name>Mary Jones</name>
                <phone>555-219-2000</phone>
                <email>mjones@fictitious.com</email>
                <active>true</active>
            </employee>
            <employee>
                <name>Maurice Smith</name>
                <phone>555-219-2012</phone>
                <email>maurice@fictitious.com</email>
                <active>false</active>
            </employee>
            <employee>
                <name>Dave Davis</name>
                <phone>555-219-2000</phone>
                <email>ddavis@fictitious.com</email>
                <active>true</active>
            </employee>
            <employee>
                <name>Tom Maple</name>
                <phone>555-219-2000</phone>
                <email>tmaple@fictitious.com</email>
                <active>true</active>
            </employee>
        </fx:XMLList>
        <s:XMLListCollection id="employees2" source="{employees}"/>
    </fx:Declarations>
    <s:DataGrid id="dg" width="500" dataProvider="{employees2}">
        <s:columns>
            <s:ArrayList>
                <s:GridColumn dataField="name" headerText="Name"/>
                <s:GridColumn dataField="phone" headerText="Phone"/>
                <s:GridColumn dataField="email" headerText="Email"/>
            </s:ArrayList>
        </s:columns>
    </s:DataGrid>

    <s:Form>
        <s:FormItem label="Name">
            <s:Label text="{dg.selectedItem.name}"/>
        </s:FormItem>
        <s:FormItem label="Email">
            <s:Label text="{dg.selectedItem.email}"/>
        </s:FormItem>
        <s:FormItem label="Phone">
            <s:Label text="{dg.selectedItem.phone}"/>
        </s:FormItem>
    </s:Form>
</s:Application>
```

You can use Flex data access components: HTTPService, WebService, and RemoteObject, to supply data to the DataGrid. To use a remote data source to provide data, you represent the result of the remote service with the appropriate object, as follows:

- A RemoteObject component automatically returns an ArrayCollection for any data that is represented on the server as a java.util.List object, and you can use the returned object directly.
- For HTTPService and WebService results, cast the result data to a collection class if the data changes or if you use the same result in multiple places (the latter case is more efficient). As a rule, use an ArrayCollection for serialized (list-based) objects and an XMLListCollection for XML data.

The following code snippet shows this use, casting a list returned by a web service to an ArrayCollection:

```
<s:WebService id="employeeWS" wsdl="http://server.com/service.wsdl"
    showBusyCursor="true"
    fault="alert(event.fault.faultstring)">
    <s:operation name="getList">
        <mx:request>
            <deptId>{dept.selectedItem.data}</deptId>
        </mx:request>
    </s:operation>
    ...
</s:WebService>

<fx:ArrayCollection id="ac"
    source="mx.utils.ArrayUtil.toArray(employeeWS.getList.lastResult)"/>
<s:DataGrid dataProvider="{ac}" width="100%">
```

For more information on using data access component, see Accessing server-side data.

Configuring columns

A GridColumn object represents each column in a DataGrid control. By default, the DataGrid control creates a column for every property in the first item of the data provider.

Use the `DataGrid.columns` property to explicitly define the columns of the DataGrid. By explicitly defining the columns, you can set the column order, set column visibility, and set additional column properties.

The data type of the `columns` property is IList. That lets you use an ArrayList, ArrayCollection, or any other class that implements IList as the data provider. Most of the applications in this document use ArrayList to set the `columns` property.

To support column sorting, use a class that implements the ICollectionView interface, such as ListCollectionView. Typically, you use a subclass of ListCollectionView, such as ArrayCollection, as the data provider.

***Note:** You can only sort the columns of the DataGrid programmatically by sorting the IList passed to the `columns` property. That is, you cannot use the mouse to drag a column to rearrange the columns.*

Use the `GridColumn.dataField` property to specify the property of the data provider items displayed in a column, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- dpcontrols\sparkdpcontrols\SparkDGSpecifyColumns.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:DataGrid>
        <s:dataProvider>
            <s:ArrayCollection>
                <fx:Object Artist="Pavement" Price="11.99"
                           Album="Slanted and Enchanted"/>
                <fx:Object Artist="Pavement"
                           Album="Brighten the Corners" Price="11.99"/>
            </s:ArrayCollection>
        </s:dataProvider>
        <s:columns>
            <s:ArrayList>
                <s:GridColumn dataField="Album"/>
                <s:GridColumn dataField="Price"/>
            </s:ArrayList>
        </s:columns>
    </s:DataGrid>
</s:Application>
```

When you use the `<s:columns>` tag, the DataGrid only displays the columns corresponding to the specified GridColumn objects. In this example, you only define columns for the Album and Price properties of the data provider. Therefore, the DataGrid does not display a column for the Price property.

You can reorder the columns by changing the order of the GridColumn objects, as the following example shows:

```
<s:columns>
    <s:ArrayList>
        <s:GridColumn dataField="Price"/>
        <s:GridColumn dataField="Album"/>
    </s:ArrayList>
</s:columns>
```

In this example, you specify that the Price column is the first column in the DataGrid control, and that the Album column is the second.

You can also use the `<s:GridColumn>` tag to set other options. The following example uses the `headerText` property to set the name of the column to a value different from the default name of Album, and uses the `width` property to set an explicit column width:

```
<s:columns>
    <s:ArrayList>
        <s:GridColumn dataField="Album" width="200"/>
        <s:GridColumn dataField="Price" headerText="List Price"/>
    </s:ArrayList>
</s:columns>
```

Rather than explicitly set the width of a column, you can define a typical item for the DataGrid control. The DataGrid uses the typical item, and any item renderer associated with a column, to compute the initial width of each column that does not specify an explicit width. Use the `typicalItem` property to specify the data item, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- dpcontrols\sparkdpcontrols\SparkDGTypicalItem.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:DataGrid requestedRowCount="5">
        <s:typicalItem>
            <s:DataItem key="9999999" name="Typical name length"
                price="1234.56" call="false"/>
        </s:typicalItem>

        <s:ArrayCollection id="items">
            <s:DataItem key="1000" name="Abrasive" price="100.11" call="false"/>
            <s:DataItem key="1001" name="Brush" price="110.01" call="true"/>
            <s:DataItem key="1002" name="Clamp" price="120.02" call="false"/>
            <s:DataItem key="1003" name="Drill" price="130.03" call="true"/>
            <s:DataItem key="1004" name="Epoxy" price="140.04" call="false"/>
            <s:DataItem key="1005" name="File" price="150.05" call="true"/>
        </s:ArrayCollection>
    </s:DataGrid>
</s:Application>
```

Sorting the columns of the Spark DataGrid control

By default, the DataGrid control displays rows in the order specified in the data items passed to its `dataProvider` property. The control lets you sort data based on the cell value of a single column. To sort ascending order of a column, select the column header. Select it again to sort in descending order.

To disable sorting for the control, set the `DataGrid.sortableColumns` property to `false`. To disable sorting for an individual column, set the `GridColumn.sortable` property to `false`.

Create a custom sort by implementing a sort compare function. You can define a different sort compare function for each column of the control. For more information, see “Create a custom sort for the Spark DataGrid control” on page 571.

Hiding and displaying columns

If you display a column at some times, but not at others, you can specify the GridColumn class `visible` property to hide or show the column. The following example lets you hide or show the album price by clicking a button:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- dpcontrols\sparkdpcontrols\SparkDGVisibleColumn.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <s:DataGrid id="myDG" width="350">
        <s:ArrayCollection>
            <fx:Object Artist="Pavement" Price="11.99"
                Album="Slanted and Enchanted"/>
            <fx:Object Artist="Pavement"
                Album="Brighten the Corners" Price="11.99"/>
        </s:ArrayCollection>
        <s:columns>
            <s:ArrayList>
                <s:GridColumn dataField="Artist"/>
                <s:GridColumn dataField="Album"/>
                <s:GridColumn id="price" dataField="Price" visible="false"/>
            </s:ArrayList>
        </s:columns>
    </s:DataGrid>

    <!-- The column id property specifies the column to show.-->
    <s:Button label="Toggle Price Column"
        click="price.visible = !price.visible;" />
</s:Application>
```

The Spark Grid control

The Spark DataGrid control is a skinnable component that uses a Grid control as a skin part. The Grid control displays a list of data items in a two-dimensional grid of cells. Each object in the data provider of the Grid control defines a single row. Individual properties of each object define each cell of the row.

A GridColumn object represents each column of the Grid control. The GridColumn object is responsible for displaying a cell value for each row of the grid. To display a cell, the GridColumn object specifies an item renderer. To edit a cell, the GridColumn object specifies an item editor.

The Grid control only creates as many item renderers as are required to display the currently visible cells. For example, you define a Grid control with hundreds or thousands of rows. Flex only creates enough item renderers to display the currently visible cells, but not for the cells that are currently off the screen.

When a cell is moved off the visible area of the screen, its item renderer is recycled. That means the item renderer can be reused when a new cell moves onto the visible area of the screen. Recycling item renderers greatly reduces the overhead required to use the Grid control.

The following list describes some other differences between the DataGrid and Grid controls:

- Unlike the DataGrid control, the Grid control is not skinnable.
- By default, the Grid control does not display scroll bars. To add scroll bars, wrap the Grid control in the Scroller component.
- The Grid control does not provide default mouse or keyboard event handling. You must add support for those events yourself.

Handling events in a Spark DataGrid control

The DataGrid control defines event types that let you respond to user interaction. Many of these events are similar to events used by other Spark controls. For example, the DataGrid control dispatches a `gridClick` event when a user clicks any cell in the DataGrid control, similar to the `click` event used by other controls. Similarly, use the `gridMouseDown` and `gridMouseUp` events with the DataGrid control instead of the `mouseDown` and `mouseUp` events.

The DataGrid uses its own event types because it lets the DataGrid pass additional information to event handlers in the event object. For example, the DataGrid passes a spark.events.GridEvent object to the event handler of a `gridClick` event. The GridEvent class includes the cell location, and other information necessary to handle the event.

In your event handler, you often access properties of the DataGrid control. For example, you can access the DataGrid control by using the `event.currentTarget` property, where `event` is the event object passed to the event handler.

However, most of the properties of the DataGrid control are just references to properties of the underlying Grid control. Therefore, it is more efficient to access the Grid control directly in your event handler. You can access the Grid control by using the `grid` skin part of the DataGrid control, as shown below:

```
event.currentTarget.grid
```

The `grid` property in many event objects, such as event objects of type spark.events.GridEvent, also contains a reference to the underlying Grid control. Therefore, in an event handler where the event object contains a reference to the Grid control, you can reference it as follows:

```
event.grid
```

In the following example, you handle the `gridClick` event. In the event handler, you then reference the properties of the `event` object, in this case the spark.events.GridEvent class, and properties of the underlying Grid control:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- dpcontrols\sparkdpcontrols\SparkDGEvents.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    minWidth="450" minHeight="450">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            import spark.events.GridEvent;

            private function gridClickEvent(event:GridEvent):void {
                // Access the colunm index, row index, and event type
                // by using the GridEvent object.
                clickColumn.text = String(event.columnIndex);
                clickRow.text = String(event.rowIndex);
                eventType.text = event.type;
                // Access the selection mode of the Grid control.
                selectionType.text = String(event.grid.selectionMode);
            }
        ]]>
    </fx:Script>

    <s:DataGrid id="myGrid" width="350" height="150"
        selectionMode="multipleCells"
        gridClick="gridClickEvent(event);">
        <s:ArrayCollection>
            <fx:Object Artist="Pavement" Price="11.99"
                Album="Slanted and Enchanted" />
            <fx:Object Artist="Pavement" Album="Brighten the Corners"
                Price="11.99" />
        </s:ArrayCollection>
    </s:DataGrid>

    <s:Form>
        <s:FormItem label="Column Index:">
            <s:Label id="clickColumn"/>
        </s:FormItem>
        <s:FormItem label="Row Index:">
            <s:Label id="clickRow"/>
        </s:FormItem>
        <s:FormItem label="Selection type:">
            <s:Label id="selectionType"/>
        </s:FormItem>
        <s:FormItem label="Type:">
            <s:Label id="eventType"/>
        </s:FormItem>
    </s:Form>
</s:Application>
```

In this example, you use the event handler to display the column index, row index, event type, and selection mode.

Selecting cells and rows in the Spark DataGrid control

The DataGrid control lets you configure how the user can select cells and rows. For example, you can configure the control so that selection is disabled, or so that the user can select multiple cells of the grid, or multiple rows.

The following properties of the DataGrid control determine selection:

- `selectionMode` Specifies the selection mode of the control. Possible values are: `none` (selection disabled), `singleCell`, `singleRow` (default), `multipleCells`, and `multipleRows`.
- `requireSelection` Specifies that a cell or row must always be selected. The default value is `false`. If `true`, and the `selectionMode` property is not `none`, then the first cell or row is selected by default until the user makes a selection, or until you set the selection programmatically.

Use the keyboard or mouse to interact with the DataGrid control and to change selection. For example, when using the keyboard, use the Arrow keys to change the selected item. If you configure the DataGrid control for multiple selection, select multiple items by using the Shift and Arrow keys. For more information on keyboard navigation, see "Spark DataGrid control keyboard shortcuts" on page 573.

Handling selection events

Interactive changes to selection performed with a mouse or keyboard are processed in three steps:

1. The DataGrid control dispatches the `selectionChanging` event. In the event handler for the `selectionChanging` event, you can call the `preventDefault()` method to cancel the proposed selection change.
2. If the `selectionChanging` event is not canceled, the control dispatches a `selectionChange` event to indicate that the selection change has been committed.
3. If the selection change is committed, or if there was a change to the caret with no change to the selected item, dispatch a `caretChange` event.

You can change the selection programmatically by using methods of the DataGrid control. The control dispatches a `valueCommit` event on the change. Programmatic changes of selection are unconditionally committed, meaning that you cannot cancel them by calling the `preventDefault()` method.

"Working with the caret in the Spark DataGrid control" on page 558

Handle single cell and single row selection in the spark DataGrid control

Several properties of the DataGrid and Grid control handle cell and row selection in the control. These properties include the following:

- `selectedCell` If the `selectionMode` property is `singleCell`, this property contains the position of the cell in the grid as represented by the CellPosition class. The `CellPosition.columnIndex` and `CellPosition.rowIndex` properties contain the cell location.
- `selectedIndex` If the `selectionMode` property is `singleRow`, this property contains the index of the currently selected row.
- `selectedItem` The object from the data provider corresponding to the currently selected data item. This object represents the entire row of the grid.

***Note:** While the `selectedCell`, `selectedIndex`, and `selectedItem` properties are all writable, Adobe recommends that you use methods of the DataGrid to change selection programmatically.*

In the following example, when you select a row in the control, the event handler for the `selectionChange` event displays the row index and the lastName field of the data item in TextArea controls:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- dpcontrols\sparkdpcontrols\SparkDGSelection.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    height="450" width="450">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            import spark.components.Grid;
            import spark.events.GridSelectionEvent;

            protected function selectionChangeHandler(event:GridSelectionEvent):void {
                const eventGrid:Grid = event.currentTarget.grid;
                var currentIndx:int = eventGrid.selectedIndex;
                var currentDataItem:Object = eventGrid.selectedItem;
                selIndex.text = String(currentIndx);
                selLName.text = String(currentDataItem.lastName);
            }
        ]]>
    </fx:Script>

    <s:DataGrid id="myDG" width="100%"
        selectionChange="selectionChangeHandler(event)">
        <s:ArrayCollection>
            <fx:Object firstName="Bill" lastName="Smith" companyID="11233"/>
            <fx:Object firstName="Dave" lastName="Jones" companyID="13455"/>
            <fx:Object firstName="Mary" lastName="Davis" companyID="11543"/>
            <fx:Object firstName="Debbie" lastName="Cooper" companyID="14266"/>
        </s:ArrayCollection>
    </s:DataGrid>

    <s:Label text="Selected index:"/>
    <s:TextArea id="selIndex" height="50"/>

    <s:Label text="Selected Last Name:"/>
    <s:TextArea id="selLName" height="50"/>

</s:Application>
```

Handle multiple cell and multiple row selection in the Spark DataGrid control

Use the `selectionMode` property of the DataGrid control to configure it for multiple selection. The default value of the `selectionMode` property is `singleRow`, which means that you can select only a single row at a time. Set the `selectionMode` property to `multipleRows` or to `multipleCells` to select multiple rows or cells.

Several properties of the DataGrid and Grid control multiple selection. These properties include the following:

- `selectedCells` If the `selectionMode` property is `multipleCells`, a Vector of CellPosition objects containing the selected cell locations.
- `selectedIndices` If the `selectionMode` property is `multipleRows`, a Vector of integers containing the indexes of the currently selected rows.
- `selectedItems` If the `selectionMode` property is `multipleRows`, a Vector of data provider items corresponding to the currently selected rows.

Note: *While the `selectedCells`, `selectedIndices`, and `selectedItems` properties are all writable, Adobe recommends that you use methods of the DataGrid to change selection programmatically.*

For multiple selection, the set of selected cells or rows extends from the selection *anchor* to the last selected row or cell. The `Grid.anchorRowIndex` and `Grid.anchorColumnIndex` properties represent the location of the selection anchor.

The `selectedIndex` and `selectedItem` properties are valid in multiple selection mode. These properties contain information about the first cell or row selected in the list of currently selected items.

Select contiguous items in the control

1 Click the first item, either a row or cell, to select it.

2 Hold down the Shift key as you select an additional item.

- If the `selectionMode` property is set to `multipleRows`, click any cell in another row to select multiple, contiguous rows.
- If the `selectionMode` property is set to `multipleCells`, click any cell to select multiple, contiguous cells.

Select discontiguous items in the control

1 Click the first item, either a row or cell, to select it.

2 Hold down the Control key (Windows) or the Command key (OSX) as you select an additional item.

- If the `selectionMode` property is set to `multipleRows`, click any cell in another row to select that single row.
- If the `selectionMode` property is set to `multipleCells`, click any cell to select that single cell.

***Note:** You can also use the keyboard to select multiple contiguous or discontiguous items. For information on keyboard navigation, see "Spark DataGrid control keyboard shortcuts" on page 573.*

Example: Spark DataGrid using multiple selection

The following example sets the `selectionMode` property to `multipleCells`. This application uses an event handler for the `keyUp` event to recognize the Control+C key combination and, if detected, copies the selected cells from the DataGrid control to your system's clipboard.

After you copy the cells, you can paste the cells in another location in the application, or paste them in another application. In this example, you paste them to the TextArea control located at the bottom of the application:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- dpcontrols\sparkdpcontrols\SparkDGMultiSelect.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            import flash.events.KeyboardEvent;
            import flash.system.System;
            import spark.components.gridClasses.CellPosition;
            import flash.ui.Keyboard;

            // Event handler to recognize when Ctrl-C is pressed,
            // and copy the selected cells to the system clipboard.
            private function myKeyUpHandler(event:KeyboardEvent):void
            {
                if (event.ctrlKey && event.keyCode == Keyboard.C)
                {
                    // Separator used between Strings sent to clipboard
                    // to separate selected cells.
                    const separator:String = ",";
                    // The String sent to the clipboard
                    var dataString:String = "";

                    // Loop over the selectedCells property.
                    // Data in selectedCells is ordered so that
                    // the last selected cell is at the head of the list.
               const selectedCells:Vector.<CellPosition> = event.currentTarget.selectedCells;
                    const n:int = selectedCells.length;
                    for (var i:int = 0; i < n; i++)
                    {
                        // Get the cell position.
                        var cell:CellPosition = selectedCells[i];
                        // Get the row for the selected cell.
                        var data:Object =
                            event.currentTarget.grid.dataProvider[cell.rowIndex];

                        // Get the name of the field for the selected cell.
                        var dataField:String =
                            event.currentTarget.grid.columns[cell.columnIndex].dataField;

                        // Get the cell data using the field name.
                        dataString = data[dataField] + separator + dataString;
                    }

                    // Remove trailing separator.
                    dataString =
                        dataString.substr(0, dataString.length - separator.length);

                    // Write dataString to the clipboard.
                    System.setClipboard(dataString);
                }
            }
        ]]>
    </fx:Script>

    <s:DataGrid
        selectionMode="multipleCells"
        keyUp="myKeyUpHandler(event);">
        <s:ArrayCollection>
            <fx:Object>
                <fx:Artist>Pavement</fx:Artist>
                <fx:Price>11.99</fx:Price>
                <fx:Album>Slanted and Enchanted</fx:Album>
            </fx:Object>
            <fx:Object>
                <fx:Artist>Pavement</fx:Artist>
                <fx:Album>Brighten the Corners</fx:Album>
                <fx:Price>11.99</fx:Price>
            </fx:Object>
        </s:ArrayCollection>
        <s:columns>
            <s:ArrayCollection>
                <s:GridColumn dataField="Artist"/>
                <s:GridColumn dataField="Album"/>
                <s:GridColumn dataField="Price"/>
            </s:ArrayCollection>
        </s:columns>
    </s:DataGrid>

    <s:TextArea id="myTA" text="Paste selected cells here ..."/>
</s:Application>
```

Working with the caret in the Spark DataGrid control

Depending on the selection mode of the DataGrid control, the *caret* is the row or cell that currently responds to keyboard input. The caret can be the currently selected cell or row, or a different cell or row. The `Grid.caretRowIndex` and `Grid.caretColumnIndex` properties represent the caret location.

Change the caret with a combination of the Control and Arrow keys. You can select the caret by pressing the Space key. If multiple selection is enabled, press the Space key to add the caret to the list of selected cells or rows. Toggle selection of the caret by using the Control-Space keys.

The following example uses the `caretChange` event and the `selectionChange` event to display the location of the caret and of the selected row:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- dpcontrols\sparkdpcontrols\SparkDGCaret.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    height="450" width="450">
    <s:layout>
        <s:VerticalLayout paddingTop="5" paddingLeft="5"/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import spark.events.GridCaretEvent;
            import spark.events.GridSelectionEvent;
            import spark.components.Grid;
            protected function selectionChangeHandler(event:GridSelectionEvent):void {
                const eventGrid:Grid = event.currentTarget.grid;
                selLabel.text = "The selected row is: " +
                    String(eventGrid.selectedIndex);
                caretLabel.text = "The caret row is: " +
                    String(eventGrid.caretRowIndex);
            }
            protected function caretChangeHandler(event:GridCaretEvent):void {
                const eventGrid:Grid = event.currentTarget.grid;
                selLabel.text = "The selected row is: " +
                    String(eventGrid.selectedIndex);
                caretLabel.text = "The caret row is: " +
                    String(eventGrid.caretRowIndex);
            }
        ]]>
    </fx:Script>

    <s:Label id="selLabel"/>
    <s:Label id="caretLabel"/>

    <s:DataGrid id="myDG" width="100%"
        selectionChange="selectionChangeHandler(event);"
        caretChange="caretChangeHandler(event);">
        <s:ArrayCollection>
            <fx:Object firstName="Bill" lastName="Smith" companyID="11233"/>
            <fx:Object firstName="Dave" lastName="Jones" companyID="13455"/>
            <fx:Object firstName="Mary" lastName="Davis" companyID="11543"/>
            <fx:Object firstName="Debbie" lastName="Cooper" companyID="14266"/>
        </s:ArrayCollection>
    </s:DataGrid>
</s:Application>
```

To see the difference between the `selectedIndex` and the `caretIndex` properties:

1 Select a row in the DataGrid control by clicking it. Notice that the selected row is also the caret, and that the `selectedIndex` and the `caretIndex` properties have the same value.

2 Use the Up Arrow and Down Arrow keys to move the selected row. Notice that the `selectedIndex` and the `caretIndex` properties have the same value.

3 With a row selected:

- (On Windows) Hold down the Control key, and then use the Up Arrow and Down Arrow keys to move the caret.
- (On OSX) Hold down the Command key, and then use the Up Arrow and Down Arrow keys to move the caret.

Notice that the control highlights the caret row, but the index of the selected row does not change. Press the Space key to select the caret row.

Handle data binding warnings for the Spark DataGrid control

The Spark DataGrid can work with static data, meaning data that does not change at runtime. For example, you can define static data as an ArrayCollection of Objects. The following example defines static data in the DataGrid control:

```
<s:DataGrid>
    <s:dataProvider>
        <s:ArrayCollection>
            <fx:Object Artist="Pavement" Album="Slanted and Enchanted"
                Price="11.99" Cover="../assets/slanted.jpg"/>
            <fx:Object Artist="Pavement" Album="Brighten the Corners"
                Price="11.99" Cover="../assets/brighten.jpg"/>
        </s:ArrayCollection>
    </s:dataProvider>
...
</s:DataGrid>
```

Dynamic data is data that can change at runtime. When dynamic data changes, you want to ensure that the DataGrid recognizes those changes so that it updates its display accordingly.

The item renderer and item editor mechanism used by the Spark DataGrid control relies on data binding to items in the data provider. Data binding is event driven. That means an item in the data provider must be able to dispatch events to indicate that the item has changed. By using the data binding mechanism, the DataGrid control can update its display at runtime when an item changes.

In the previous example that used static data, you used the Object class to define the items of the data provider. The Object class does not dispatch events when it changes and, therefore, does not support data binding. The compiler recognizes this situation and issues a warning when you compile the application. You can ignore that warning for applications that use static data.

One way to add event support to items in the data provider is to make sure the class that defines the items is a subclass of the flash.events.EventDispatcher class. Or, ensure that the class implements the event mechanism.

Flex provides the spark.utils.DataItem class that is a subclass of Object and supports events. Therefore, you can rewrite the previous example to use DataItem and support data binding, as shown below:

```
<s:DataGrid>
    <s:dataProvider>
        <s:ArrayCollection>
            <fx:DataItem Artist="Pavement" Album="Slanted and Enchanted"
                Price="11.99" Cover="../assets/slanted.jpg"/>
            <fx:DataItem Artist="Pavement" Album="Brighten the Corners"
                Price="11.99" Cover="../assets/brighten.jpg"/>
        </s:ArrayCollection>
    </s:dataProvider>
...
</s:DataGrid>
```

Because the DataItem class can dispatch events when the data changes, you can modify the data at runtime and have those changes reflected in the DataGrid.

Alternatively, you can represent your data by creating a class that includes the `[Bindable]` metadata tag in the class definition. When you include the `[Bindable]` metadata tag, Flex automatically adds support for event dispatching to the class.

For example, you create the following subclass of Object that supports data binding by using the `[Bindable]` metadata tag:

```
package myComponents
{
    [Bindable]
    public class MyBindableObj extends Object
    {
        public function MyBindableObj() {
            super();
        }

        public var Artist:String;

        public var Album:String;

        public var Price:Number;

        public var Cover:String;
    }
}
```

By inserting the `[Bindable]` metadata tag before the class definition, you specify that all public properties support data binding. You can then use your custom class to define the data provider, as the following example shows:

```
<?xml version="1.0"?>
<!-- binding/SparkDGBindingClass.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:myComp="myComponents.*">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <s:DataGrid>
        <s:dataProvider>
            <s:ArrayCollection>
                <myComp:MyBindableObj Artist="Pavement"
                    Album="Slanted and Enchanted"
                    Price="11.99"
                    Cover="../assets/slanted.jpg"/>
                <myComp:MyBindableObj Artist="Pavement"
                    Album="Brighten the Corners"
                    Price="11.99"
                    Cover="../assets/brighten.jpg"/>
            </s:ArrayCollection>
        </s:dataProvider>
    </s:DataGrid>
</s:Application>
```

Creating item renderers and item editors for the Spark DataGrid control

You can create custom item renderers and item editors to control the display of the cells of the Spark DataGrid and Grid controls. You can also create custom item renderers for the header cells of each column of the grid.

You set a custom renderer or editor for each column of the grid. Use the `GridColumn.itemRenderer`, `GridColumn.itemEditor`, and `GridColumn.headerRenderer` properties to specify your custom renderer or editor.

You typically create custom item renderers and item editors in MXML. However, for the highest performance, create them in ActionScript.

Adobe Engineer Joan Lafferty creates a custom item renderer for the Spark DataGrid control in Using a DateField itemRenderer for a Spark DataGrid

The IGridItemRenderer and IGridItemEditor interfaces

Item and header renderers must implement the IGridItemRenderer interface. Item editors must implement the IGridItemEditor interface. The following table describes these interfaces:

Interface	Implemented by	Notes
IGridItemRenderer	Custom item and header renderers	All custom item and header renderers must implement the IGridItemRenderer interface. The base interface of IGridItemRenderer is IDataRenderer, the interface implemented by item renderers for the Spark list-based controls.
IGridItemEditor	Custom item editors	All custom item editors must implement the IGridItemEditor interface. The base interface of IGridItemEditor is IDataRenderer.

Using the predefined item renderers

When using the DataGrid control, you want to ensure the highest performance possible. One of the main factors affecting performance is the time required to render of each visible cell of the grid. Therefore, you want your item renderers to perform at the highest level.

Flex defines several item renderers that you can use to achieve high performance with the DataGrid control. By default, the DataGrid control uses the DefaultGridItemRenderer renderer. This renderer is written in ActionScript to provide good performance across all platforms.

The following table describes the item renderer classes that ship with Flex:

Item Renderer	Use
spark.skins.spark.DefaultGridItemRenderer	The default item renderer that displays the cell data in a text label using the UIFTETextField control. This class is not intended to be extended. Create a custom item renderer based on the GridItemRenderer class. Because it supports the Flash Text Engine (FTE), this item render also supports bidirectional text.
spark.skins.spark.UITextFieldGridItemRenderer	Optimized for deployment on Microsoft Windows. For Windows, it provides improved performance over the DefaultGridItemRenderer. For other operating systems, use DefaultGridItemRenderer for best performance. Because it is based on the TextField component, this item renderer does not support bidirectional text.
spark.components.gridClasses.GridItemRenderer	The base class for custom item renderers. This class implements the IGridItemRenderer interface.

Creating an item renderer for a Spark DataGrid

Item renderers for the Spark list-based controls, such as List, must implement the IDataRenderer interface. Item renderers for the Spark DataGrid must implement the IGridItemRenderer interface, which is derived from the IDataRenderer interface. Therefore, the process of creating an item renderer for the DataGrid is similar to creating one for the List control.

An item renderer is associated with a column of the DataGrid control. The item renderer then controls the appearance of each cell in the column. However, each item renderer has access to the data item for an entire row of the DataGrid control. Use the `data` property of the item renderer to access the data item.

By accessing the data item for the entire row, the item renderer can display multiple data fields, or display a single value created from multiple fields. For example, each row of the data provider for the DataGrid control in the following example contains four fields:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- dpcontrols\sparkdpcontrols\SparkDGComplexIR.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    width="450" height="450">

    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;

            // Data includes URL to album cover.
            [Bindable]
            private var initDG:ArrayCollection = new ArrayCollection([
                {Artist:'Pavement', Album:'Slanted and Enchanted',
                    Price:11.99, Cover:'assets/slanted.jpg'},
                {Artist:'Pavement', Album:'Brighten the Corners',
                    Price:11.99, Cover:'assets/brighten.jpg'}
            ]);
        ]]>
    </fx:Script>

    <s:DataGrid id="myGrid"
        dataProvider="{initDG}"
        variableRowHeight="true">
        <s:columns>
            <s:ArrayList>
                <s:GridColumn dataField="Artist"/>
                <s:GridColumn dataField="Album" itemRenderer="myComponents.DGComplexIR"/>
                <s:GridColumn dataField="Price"/>
            </s:ArrayList>
        </s:columns>
    </s:DataGrid>
</s:Application>
```

However, the DataGrid control only defines three columns. It then uses the DGComplexIR.mxml item renderer to display the Album and Cover fields in a single column. The item render is shown below:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- dpcontrols\sparkdpcontrols\myComponents\DGComplexIR.mxml -->
<s:GridItemRenderer xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:VGroup height="100" paddingTop="10">
        <s:Label id="albumName"
            width="100%"
            text="{data.Album}"/>
        <s:Image id="albumImage"
            source="{data.Cover}"/>
    </s:VGroup>
</s:GridItemRenderer>
```

Notice how the item renderer uses the `data` property of the item renderer to access the data item that corresponds to the entire row of the DataGrid control.

Creating inline renderers

In the previous example, the item renderer was defined in a file separate from the main application file. You can define inline item renderers for the DataGrid control. By using an inline item renderer, your code can all be defined in a single file. To define an inline item renderer, you use the `<fx:Component>` tag. For example using inline item renderers, see "Defining an inline item renderer for a Spark container" on page 491.

The following example creates an inline item renderer by using the Spark Label control:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- dpcontrols\sparkdpcontrols\SparkDGStyledIR.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    width="450" height="450">

    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;

            // Data includes URL to album cover.
            [Bindable]
            private var initDG:ArrayCollection = new ArrayCollection([
                {Artist:'Pavement', Album:'Slanted and Enchanted',
                    Price:11.99, Cover:'../assets/slanted.jpg'},
                {Artist:'Pavement', Album:'Brighten the Corners',
                    Price:11.99, Cover:'../assets/brighten.jpg'}
            ]);
        ]]>
    </fx:Script>

    <s:DataGrid id="myGrid"
        dataProvider="{initDG}"
        variableRowHeight="true">
        <s:columns>
            <s:ArrayList>
                <s:GridColumn dataField="Artist">
                    <s:itemRenderer>
                        <fx:Component>
                            <s:GridItemRenderer>
                                <s:Label id="labelDisplay" fontSize="24"/>
                            </s:GridItemRenderer>
                        </fx:Component>
                    </s:itemRenderer>
                </s:GridColumn>
                <s:GridColumn dataField="Album"/>
                <s:GridColumn dataField="Price"/>
            </s:ArrayList>
        </s:columns>
    </s:DataGrid>
</s:Application>
```

Creating a header renderer for a Spark DataGrid

The DataGridSkin class uses the GridColumnHeaderGroup component to control the display of the column headers. The GridColumnHeaderGroup component displays a row of headers cells, where the vertical edges of the header cells are aligned with the grid columns.

The GridColumnHeaderGroup component arranges header renderer instances in a row, where the left and right edge of each renderer match the corresponding column. The renderers' height is the maximum preferred height for all of the displayed header renderers.

Like the Grid control and item renderers, the GridColumnHeaderGroup class only creates as many column header renderers and separators as are visible. Renderers and separators that have been scrolled out of view are recycled.

By default, the GridColumnHeaderGroup component uses the spark.skins.spark.DefaultGridHeaderRenderer class as the header renderer. To create a custom header renderer, define the renderer in MXML or ActionScript. Header renderers must implement the IGridItemRenderer interface.

Then, use the `Grid.headerRenderer` property to specify to use the custom renderer for the column.

Creating an item editor for a Spark DataGrid

The DataGrid control includes an `editable` property that you set to `true` to let users edit grid cells. By default, the value of the `editable` property is `false`, which means that you cannot edit the cells.

For a DataGrid control, setting the `editable` property to `true` enables editing for all columns of the grid. You can disable editing for any column by setting the `GridColumn.editable` property to `false`.

Item editing is cell based. To edit a cell, first select the cell or cell row, depending on the selection mode of the grid. Then select the cell to edit. If editing is enabled, an item editor appears over the selected cell.

***Note:** While an item editor is associated with a single cell, the editor actually has access to the data provider element for the entire row of the selected cell. Therefore, the item editor can access and modify any data for the row.*

All item editors must implement the IGridItemEditor interface. The GridItemEditor class implements the IGridItemEditor interface. GridItemEditor also adds the `value` property that you can use to pass data to and from the item editor. Most custom item editors are created as subclasses of GridItemEditor.

The two most important questions when dealing with an item editor are:

- How do you pass data to the item editor?

  Use the bindable `GridItemEditor.value` property to pass data to the item editor. The data type of the `value` property is Object, so you can use it to pass a single value to the item editor, or you can use it to pass multiple items as fields of the Object.

  The GridItemEditor class implements the `value` property as a setter and a getter method. When the item editor is created, Flex calls the setter method, passing the cell data from the data provider item for the row. Typically, you override the setter method in your item editor to initialize any items in the item editor from the cell data. The `value` property only exists while the item editor is open.

  To access the data provider element for the entire row, use the `data` property of the item renderer.

- How do you pass data back to the DataGrid control from the item editor?

  Use the `GridItemEditor.value` property to pass data back to the control. Typically, in your item editor you override the getter method for the `value` property to return any results back to the DataGrid control. The DataGrid control writes the returned value to the data field of the data provider element for the row that corresponds to the edited cell.

  The item editor uses the `IGridItemEditor.save()` method to write the `value` property to the data provider of the DataGrid control. You can override the `save()` method to control how the `value` property is written to the data provider. For example, the item editor might return multiple values that you want to write to multiple fields of the data provider element for the row. Override the `save()` method in this situation to update the data provider.

Using the predefined item editors

Flex ships with two item editors that you can use in your application. The following table describes these item editor classes:

Item Editor	Use
spark.components.gridClasses.DefaultGridItemEditor	Uses a Spark TextArea control to let you edit the text value of a cell. By default, the DataGrid control uses the DefaultGridItemEditor class.
spark.components.gridClasses.ComboBoxGridItemEditor	Uses a Spark ComboBox control to display a drop-down list of cell values. Select a value to set the new value of the cell.

The following example shows a DataGrid control that uses the ComboBoxGridItemEditor class as the item editor:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- dpcontrols\sparkdpcontrols\SparkDGComboBoxIE.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
               xmlns:s="library://ns.adobe.com/flex/spark"
               xmlns:mx="library://ns.adobe.com/flex/mx"
               width="450">
    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;

            [Bindable]
            private var myDP:ArrayCollection = new ArrayCollection([
                {label1:"Order #2314", quant:3, color:'red'},
                {label1:"Order #2315", quant:3, color:'red'}
            ]);
        ]]>
    </fx:Script>

    <s:DataGrid id="myDG" width="100%"
                dataProvider="{myDP}"
                variableRowHeight="true"
                editable="true" >
        <s:columns>
            <s:ArrayList>
                <s:GridColumn dataField="label1" headerText="Order #"/>
                <s:GridColumn dataField="quant" headerText="Qty"/>
                <s:GridColumn dataField="color" headerText="Color">
                    <s:itemEditor>
                        <fx:Component>
                            <s:ComboBoxGridItemEditor>
                                <s:dataProvider>
                                    <s:ArrayList>
                                        <fx:String>red</fx:String>
                                        <fx:String>green</fx:String>
                                        <fx:String>blue</fx:String>
                                    </s:ArrayList>
                                </s:dataProvider>
                            </s:ComboBoxGridItemEditor>
                        </fx:Component>
                    </s:itemEditor>
                </s:GridColumn>
            </s:ArrayList>
        </s:columns >
    </s:DataGrid>
</s:Application>
```

The item editing process

The following steps describe the lifecycle of an item editor:

1 An editing session begins in response to a user gesture, such as the user clicking a selected cell. You can also make an explicit call to the `DataGrid.startItemEditorSession()` method to start the editing session.

2 Before the item editor appears, the DataGrid dispatches the `gridItemEditorSessionStarting` event.

You can cancel the editing session by calling the `preventDefault()` method in the event handler for the `gridItemEditorSessionStarting` event.

3 Flex sets the `rowIndex`, `column`, and `data` properties of the item editor. The `data` property contains the data provider item for the entire row.

Flex sets the `value` property of the item editor to the value of the field in the data provider element that corresponds to the cell being edited.

4 Flex calls the `IGridItemEditor.prepare()` method.

When the `prepare()` method is called, the editor's size and location have been set and the editor's layout has been validated. You can override the `prepare()` method to make any final modifications to the editor, such as modifying its visual characteristics or attaching event handlers.

5 Flex makes the editor visible by setting its `visible` property to `true`.

6 The DataGrid dispatches the `gridItemEditorStart` event.

7 When the item editor is first displayed, it is given keyboard focus and its `setFocus()` method is called. You typically override the `setFocus()` method of the item editor to shift the focus to a specific component in the item editor.

8 The user interacts with the editor.

9 The edit session ends when the user presses the Enter key to save the data, or the Escape key to cancel the edit. The session also ends, and the data is saved, when the users clicks outside the editor, or the editor loses keyboard focus.

If the editing session is saved, Flex calls the `IGridtemEditor.saved()` method to write the `value` property back to the data provider.

You can end the editing sessions programmatically by calling the `DataGrid.endEditorSession()` method.

10 Flex calls the `IGridtemEditor.discard()` method.

Override the `discard()` method to reverse any settings you made in the `prepare()` method, such as removing event handles, or perform any other cleanup.

11 The DataGrid dispatches either the `gridItemEditorSessionSave` or `gridItemEditorSessionCancel` event.

Example custom item editor

The following example shows a DataGrid control that uses and item editor to let the user change the value of the quant field of the data provider. The second column of the control specifies to use the DGNumStepperEditor.mxml item editor:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- dpcontrols\sparkdpcontrols\SparkDGItemEditor.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    width="450">
    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;

            [Bindable]
            private var myDP:ArrayCollection = new ArrayCollection([
                {label1:"Order #2314", quant:3, Sent:true},
                {label1:"Order #2315", quant:3, Sent:false}
            ]);
        ]]>
    </fx:Script>

    <s:DataGrid id="myDG" width="100%"
        dataProvider="{myDP}"
        variableRowHeight="true"
        editable="true" >
        <s:columns>
            <s:ArrayList>
                <s:GridColumn dataField="label1" headerText="Order #"/>
                <s:GridColumn dataField="quant"
                    headerText="Qty"
                    itemEditor="myComponents.DGNumStepperEditor"/>
            </s:ArrayList>
        </s:columns >
    </s:DataGrid>
</s:Application>
```

The DGNumStepperEditor.mxml item editor defines a NumericStepper control to set an integer value. The item editor overrides the setter method for the `value` property to initialize the NumericStepper control with the current value of the cell.

The override of the getter method for the `value` property returns the current value of the NumericStepper control. The `save()` method updates the data provider element for the row of the grid with this value. The DGNumStepperEditor.mxml item editor is shown below:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- dpcontrols\sparkdpcontrols\myComponents\DGNumStepperEditor.mxml -->
<s:GridItemEditor xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[

            // Override the setter to initialize the NumericStepper control
            // with the cell data.
            override public function set value(newValue:Object):void {
                ns.value = newValue as Number;
            }
            // Override the getter to return the current value of
            // the NumericStepper control.
            // The save() method updates the data provider element for the
            // row of the grid with this value.
            override public function get value():Object {
                return ns.value;
            }

            // Override setFocus() to shift focus to the NumericStepper.
            override public function setFocus():void {
                ns.setFocus();
            }
        ]]>
    </fx:Script>
    <s:NumericStepper id="ns" width="100%"
        fontWeight="bold"/>
</s:GridItemEditor>
```

Keyboard and mouse shortcuts with item editors for the Spark DataGrid

The following table describes how the item editor responds to user interaction:

User interaction	Response
F2	If cell selection mode is enabled, edit the cell indicated by the caret. If row selection mode is enabled, and a cell has not been edited before, edit the first visible cell in the row indicated by the caret. Otherwise edit the cell in the last edited column in the caret row.
Enter	Save the editor's value and close the editor.
Esc	Cancel the editing session by closing the editor without saving the value.
Tab	Save the editor's value, close the editor, and open the editor in the next column that is editable.
Shift+Tab	Save the editor's value, close the editor, and open the editor in the first previous column that is editable.
Ctrl+.	Cancel the editing session by closing the editor without saving the value.
Ctrl+Enter	Save the editor's value, close the editor, and move selection to the same column in the next row.
Ctrl+Shift+Enter	Save the editor's value, close the editor, and move selection to the same column in the previous row.
Single mouse click	Open the editor in response to a single click on the selected cell. The cell must already be selected. If the Shift or Ctrl key is pressed when the click occurs, then the editor does not open because the Shift and Ctrl keys are used to modify the selection.

Create a custom sort for the Spark DataGrid control

By default, users can sort the row of a DataGrid by clicking the column headers. Clicking the column header initially sorts the display in descending order of the entries in the selected column, and clicking the header again reverses the sort order. For an example, see "Sorting the columns of the Spark DataGrid control" on page 551.

The GridColumn`sortCompareFunction` property lets you specify a custom comparison function used to sort the rows by that column. This property sets the `compareFunction` property of the default Spark SortField class object used by the DataGrid.

The `sortCompareFunction` property lets you specify the function that compares two objects and determines which would be higher in the sort order, without requiring you to explicitly create a Sort object on your data provider.

The comparison function passed to the `sortCompareFunction` property must have the following signature:

```
function sortCompareFunction(obj1:Object, obj2:Object, gc:GridColumn):int {
    // Sort logic
}
```

The `obj1` and `obj2` arguments specify the objects to compare, and `gc` specifies the column of the DataGrid control to sort.

Flex ships with two collator classes to help you write your comparison function. The spark.globalization.MatchingCollator and spark.globalization.SortingCollator provide locale-sensitive string comparison functions.

By default, the sorting used by the DataGrid control is case sensitive. In the following example, you use the SortingCollator class to perform a case-insensitive comparison of two cells to sort the Name column of the DataGrid:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- dpcontrols\sparkdpcontrols\SparkDGXMLSort.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    width="500" height="600">
    <s:layout>
        <s:VerticalLayout paddingTop="10"/>
    </s:layout>
    <fx:Declarations>
        <fx:XMLList id="employees">
            <employee>
                <name>Joanne Wall</name>
                <phone>555-219-2012</phone>
                <email>jwall@fictitious.com</email>
                <active>true</active>
            </employee>
            <employee>
                <name>Mary Jones</name>

    </s:DataGrid>
</s:Application>
```

Spark DataGrid control keyboard shortcuts

A DataGrid control displays a grid of rows and columns. Depending on the available screen space, all rows and columns might not be currently visible. Paging down through the data items displayed by a 10-row control shows items 0-9, 10-19, 20-29, and so on.

The user clicks individual data items to select them. If the DataGrid is configured for multiple selection, holds down Shift key while clicking to select multiple items.

The control has the following default keyboard navigation features:

Key	Action
Up Arrow	Moves selection up one item. Hold down the Control key (Windows) or Command key (OSX) to only move the caret, but not change selection.
Down Arrow	Moves selection down one item. Hold down the Control key (Windows) or Command key (OSX) to only move the caret, but not change selection.
Left Arrow	In cell selection mode, moves selection one column to the left. Hold down the Control key (Windows) or Command key (OSX) to only move the caret, but not change the selected cell.
Right Arrow	In cell selection mode, moves selection one column to the right. Hold down the Control key (Windows) or Command key (OSX) to only move the caret, but not change the selected cell.
Page Up	Moves selection up one page.
Page Down	Moves selection down one page.
Home	Moves selection to the top of the grid.
End	Moves selection to the bottom of the grid.
Control key (Windows) and Command key (OSX) and a navigation key	Allows for multiple, noncontiguous selection and deselection in multiple selection mode. Works with Arrow keys, Page Up key, Page Down key, mouse click, and mouse drag.
Shift key and a navigation key	Allows for contiguous selection in multiple selection mode. Works with keypresses, click selection, and drag selection. Works with Arrow keys, Page Up key, Page Down key, mouse click, and mouse drag.

Key	Action
Control-A	Select all grid items
Space	Adds the caret to the selection list
Control-Space	Toggle the selection of the caret.
Shift-Space	Extends selection from the anchor to the caret

MX layout containers

In Adobe® Flex®, MX layout containers provide a hierarchical structure to arrange and configure the components, such as Button and ComboBox controls, of a Flex application.

For detailed information on how Flex lays out containers and their children, see “Laying out components” on page 359.

Flex also provides a set of Spark containers. These containers are designed to simplify skinning and optimize performance. Adobe recommends that you use the Spark containers when possible. For more information, see “Spark containers” on page 417.

About layout containers

A layout container defines a rectangular region of the Adobe® Flash® Player drawing surface and controls the sizing and positioning of the child controls and child containers defined within it. For example, a Form layout container sizes and positions its children in a layout similar to an HTML form.

To use a layout container, you create the container, and then add the components that define your application.

MX Canvas layout container

A Canvas layout container defines a rectangular region in which you place child containers and controls. Unlike all other components, you cannot let Flex lay child controls out automatically. You must use *absolute* or *constraint-based* layout to position child components. With absolute layout you specify the *x* and *y* positions of the children; with constraint-based layout you specify side, baseline, or center anchors. For detailed information on using these layout techniques, see “Laying out components” on page 359.

***Note:** Adobe recommends that, when possible, you use the Spark containers with BasicLayout instead of the MX Canvas container. For more information, see “Spark containers” on page 417.*

For complete reference information, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

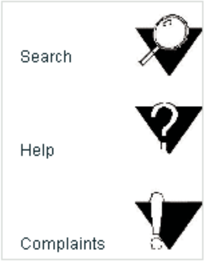
Creating and using a Canvas control

You define a canvas control in MXML by using the `<mx:Canvas>` tag. Specify an `id` value if you intend to refer to a component elsewhere in your MXML, either in another tag or an ActionScript block.

Creating a Canvas Control by using absolute positioning

You can use the x and y properties of each child to specify the child's location in the Canvas container. These properties specify the *x* and *y* coordinates of a child relative to the upper-left corner of the Canvas container, where the upper-left corner is at coordinates (0,0). Values for the *x* and *y* coordinates can be positive or negative integers. You can use negative values to place a child outside the visible area of the container, and then use ActionScript to move the child to the visible area, possibly as a response to an event.

The following example shows a Canvas container with three LinkButton controls and three Image controls:



The following MXML code creates this Canvas container:

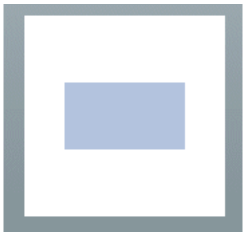
```
<?xml version="1.0"?>
<!-- containers\layouts\CanvasSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <mx:Canvas id="myCanvas"
      height="200" width="200"
      borderStyle="solid"
      backgroundColor="white">
      <mx:LinkButton label="Search"
        x="10" y="30"
        click="navigateToURL(new
URLRequest('http://www.adobe.com/cfusion/search/index.cfm'))"/>
      <mx:Image
        height="50" width="50"
        x="100" y="10"
        source="@Embed(source='assets/search.jpg')"
        click="navigateToURL(new
URLRequest('http://www.adobe.com/cfusion/search/index.cfm'))"/>
      <mx:LinkButton label="Help"
        x="10" y="100"
        click="navigateToURL(new URLRequest('http://www.adobe.com/go/gn_supp'))"/>
      <mx:Image
        height="50" width="50"
        x="100" y="75"
        source="@Embed(source='assets/help.jpg')"
        click="navigateToURL(new URLRequest('http://www.adobe.com/go/gn_supp'))"/>
      <mx:LinkButton label="Complaints"
        x="10" y="170"
        click="navigateToURL(
            new URLRequest('http://www.adobe.com/go/gn_contact'))"/>
      <mx:Image
        height="50" width="50"
        x="100" y="140"
        source="@Embed(source='assets/complaint.jpg')"
        click="navigateToURL(
            new URLRequest('http://www.adobe.com/go/gn_contact'))"/>
    </mx:Canvas>
</s:Application>
```

Creating a Canvas container by using constraint-based layout

You can also use *constraint-based layout* to anchor any combination of the top, left, right, bottom sides, and baseline of a child at a specific distance from the Canvas edges, or to anchor the horizontal or vertical center of the child at a specific (positive or negative) pixel distance from the Canvas center. To specify a constraint-based layout, use the `top`, `bottom`, `left`, `right`, `baseline`, `horizontalCenter`, and `verticalCenter` styles. When you anchor the top and bottom, or the left and right sides of the child container to the Canvas sides, if the Canvas control resizes, the children also resize. The following example uses constraint-based layout to position an HBox horizontally, and uses absolute values to specify the vertical width and position:

```
<?xml version="1.0"?>
<!-- containers\layouts\CanvasConstraint.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    backgroundColor="gray"
    height="200" width="200">
    <mx:Canvas
        width="150" height="150"
        horizontalCenter="0" verticalCenter="0"
        backgroundColor="#FFFFFF">
        <mx:HBox id="hBox2"
            left="30"
            right="30"
            y="50"
            height="50"
            backgroundColor="#A9C0E7">
        </mx:HBox>
    </mx:Canvas>
</s:Application>
```

The example produces the following image:



Preventing overlapping children

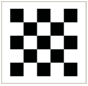
When you use a Canvas container, some of your components may overlap, because the Canvas container ignores its children's sizes when it positions them. Similarly, children components may overlap any borders or padding, because the Canvas container does not adjust the coordinate system to account for them.

In the following example, the size and position of each component is carefully calculated to ensure that none of the components overlap:

```
<?xml version="1.0"?>
<!-- containers\layouts\CanvasOverlap.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    width="100" height="100">
    <fx:Script>
        <![CDATA[
            [Embed(source="assets/BlackBox.jpg")]
            [Bindable]
            public var imgCls:Class;
        ]]>
    </fx:Script>

    <mx:Canvas id="chboard" backgroundColor="#FFFFFF">
        <mx:Image source="{imgCls}"
            width="10" height="10" x="0" y="0"/>
        <mx:Image source="{imgCls}"
            width="10" height="10" x="20" y="0"/>
        <mx:Image source="{imgCls}"
            width="10" height="10" x="40" y="0"/>
        <mx:Image source="{imgCls}"
            width="10" height="10" x="10" y="10"/>
        <mx:Image source="{imgCls}"
            width="10" height="10" x="30" y="10"/>
        <mx:Image source="{imgCls}"
            width="10" height="10" x="0" y="20"/>
        <mx:Image source="{imgCls}"
            width="10" height="10" x="20" y="20"/>
        <mx:Image source="{imgCls}"
            width="10" height="10" x="40" y="20"/>
        <mx:Image source="{imgCls}"
            width="10" height="10" x="10" y="30"/>
        <mx:Image source="{imgCls}"
            width="10" height="10" x="30" y="30"/>
        <mx:Image source="{imgCls}"
            width="10" height="10" x="0" y="40"/>
        <mx:Image source="{imgCls}"
            width="10" height="10" x="20" y="40"/>
        <mx:Image source="{imgCls}"
            width="10" height="10" x="40" y="40"/>
    </mx:Canvas>
</s:Application>
```

This example produces the following image:



If you set the `width` and `height` properties of one of the images to 20 pixels but don't change the positions accordingly, that image overlaps other images in the checkerboard. For example, if you replace the seventh `<mx:Image>` tag in the preceding example with the following line, the resulting image looks like the following image:

```
<mx:Image source="{imgCls}" width="20" height="20" x="20" y="20"/>
```

Repositioning children at run time

You can build logic into your application to reposition a child of a Canvas container at run time. For example, in response to a button click, the following code repositions an input text box that has the `id` value `text1` to the position x=110, y=110:

```
<?xml version="1.0"?>
<!-- containers\layouts\CanvasRepos.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <mx:Canvas
        width="300" height="185"
        backgroundColor="#FFFFFF">
        <mx:TextInput id="text1"
            text="Move me"
            x="10" y="10"
        />
        <mx:Button id="button1"
            label="Move text1"
            x="10" y="150"
            click="text1.x=110; text1.y=110;"
        />
        <mx:Button label="Reset"
            click="text1.x=10; text1.y=10;" x="111" y="150"/>
    </mx:Canvas>
</s:Application>
```

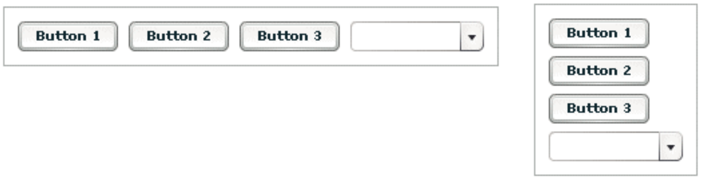
MX Box, HBox, and VBox layout containers

The Box layout container lays out its children in a single vertical column or a single horizontal row. You use the `direction` property of a Box container to determine either vertical (default) or horizontal layout. The HBox and VBox containers are Box containers with `horizontal` and `verticaldirection` property values.

Note: *Adobe recommends that, when possible, you use the Spark containers with HorizontalLayout or VerticalLayout instead of the MX box containers. For more information, see "Spark containers" on page 417.*

To lay out children in multiple rows or columns, use a Tile or Grid container. For more information, see "MX Tile layout container" on page 612 and "MX Grid layout container" on page 603.

The following example shows one Box container with a horizontal layout and one with a vertical layout:



For complete reference information, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Creating a Box, HBox, or VBox container

You use the `<mx:Box>`, `<mx:VBox>`, and `<mx:HBox>` tags to define Box containers. Use the VBox (vertical box) and HBox (horizontal box) containers as shortcuts so you do not have to specify the `direction` property in the Box container. Specify an `id` value if you intend to refer to a component elsewhere in your MXML, either in another tag or in an ActionScript block.

The following example creates a Box container with a vertical layout:

```
<?xml version="1.0"?>
<!-- containers\layouts\BoxSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <mx:Box direction="vertical"
        borderStyle="solid"
        paddingTop="10"
        paddingBottom="10"
        paddingLeft="10"
        paddingRight="10">
        <mx:Button id="fname" label="Button 1"/>
        <mx:Button id="lname" label="Button 2"/>
        <mx:Button id="addr1" label="Button 3"/>
        <mx:ComboBox id="state">
              <mx:ArrayList>
                 <fx:String>ComboBox 1</fx:String>
              </mx:ArrayList>
        </mx:ComboBox>
    </mx:Box>
</s:Application>
```

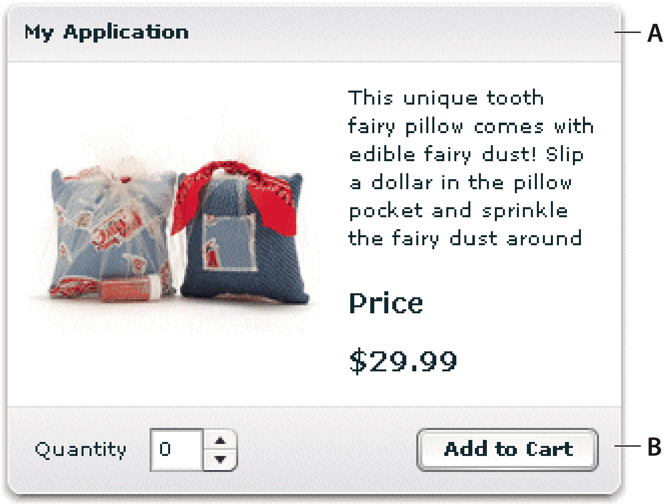
The following code example is equivalent to the previous example, except that this example defines a vertical Box container by using the `<mx:VBox>` tag:

```
<?xml version="1.0"?>
<!-- containers\layouts\VBoxSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <mx:VBox borderStyle="solid"
        paddingTop="10"
        paddingBottom="10"
        paddingLeft="10"
        paddingRight="10">

        <mx:Button id="fname" label="Button 1"/>
        <mx:Button id="lname" label="Button 2"/>
        <mx:Button id="addr1" label="Button 3"/>
        <mx:ComboBox id="state">
              <mx:ArrayList>
                 <fx:String>ComboBox 1</fx:String>
              </mx:ArrayList>
        </mx:ComboBox>
    </mx:VBox>
</s:Application>
```

MX ControlBar layout container

You use the MX ControlBar container with a MX Panel or MX TitleWindow container to hold components that can be shared by the other children in the Panel or TitleWindow container. For a product catalog, the ControlBar container can hold the Flex controls to specify quantity and to add an item to a shopping cart, as the following example shows:



My Application
This unique tooth fairy pillow comes with edible fairy dust! Slip a dollar in the pillow pocket and sprinkle the fairy dust around
Price
$29.99
Quantity
0
Add to Cart
A
B

A. Panel container *B.* ControlBar container

Note: *You cannot use the MX ControlBar container with the Spark Panel container. The Spark Panel container defines the controlBarContent and controlBarLayout properties that you use the add this functionality. For more information, see "The Spark Panel container" on page 434*

For complete reference information, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Creating an MX ControlBar container

You use the `<mx:ControlBar>` tag to define a ControlBar control in MXML. Specify an `id` value if you intend to refer to a component elsewhere in your MXML code, either in another tag or in an ActionScript block. You specify the `<mx:ControlBar>` tag as the last child tag of an `<mx:Panel>` tag, as the following example shows:

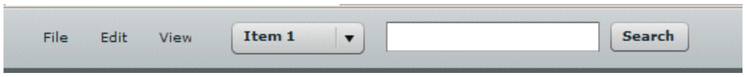
```
<?xml version="1.0"?>
<!-- containers\layouts\CBarSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
            private function addToCart():void {
                // Handle event.
            }
        ]]>
    </fx:Script>
    <mx:Panel title="My Application"
        paddingTop="10" paddingBottom="10"
        paddingLeft="10" paddingRight="10">
        <mx:HBox width="250" height="200">
            <!-- Area for your catalog. -->
        </mx:HBox>

        <mx:ControlBar width="250">
            <mx:Label text="Quantity"/>
            <mx:NumericStepper/>
            <!-- Use Spacer to push Button control to the right. -->
            <mx:Spacer width="100%"/>
            <mx:Button label="Add to Cart"
                click="addToCart();"/>
        </mx:ControlBar>
    </mx:Panel>
</s:Application>
```

MX ApplicationControlBar layout container

You use the MX ApplicationControlBar container to hold components that provide access to application navigation elements and commands. An ApplicationControlBar container for an editor, for example, could include Button controls for setting the font weight, a ComboBox to select the font, and a MenuBar control to select the edit mode. The ApplicationControlBar is a subclass of the ControlBar class; however, it has a different look and feel.

Typically, you place an ApplicationControlBar container at the top of the application, as the following example shows:



If you dock the ApplicationControlBar container at the top of an application, it does not scroll with the application contents.

***Note:** You cannot use the MX ApplicationControlBar container with the Spark Application container. The Spark Application container defines the controlBarContent and controlBarLayout properties that you use the add this functionality. For more information, see “Adding a control bar area to the application container” on page 400*

For complete reference information, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Creating an ApplicationControlBar container

You use the `<mx:ApplicationControlBar>` tag to define a ControlBar control in MXML. Specify an `id` value if you intend to refer to a component elsewhere in your MXML code, either in another tag or in an ActionScript block.

The ApplicationControlBar container can be in either of the following modes:

Docked mode The bar is always at the top of the application's drawing area. Any application-level scroll bars don't apply to the container, so it always remains at the top of the visible area, and the bar expands to fill the width of the application. To created a docked ApplicationControlBar container, set its `dock` property to `true`.

Normal mode The bar can be placed anywhere in the application, is sized and positioned just like any other component, and scrolls with the application. The ApplicationControlBar floats if its `dock` property is `false`. The default value is `false`.

***Note:** In contrast to the ControlBar container, it is possible to set the `backgroundColor` style for an instance of the ApplicationControlBar. The ApplicationControlBar container has two styles, `fillColors` and `fillAlpha`, that are not supported by the ControlBar container.*

The following example shows an application with a simple docked ApplicationControlBar that includes a MenuBar. The Application also includes an HBox control that exceeds the application size; when you scroll the application to view the bottom of the HBox control, the ApplicationControlBar control does not scroll.

```
<?xml version="1.0"?>
<!-- containers\layouts\AppCBarSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    width="550">

            labelField="@label"
            showRoot="true"/>
        <mx:HBox paddingBottom="5"
            paddingTop="5">
            <mx:ComboBox dataProvider="{cmbDP}"/>
            <mx:Spacer width="100%"/>
            <mx:TextInput id="myTI" text=""/>
            <mx:Button id="srch1"
                label="Search"
                click="Alert.show('Searching')"/>
        </mx:HBox>
    </mx:ApplicationControlBar>

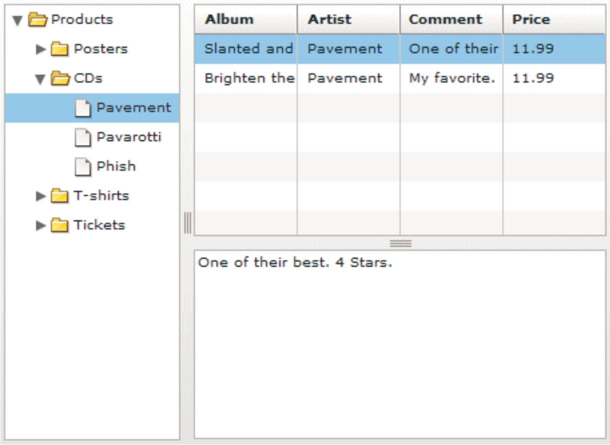
    <mx:TextArea width="300" height="200"/>
</s:Application>
```

MX DividedBox, HDividedBox, and VDividedBox layout containers

The DividedBox layout container lays out its children horizontally or vertically, similar to a Box container, except that it inserts a divider between each child. You can use a mouse pointer to move the dividers in order to resize the area of the container allocated to each child. The DividedBox container can use MX and Spark components as children.

Use the `direction` property of a DividedBox container to determine vertical (default) or horizontal layout. The HDividedBox and VDividedBox containers are DividedBox containers with `horizontal` and `verticaldirection` property values.

The following example shows a DividedBox container:



Album	Artist	Comment	Price
Slanted and	Pavement	One of their	11.99
Brighten the	Pavement	My favorite.	11.99

One of their best. 4 Stars.

In this example, the outermost container is a horizontal DividedBox container. The horizontal divider marks the border between a Tree control and a vertical DividedBox container.

The vertical DividedBox container holds a DataGrid control (top) and a TextArea control (bottom). The vertical divider marks the border between these two controls.

For complete reference information, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Creating a DividedBox, HDividedBox, or VDividedBox container

You use the `<mx:DividedBox>`, `<mx:VDividedBox>`, and `<mx:HDividedBox>` tags to define DividedBox containers. Specify an `id` value if you intend to refer to a component elsewhere in your MXML, either in another tag or in an ActionScript block. Typically, you use the VDividedBox (vertical DividedBox) and HDividedBox (horizontal DividedBox) containers as shortcuts so that you do not have to specify the `direction` property.

The following code example creates the image shown in "MX DividedBox, HDividedBox, and VDividedBox layout containers" on page 584:

```
<?xml version="1.0"?>
<!-- containers\layouts\HDivBoxSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    backgroundColor="white">
    <fx:Script>
      <![CDATA[
        private function myGrid_initialize():void {
          myGrid.dataProvider = [
            {Artist:'Pavement', Album:'Slanted and Enchanted',
                Price:11.99, Comment:'One of their best. 4 Stars.'},
            {Artist:'Pavement', Album:'Brighten the Corners',
                Price:11.99, Comment:'My favorite.'}
          ];
        }
      ]]>
    </fx:Script>
    <mx:HDividedBox width="100%" height="100%">
        <mx:Tree id="tree1"
            width="30%" height="100%"
            labelField="@label"
            showRoot="true">
            <fx:XMLList>
                <fx:menuitem label="Products">
                    <fx:menuitem label="Posters" isBranch="true"/>
                    <fx:menuitem label="CDs">
                        <fx:menuitem label="Pavement"/>
                        <fx:menuitem label="Pavarotti"/>
                        <fx:menuitem label="Phish"/>
                    </fx:menuitem>
                    <fx:menuitem label="T-shirts" isBranch="true"/>
                    <fx:menuitem label="Tickets" isBranch="true"/>
                </fx:menuitem>
            </fx:XMLList>
        </mx:Tree>
        <mx:VDividedBox width="70%" height="100%">
            <mx:DataGrid id="myGrid"
                width="100%" height="100%"
                initialize="myGrid_initialize();"
                change="currentMessage.text=
                    event.currentTarget.selectedItem.Comment;"/>
            <mx:TextArea id="currentMessage"
                width="100%"
                height="60"
                text="One of their best. 4 Stars."/>
        </mx:VDividedBox>
    </mx:HDividedBox>
</s:Application>
```

Notice that this example does not implement the logic to change the top area of the VDividedBox container when you select a node in the Tree control.

Using the dividers

The dividers of a DividedBox container let you resize the area of the container allocated for a child. However, for the dividers to function, the child has to be resizable; that is, it must specify a percentage-based size. So, a child with an explicit or default height or width cannot be resized in the corresponding direction by using a divider. Therefore, when you use the DividedBox container, you typically use percentage sizing for its children to make them resizable.

When you specify a percentage value for the `height` or `width` properties of a child to make it resizable, Flex initially sizes the child to the specified percentage, if possible. Then Flex can resize the child to take up all available space.

You can use the dividers to resize a percentage-sized child up to its maximum size, or down to its minimum size. To constrain the minimum size or maximum size of an area of the DividedBox, set an explicit value for the `minWidth` and `minHeight` properties or the `maxWidth` and `maxHeight` properties of the children in that area.

Using live dragging

By default, the DividedBox container disables live dragging. This means that the DividedBox container does not update the layout of its children until the user finishes dragging the divider, when the user releases the mouse button on a selected divider.

You can configure the DividedBox container to use live dragging by setting the `liveDragging` property to `true`. With live dragging enabled, the DividedBox container updates its layout as the user moves a divider. In some cases, you may encounter decreased performance if you enable live dragging.

MX Form, FormHeading, and FormItem layout containers

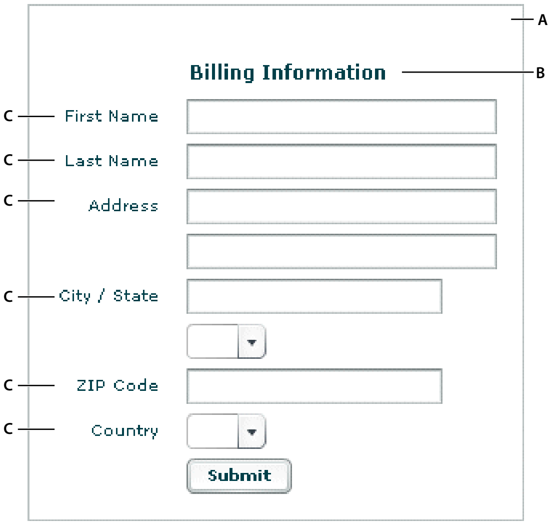
Forms are one of the most common methods that web applications use to collect information from users. Forms are used for collecting registration, purchase, and billing information, and for many other data collection tasks.

Note: *Adobe recommends that, when possible, you use the Spark Form container instead of the MX Form container. For more information, see "The Spark Form, Spark FormHeading, and Spark FormItem containers" on page 456.*

About forms

Flex supports form development by using the Form layout container and several child components of the Form container. The Form container lets you control the layout of a form, mark form fields as required or optional, handle error messages, and bind your form data to the Flex data model to perform data checking and validation. Also, you can apply style sheets to configure the appearance of your forms.

You use three different components to create your forms, as the following example shows:



A. *Form container* ***B.*** *FormHeading control* ***C.*** *FormItem containers*

For complete reference information, see Form, FormHeading, and FormItem in the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Creating forms

You typically create a form by defining the following elements:

- The Form control
- FormHeading components, nested inside the Form control
- FormItem containers, nested inside the Form control
- Form fields, such as ComboBox and TextInput controls, nested inside the FormItem containers

  You can also include other components inside a form, such as HRule controls, as needed.

Creating the Form container

The Form container is the outermost container of a Flex form. The primary use of the Form container is to control the sizing and layout of the contents of the form, including the size of labels and the gap between items. The Form container always arranges its children vertically and left-aligns them in the form. The form container contains one or more FormHeading and FormItem containers.

You use the `<mx:Form>` tag to define the Form container. Specify an `id` value if you intend to refer to the entire form elsewhere in your MXML, either in another tag or in an ActionScript block.

The following code example shows the Form container definition for the form shown in the previous image in “About forms” on page 587:

```
<?xml version="1.0"?>
<!-- containers\layouts\FormSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <mx:Form id="myForm" width="400" height="100">
        <!-- Define FormHeading and FormItem components here -->
    </mx:Form>
</s:Application>
```

For complete reference information, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Creating a FormHeading control

A FormHeading control specifies an optional label for a group of FormItem containers. The left side of the label is aligned with the left side of the controls in the form. You can have multiple FormHeading controls in your form to designate multiple content areas. You can also use FormHeading controls with a blank `label` to create vertical space in your form.

You use the `<mx:FormHeading>` tag to define a FormHeading container. Specify an `id` value if you intend to refer to the heading elsewhere in your MXML, either in another tag or in an ActionScript block.

The following code example defines the FormHeading control for the image shown in "About forms" on page 587:

```
<?xml version="1.0"?>
<!-- containers\layouts\FormHeadingSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <mx:Form id="myForm" width="400" height="100">
        <mx:FormHeading label="Billing Information"/>
        <!--Define FormItem containers here. -->
    </mx:Form>
</s:Application>
```

For complete reference information, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Creating a FormItem container

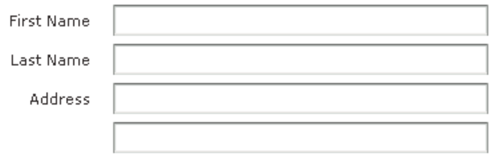
A FormItem container specifies a form element consisting of the following parts:

- A single label
- One or more child controls or containers, such as input controls

  The label is vertically aligned with the first child in the FormItem container and is right-aligned in the region to the left of the container.

  You use the `<mx:FormItem>` tag to define a FormItem container. Specify an `id` value if you intend to refer to the item elsewhere in your MXML, either in another tag or in an ActionScript block.

  Form containers typically contain multiple FormItem containers, as the following example shows:



In this example, you define three FormItem containers: one with the label First Name, one with the label Last Name, and one with the label Address. The Address FormItem container holds two controls to let a user enter two lines of address information. Each of the other two FormItem containers includes a single control.

For complete reference information, see FormItem in the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Specifying form item direction

When you create a FormItem container, you specify its direction by using the value `vertical` (default) or `horizontal` for the `direction` property:

vertical Flex positions children vertically to the right of the FormItem label.

horizontal Flex positions children horizontally to the right of the FormItem label. If all children do not fit on a single row, they are divided into multiple rows with equal-sized columns. You can ensure that all children fit on a single line by using percentage-based widths or by specifying explicit widths wide enough for all of the components.

Controlling form item label style

You control the style of a FormItem label by setting the `labelStyleName` style property. The following example sets the FormItem label color to dark blue and its font size to 20 pixels:

```
<?xml version="1.0"?>
<!-- containers\layouts\FormItemStyle.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Style>
        .myFormItemLabelStyle {
            color: #333399;
            fontSize: 20;
         }

    </fx:Style>
    <fx:Script>
        <![CDATA[
            private function processValues(zip:String, pn:String):void {
                // Validate and process data.
            }
        ]]>
    </fx:Script>
    <mx:Form id="myForm" defaultButton="{mySubmitButton}">
        <mx:FormItem label="Zip Code"
            labelStyleName="myFormItemLabelStyle">
            <mx:TextInput id="zipCode"/>
        </mx:FormItem>
        <mx:FormItem label="Phone Number">
            <mx:TextInput id="phoneNumber"/>
        </mx:FormItem>

        <mx:FormItem>
            <mx:Button label="Submit" id="mySubmitButton"
                click="processValues(zipCode.text, phoneNumber.text);"/>
        </mx:FormItem>

    </mx:Form>
</s:Application>
```

Example: A simple form

The following example shows the FormItem container definitions for the example form:

```
<?xml version="1.0"?>
<!-- containers\layouts\FormComplete.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
            private function submitForm():void {
                // Handle the form submission.
            }
        ]]>
    </fx:Script>
    <mx:Form id="myForm" width="400">
        <mx:FormHeading label="Billing Information"/>
        <mx:FormItem label="First Name">
            <mx:TextInput id="fname" width="100%"/>
        </mx:FormItem>
        <mx:FormItem label="Last Name">
            <mx:TextInput id="lname" width="100%"/>
        </mx:FormItem>
        <mx:FormItem label="Address">
            <mx:TextInput id="addr1" width="100%"/>
            <mx:TextInput id="addr2" width="100%"/>
        </mx:FormItem>
        <mx:FormItem label="City / State" direction="vertical">
            <mx:TextInput id="city"/>
            <mx:ComboBox id="st" width="75">
              <mx:ArrayList>
                 <fx:String>MA</fx:String>
                 <fx:String>NH</fx:String>
                 <fx:String>RI</fx:String>
              </mx:ArrayList>
            </mx:ComboBox>
        </mx:FormItem>
        <mx:FormItem label="ZIP Code">
            <mx:TextInput id="zip" width="100"/>
        </mx:FormItem>
        <mx:FormItem label="Country">
            <mx:ComboBox id="cntry">
              <mx:ArrayList>
                 <fx:String>USA</fx:String>
                 <fx:String>UAE</fx:String>
                 <fx:String>UAW</fx:String>
              </mx:ArrayList>
            </mx:ComboBox>
        </mx:FormItem>
        <mx:FormItem>
            <mx:HRule width="200" height="1"/>
            <mx:Button label="Submit Form" click="submitForm();"/>
        </mx:FormItem>
    </mx:Form>
</s:Application>
```

Laying out forms

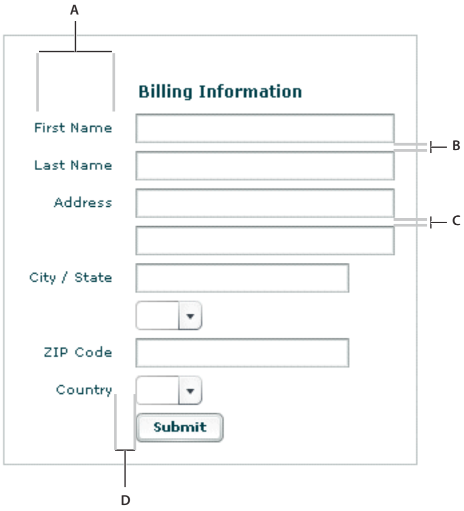
Flex determines the default size of a form in the following ways:

- The default height is large enough to hold the default or explicit heights of all the container children, plus the Form container top and bottom padding and the gaps between children.
- The default width is large enough to accommodate the widest FormItem label, plus the `indicatorGap` between the labels and the child controls, plus the widest default or explicit width among the child controls in the FormItems.

Aligning and spacing Form container children

All Form container labels are right-aligned, and all children are left-aligned in the container. You cannot override this alignment.

The following example shows the spacing of Form container children that you can control:



***A.** Form container: labelWidth **B.** Form container: verticalGap = 6 **C.** FormItem container: verticalGap = 6 **D.** Form container: indicatorGap = 14*

The following table describes the style properties that you use to control spacing and their default values:

Component	Style	Description	Default value
Form	`verticalGap`	Vertical space between Form container children	6 pixels
	`horizontalGap`	Horizontal space between Form container children	8 pixels
	`labelWidth`	Width of labels	Calculated by the container based on the child labels

	`paddingTop`
	`paddingBottom`
	`paddingLeft`
	`paddingRight`
		Border spacing around children	16 pixels on all sides

	`indicatorGap`	Gap between the end of the area in the form reserved for labels and the FormItem children or FormHeading heading	14 pixels

Component	Style	Description	Default value
FormHeading	`indicatorGap`	Overrides the indicator gap set by the `<mx:Form>` tag	14 pixels
	`paddingTop`	Gap between the top of the component and the label text	16 pixels
FormItem	`direction`	Direction of FormItem children: `vertical` or `horizontal`	`vertical`
	`horizontalGap`	Horizontal spacing between children in a FormItem container	8 pixels
	`labelWidth`	The width for the FormItem heading	The width of the label text

	`paddingTop`
	`paddingBottom`
	`paddingLeft`
	`paddingRight`
		Border spacing around the FormItem	0 pixels on all sides

	`verticalGap`	Vertical spacing between children in a FormItem container	6 pixels
	`indicatorGap`	Overrides the indicator gap set by the `<mx:Form>` tag	Determined by the `<mx:Form>` tag

Sizing and positioning Form container children

The Form layout container arranges children in a vertical column. The area of the Form container that is designated for children does not encompass the entire Form container. Instead, it starts at the right of the area defined by any labels and the gap defined by the `indicatorGap` property. For example, if the width of the Form container is 500 pixels, and the labels and `indicatorGap` property allocate 100 pixels of that width, the width of the child area is 400 pixels.

By default, Flex sizes the Form layout children vertically to their default height. Flex then determines the default width of each child, and stretches the child's width to the next highest quarter of the child area—that is, to one-quarter, one-half, three-quarters, or full width of the child area.

For example, if a container has a child area 400 pixels wide, and the default width of a TextArea control is 125 pixels, Flex stretches the TextArea control horizontally to the next higher quarter of the child area, the 200-pixel boundary, which is one-half of the child area. This sizing algorithm applies only to components without an explicitly specified width. It prevents your containers from having ragged right edges caused by controls with different widths.

You can also explicitly set the height or width of any control in the form to either a pixel value or a percentage of the Form size by using the `height` and `width` properties of the child.

Defining a default button

You use the `defaultButton` property of a container to define a default Button control. Pressing the Enter key while the focus is on any form control activates the Button control just as if it was explicitly selected.

For example, a login form displays user name and password inputs and a submit Button control. Typically, the user types a user name, tabs to the password field, types the password, and presses the Enter key to submit the login information without explicitly selecting the Button control. To define this type of interaction, set the `defaultButton` to the `id` of the submit Button control. In the following example, the event listener for the `click` event of submit button displays an Alert control, to show that Flex triggers this event if the user presses the Enter key when any form field has the focus. The commented-out line in the example would perform the more realistic action of invoking a web service to let the user log in.

```
<?xml version="1.0"?>
<!-- containers\layouts\FormDefButton.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
            import flash.events.MouseEvent;
            import mx.controls.Alert;

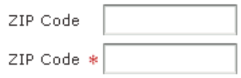
            private function submitLogin(eventObj:MouseEvent):void {
                // Display an Alert to show the event happened.
                Alert.show("Login Requested");
                // Commented out to work without a web service.
                //myWebService.Login.send();
            }
        ]]>
    </fx:Script>
    <mx:Form defaultButton="{mySubmitButton}">
        <mx:FormItem label="Username">
            <mx:TextInput id="username"
                width="100"/>
        </mx:FormItem>
        <mx:FormItem label="Password">
            <mx:TextInput id="password"
                width="100"
                displayAsPassword="true"/>
        </mx:FormItem>
        <mx:FormItem>
            <mx:Button id="mySubmitButton"
                label="Login"
                click="submitLogin(event);"/>
        </mx:FormItem>
    </mx:Form>
</s:Application>
```

***Note:** When the drop-down list of a ComboBox control is open, pressing Enter selects the currently highlighted item in the ComboBox control; it does not activate the default button.*

Specifying required fields

Flex includes support for defining required input fields of a form. To define a required field, you specify the `required` property of the FormItem container. If this property is specified, all the children of the FormItem container are marked as required.

Flex inserts a red asterisk (*) character as a separator between the FormItem label and the FormItem child to indicate a required field. For example, the following example shows an optional ZIP code field and a required ZIP code field:



The following code example defines these fields:

```
<?xml version="1.0"?>
<!-- containers\layouts\FormReqField.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <mx:Form>
        <mx:FormItem label="ZIP Code">
            <mx:TextInput id="zipOptional"
                width="100"/>
        </mx:FormItem>
        <mx:FormItem label="ZIP Code" required="true">
            <mx:TextInput id="zipRequired"
                width="100"/>
        </mx:FormItem>
    </mx:Form>
</s:Application>
```

You can enable the required indicator of a FormItem child at run time. This could be useful when the user input in one form field makes another field required. For example, you might have a form with a CheckBox control that the user selects to subscribe to a newsletter. Checking the box could make the user e-mail field required, as the following example shows:

```
<?xml version="1.0"?>
<!-- containers\layouts\FormReqFieldRuntime.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <mx:Form>
        <mx:FormItem label="Subscribe">
            <mx:CheckBox label="Subscribe?"
                click="emAddr.required=!emAddr.required;"/>
        </mx:FormItem>
        <mx:FormItem id="emAddr" label="E-mail Address">
            <mx:TextInput id="emailAddr"/>
        </mx:FormItem>
    </mx:Form>
</s:Application>
```

Flex does not perform any automatic enforcement of a required field; it only marks fields as required. You must add validation logic to your form to enforce it. As part of your enforcement logic, you can use Flex validators. All Flex validators have a `required` property, which is `true` by default. You can use validators in several ways, depending on how you enforce required fields and validation. For details, see “Validating Data” on page 1964.

Storing and validating form data

As part of designing your form, you must consider how you want to store your form data. In Flex, you have the following choices.

- Store the data within the form controls.
- Create a Flex data model to store your data.

Your decision about how to represent your data also affects how you perform input error detection or *data validation*, one of the primary tasks of a robust and stable form. You typically validate user input before you submit the data to the server. You can validate the user input within a submit function, or when a user enters data into the form.

Flex provides a set of data validators for the most common types of data collected by a form. You can use Flex validators with the following types of data:

- Credit card information
- Dates
- E-mail addresses
- Numbers
- Phone numbers
- Social Security Numbers
- Strings
- ZIP codes

As part of building your form, you can perform data validation by using your own custom logic, take advantage of the Flex data validation mechanism, or use a combination of custom logic and Flex data validation.

The following sections include information on how to initiate validation in a form; for detailed information on how to use Flex data validation, see “Validating Data” on page 1964.

Using Form controls to hold your form data

The following example uses Form controls to store the form data:

```
<?xml version="1.0"?>
<!-- containers\layouts\FormData.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
            private function processValues(zip:String, pn:String):void {
                // Validate and process data.
            }
        ]]>
    </fx:Script>
    <mx:Form id="myForm" defaultButton="{mySubmitButton}">
        <mx:FormItem label="ZIP Code">
            <mx:TextInput id="zipCode"/>
        </mx:FormItem>
        <mx:FormItem label="Phone Number">
            <mx:TextInput id="phoneNumber"/>
        </mx:FormItem>

        <mx:FormItem>
            <mx:Button label="Submit" id="mySubmitButton"
                click="processValues(zipCode.text, phoneNumber.text);"/>
        </mx:FormItem>

    </mx:Form>
</s:Application>
```

This example form defines two form controls: one for a ZIP code and one for a phone number. When you submit the form, you call a function that takes the two arguments that correspond to the data stored in each control. Your submit function can then perform any data validation on its inputs before processing the form data.

You don’t have to pass the data to the submit function. The submit function can access the form control data directly, as the following example shows:

```
<?xml version="1.0"?>
<!-- containers\layouts\FormDataSubmitNoArg.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
            private function processValues():void {
                var inputZip:String = zipCode.text;
                var inputPhone:String = phoneNumber.text;
                // Check to see if pn is a number.
                // Check to see if zip is less than 4 digits.
                // Process data.
            }
        ]]>
    </fx:Script>
    <mx:Form id="myForm" defaultButton="{mySubmitButton}">
        <mx:FormItem label="ZIP Code">
            <mx:TextInput id="zipCode"/>
        </mx:FormItem>
        <mx:FormItem label="Phone Number">
            <mx:TextInput id="phoneNumber"/>
        </mx:FormItem>

        <mx:FormItem>
            <mx:Button label="Submit" id="mySubmitButton"
                click="processValues();"/>
        </mx:FormItem>

    </mx:Form>
</s:Application>
```

The technique of using the form fields directly, however, has the problem that the function is specific to the form and cannot easily be used by other forms.

Validating form control contents data on user entry

To validate form data upon user input, you can add Flex data validators to your application. The following example uses the ZipCodeValidator and PhoneNumberValidator to perform validation.

```
<?xml version="1.0"?>
<!-- containers\layouts\FormDataValidate.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
            private function processValues():void {
                var inputZip:String = zipCode.text;
                var inputPhone:String = phoneNumber.text;
                // Perform any additional validation.
                // Process data.
            }
        ]]>
    </fx:Script>
    <fx:Declarations>
        <mx:ZipCodeValidator id="zcVal"
            source="{zipCode}" property="text"
            domain="US or Canada"/>
        <mx:PhoneNumberValidator id="pnVal"
            source="{phoneNumber}" property="text"/>
    </fx:Declarations>

    <mx:Form id="myForm" defaultButton="{mySubmitButton}">
        <mx:FormItem label="ZIP Code">
            <mx:TextInput id="zipCode"/>
        </mx:FormItem>
        <mx:FormItem label="Phone Number">
            <mx:TextInput id="phoneNumber"/>
        </mx:FormItem>

        <mx:FormItem>
            <mx:Button label="Submit" id="mySubmitButton"
                click="processValues();"/>
        </mx:FormItem>
    </mx:Form>
</s:Application>
```

If you validate the input data every time the user enters it, you might not have to do so again in your submit function. However, some validation in your submit function might still be necessary, especially if you want to ensure that two fields are valid when compared with each other.

For example, you can use Flex validators to validate a ZIP code field and state field individually. But you might want to validate that the ZIP code is valid for the specified state before submitting the form data. To do so, you perform a second validation in the submit function.

For detailed information on using validators, see “Validating Data” on page 1964.

Using a Flex data model to store form data

You can use a Flex data model to structure and store your form data and provide a framework for data validation. A data model stores data in fields that represent each part of a specific data set. For example, a *person* model might store information such as a person’s name, age, and phone number. You can then validate the data in the model based on the type of data stored in each model field.

The following example defines a Flex data model that contains two values. The two values correspond to the two input fields of a form.

```
<?xml version="1.0"?>
<!-- containers\layouts\FormDataModel.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <!-- Define the submit function that validates and
        processes the data. -->
    <fx:Script>
        <![CDATA[
            private function processValues():void {
                var inputZip:String = myFormModel.zipCodeModel;
                var inputPhone:String = myFormModel.phoneNumberModel;
                // Process data.
            }
        ]]>
    </fx:Script>
    <fx:Declarations>
        <!-- Define data model. -->
        <fx:Model id="myFormModel">
            <info>
                <zipCodeModel>{zipCode.text}</zipCodeModel>
                <phoneNumberModel>{phoneNumber.text}</phoneNumberModel>
            </info>
        </fx:Model>
    </fx:Declarations>
    <!-- Define the form. -->
    <mx:Form borderStyle="solid">
        <mx:FormItem label="ZIP Code">
            <mx:TextInput id="zipCode"/>
        </mx:FormItem>
        <mx:FormItem label="Phone Number">
            <mx:TextInput id="phoneNumber"/>
        </mx:FormItem>
        <mx:FormItem>
            <mx:Button id="b1"
                label="Submit"
                click="processValues();"/>
        </mx:FormItem>
    </mx:Form>
</s:Application>
```

You use the `<fx:Model>` tag to define the data model. Each child tag of the data model defines one field of the model. The tag body of each child tag in the model defines a *binding* to a form control. In this example, you bind the `zipCodeModel` model field to the text value of the `zipCode` TextInput control, and you bind the `phoneNumberModel` field to the text value of the `phoneNumber` TextInput control. For more information on data models, see “Storing data” on page 889.

When you bind a control to a data model, Flex automatically copies data from the control to the model upon user input. In this example, your submit function accesses the data from the model, not directly from the form controls.

Using Flex validators with form models

The following example modifies the example in the previous section by inserting two data validators—one for the ZIP code field and one for the phone number field:

```
<?xml version="1.0"?>
<!-- containers\layouts\FormDataModelVal.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <!-- Define the submit function that validates and processes the data -->
    <fx:Script>
        <![CDATA[
            private function processValues():void {
                var inputZip:String = myFormModel.zipCodeModel;
                var inputPhone:String = myFormModel.phoneNumberModel;
                // Process data.
            }
        ]]>
    </fx:Script>
    <fx:Declarations>
        <!-- Define data model. -->
        <fx:Model id="myFormModel">
            <info>
                <zipCodeModel>{zipCode.text}</zipCodeModel>
                <phoneNumberModel>{phoneNumber.text}</phoneNumberModel>
            </info>
        </fx:Model>
        <!-- Define validators. -->
        <mx:ZipCodeValidator
            source="{myFormModel}" property="zipCodeModel"
            trigger="{zipCode}"
            listener="{zipCode}"/>
        <mx:PhoneNumberValidator
            source="{myFormModel}" property="phoneNumberModel"
            trigger="{b1}"
            listener="{phoneNumber}"
            triggerEvent="click"/>
    </fx:Declarations>
    <!-- Define the form. -->
    <mx:Form borderStyle="solid">
        <mx:FormItem label="ZIP Code">
            <mx:TextInput id="zipCode"/>
        </mx:FormItem>
        <mx:FormItem label="Phone Number">
            <mx:TextInput id="phoneNumber"/>
        </mx:FormItem>
        <mx:FormItem>
            <mx:Button id="b1"
                label="Submit"
                click="processValues();"/>
        </mx:FormItem>
    </mx:Form>
</s:Application>
```

When the user enters data into the `zipCode` form field, Flex automatically copies that data to the data model. The `ZipCodeValidator` validator gets invoked when the user exits the `zipCode` form field, as specified by the validator's `trigger` property and the default value of the `triggerEvent` property, `valueCommit`. Flex then draws a red box around the `zipCode` field, as specified by the `listener` property.

When the user enters data into the `phoneNumber` form field, Flex automatically copies that data to the data model. The `PhoneNumberValidator` validator gets invoked when the user clicks the Button control, as specified by the validator's `trigger` and `triggerEvent` properties. Flex then draws a red box around the `phoneNumber` field, as specified by the `listener` property.

For detailed information on using validators, see "Validating Data" on page 1964.

Populating a Form control from a data model

Another use for data models is to include data in the model to populate form fields with values. The following example shows a form that reads static data from a data model to obtain the value for a form field:

```
<?xml version="1.0"?>
<!-- containers\layouts\FormDataFromModel.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Declarations>
        <!-- Define data model. -->
        <fx:Model id="myFormModel">
            <info>
                <fName>{firstName.text}</fName>
                <lName>{lastName.text}</lName>
                <department>Accounting</department>
            </info>
        </fx:Model>
    </fx:Declarations>
    <mx:Form>
        <mx:FormItem label="First and Last Names">
            <mx:TextInput id="firstName"/>
            <mx:TextInput id="lastName"/>
        </mx:FormItem>
        <mx:FormItem label="Department">
            <mx:TextInput id="dept" text="{myFormModel.department}"/>
        </mx:FormItem>
    </mx:Form>
</s:Application>
```

This department data is considered static because the form always shows the same value in the field. You could also create a dynamic data model that takes the value of the department field from a web service, or calculates it based on user input.

For more information on data models, see "Storing data" on page 889.

Submitting data to a server

Form data is typically processed on a server, not locally on the client. Therefore, the submit event listener must have a mechanism for packing the form data for transfer to the server, and then handling any results returned from the server. In Flex, you typically use a web service, HTTP service, or remote Java object to pass data to the server.

You can also build logic into your submit function to control navigation of your application when the submit succeeds and when it fails. When the submit succeeds, you typically navigate to an area of your application that displays the results. If the submit fails, you can return control to the form so that the user can fix any errors.

The following example adds a web service to process form input data. In this example, the user enters a ZIP code, and then selects the Submit button. After performing any data validation, the submit event listener calls the web service to obtain the city name, current temperature, and forecast for the ZIP code.

```
<?xml version="1.0"?>
<!-- containers\layouts\FormDataSubmitServer.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            private function processValues():void {
                // Check to see if ZIP code is valid.
                WeatherService.GetWeather.send();
            }
        ]]>
    </fx:Script>
    <fx:Declarations>
        <!-- Define the web service connection.
            The specified WSDL URI is not functional. -->
        <mx:WebService id="WeatherService"
            wsdl="/ws/WeatherService?wsdl">
            <mx:operation name="GetWeather">
                <mx:request>
                    <ZipCode>{zipCode.text}</ZipCode>
                </mx:request>
            </mx:operation>
        </mx:WebService>
    </fx:Declarations>
    <mx:Form>
        <mx:FormItem label="ZIP Code">
            <mx:TextInput id="zipCode"
                width="200"
                text="ZIP code please."/>
            <mx:Button
                width="60"
                label="Submit"
                click="processValues();"/>
        </mx:FormItem>
    </mx:Form>
    <mx:VBox>
        <mx:TextArea
            text=
              "{WeatherService.GetWeather.lastResult.CityShortName}"/>
        <mx:TextArea
            text=
              "{WeatherService.GetWeather.lastResult.CurrentTemp}"/>
        <mx:TextArea
            text=
          "{WeatherService.GetWeather.lastResult.DayForecast}"/>
    </mx:VBox>
</s:Application>
```

This example binds the form's input `zipCode` field directly to the `ZipCode` field of the web service request. To display the results from the web service, you bind the results to controls in a VBox container.

You have a great deal of flexibility when passing data to a web service. For example, you might modify this example to bind the input form field to a data model, and then bind the data model to the web service request. For more information on using web services, see Accessing server-side data.

You can also add event listeners for the web service to handle both a successful call to the web service, by using the `result` event, and a call that generates an error, by using the `fault` event. An error condition might cause you to display a message to the user with a description of the error. For a successful result, you might navigate to another section of your application.

The following example adds a `result` event and a `fault` event to the form. In this example, the form is defined as one child of a ViewStack container, and the form results are defined as a second child of the ViewStack container:

```
<?xml version="1.0"?>
<!-- containers\layouts\FormDataSubmitServerEvents.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
            import mx.controls.Alert;
            private function processValues():void {
                // Check to see if ZIP code is valid.
                WeatherService.GetWeather.send();
            }

            private function successfulCall():void {
                vs1.selectedIndex=1;
            }

            private function errorCall():void {
                Alert.show("Web service failed!", "Alert Box", Alert.OK);
            }
        ]]>
    </fx:Script>
    <fx:Declarations>
        <!-- Define the web service connection.
            The specified WSDL URI is not functional. -->
        <mx:WebService id="WeatherService"
            wsdl="/ws/WeatherService?wsdl"
            result="successfulCall();"
            fault="errorCall();">
            <mx:operation name="GetWeather">
                <mx:request>
                    <ZipCode>{zipCode.text}</ZipCode>
                </mx:request>
            </mx:operation>
        </mx:WebService>
    </fx:Declarations>
    <mx:ViewStack id="vs1">
        <mx:Form>
            <mx:FormItem label="ZIP Code">
                <mx:TextInput id="zipCode"
                    width="200"
                    text="ZIP code please."/>
                <mx:Button width="60"
                    label="Submit"
                    click="processValues();"/>
            </mx:FormItem>
        </mx:Form>

        <mx:VBox>
            <mx:TextArea
                text=
                    "{WeatherService.GetWeather.lastResult.CityShortName}"/>
            <mx:TextArea
                text=
                    "{WeatherService.GetWeather.lastResult.CurrentTemp}"/>
            <mx:TextArea
                text=
                    "{WeatherService.GetWeather.lastResult.DayForecast}"/>
        </mx:VBox>
    </mx:ViewStack>
</s:Application>
```

When a call to the web service succeeds, the `successfulCall()` function switches the current ViewStack child to the VBox container to show the returned results. An error from the web service displays an Alert box, but does not change the current child of the ViewStack container; the form remains visible, which lets the user fix any input errors.

You have many options for handling navigation in your application based on the results of the submit function. The previous example used a ViewStack container to handle navigation. You might also choose to use a TabNavigator container or Accordion container for this same purpose.

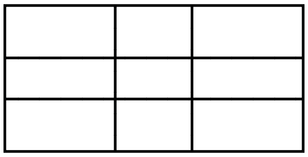
In some applications, you might choose to embed the form in a TitleWindow container. A TitleWindow container is a pop-up window that appears above the Adobe Flash Player drawing surface. In this scenario, users enter form data and submit the form from the TitleWindow container. If a submit succeeds, the TitleWindow container closes and displays the results in another area of your application. If a submit fails, Flex displays an error message and leaves the TitleWindow container visible.

Another type of application might use a dashboard layout, where you have multiple panels open on the dashboard. Submitting the form could cause another area of the dashboard to update with results, while a failure could display an error message.

For more information on the TabNavigator, Accordion, and TitleWindow containers, see "MX navigator containers" on page 628.

MX Grid layout container

You use a Grid layout container to arrange children as rows and columns of cells, much like an HTML table. The following example shows a Grid container that consists of nine cells arranged in a three-by-three pattern:



You can put zero or one child in each cell of a Grid container. If you include multiple children in a cell, put a container in the cell, and then add children to the container. The height of all cells in a row is the same, but each row can have a different height. The width of all cells in a column is the same, but each column can have a different width.

You can define a different number of cells for each row or each column of the Grid container. In addition, a cell can span multiple columns and/or multiple rows of the container.

If the default or explicit size of the child is larger than the size of an explicitly sized cell, the child is clipped at the cell boundaries.

If the child's default width or default height is smaller than the cell, the default horizontal alignment of the child in the cell is `left` and the default vertical alignment is `top`. You can use the `horizontalAlign` and `verticalAlign` properties of the `<mx:GridItem>` tag to control positioning of the child.

For complete reference information, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*. For information on the Tile container, which creates a layout where all cells have the same size, see "MX Tile layout container" on page 612.

Creating a Grid layout container

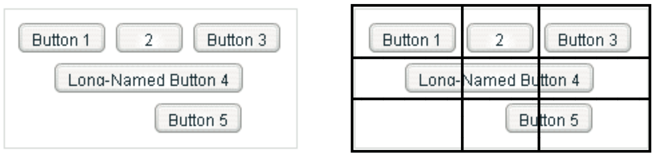
You create a Grid layout container as follows:

- You use the <mx:Grid> tag to define a Grid container; it can hold any number of `<mx:GridRow>` child tags.
- You use the <mx:GridRow> tag to define each row. It must be a child of the `<mx:Grid>` tag and can hold any number of `<mx:GridItem>` child tags.
- You use the <mx:GridItem> tag to define each row cell; it must be a child of the `<mx:GridRow>` tag.

The `<mx:GridItem>` tag takes the following optional properties that control how the item is laid out:

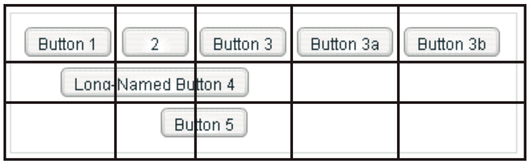
Property	Type	Use	Descriptions
`rowSpan`	Number	Property	Specifies the number of rows of the Grid container spanned by the cell. The default value is 1. You cannot extend a cell past the number of rows in the Grid container.
`colSpan`	Number	Property	Specifies the number of columns of the Grid container spanned by the cell. The default value is 1. You cannot extend a cell past the number of columns in the Grid container.

The following image shows a Grid container with three rows and three columns:



On the left, you see how the Grid container appears in Flash Player. On the right, you see the Grid container with borders overlaying it to illustrate the configuration of the rows and columns. In this example, the buttons in the first (top) row each occupy a single cell. The button in the second row spans three columns, and the button in the third row spans the second and third columns.

You do not have to define the same number of cells for every row of a Grid container, as the following image shows. The Grid container defines five cells in row one; row two has one item that spans three cells; and row 3 has one empty cell, followed by an item that spans two cells.



The following MXML code creates the Grid container with three rows and three columns shown in the first image in this section:

```
<?xml version="1.0"?>
<!-- containers\layouts\GridSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <mx:Grid id="myGrid">
        <!-- Define Row 1. -->
        <mx:GridRow id="row1">
            <!-- Define the first cell of Row 1. -->
            <mx:GridItem>
                <mx:Button label="Button 1"/>
            </mx:GridItem>
            <!-- Define the second cell of Row 1. -->
            <mx:GridItem>
                <mx:Button label="2"/>
            </mx:GridItem>
            <!-- Define the third cell of Row 1. -->
            <mx:GridItem>
                <mx:Button label="Button 3"/>
            </mx:GridItem>
        </mx:GridRow>
        <!-- Define Row 2. -->
        <mx:GridRow id="row2">
            <!-- Define a single cell to span three columns of Row 2. -->
            <mx:GridItem colSpan="3" horizontalAlign="center">
                <mx:Button label="Long-Named Button 4"/>
            </mx:GridItem>
        </mx:GridRow>
        <!-- Define Row 3. -->
        <mx:GridRow id="row3">
            <!-- Define an empty first cell of Row 3. -->
            <mx:GridItem/>
            <!-- Define a cell to span columns 2 and 3 of Row 3. -->
            <mx:GridItem colSpan="2" horizontalAlign="center">
                <mx:Button label="Button 5"/>
            </mx:GridItem>
        </mx:GridRow>
    </mx:Grid>
</s:Application>
```

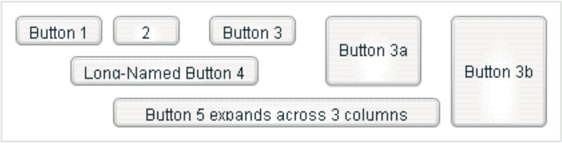
To modify the preceding example to include five buttons across the top row, you modify the first `<mx:GridRow>` tag as follows:

```
<?xml version="1.0"?>
<!-- containers\layouts\Grid5Button.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <mx:Grid id="myGrid">
        <!-- Define Row 1. -->
        <mx:GridRow id="row1">
            <!-- Define the first cell of Row 1. -->
            <mx:GridItem>
                <mx:Button label="Button 1"/>
            </mx:GridItem>
            <mx:GridItem>
                <mx:Button label="2"/>
            </mx:GridItem>
            <mx:GridItem>
                <mx:Button label="Button 3"/>
            </mx:GridItem>
            <mx:GridItem>
                <mx:Button label="Button 3a"/>
            </mx:GridItem>
            <mx:GridItem>
                <mx:Button label="Button 3b"/>
            </mx:GridItem>
        </mx:GridRow>
        <!-- Define Row 2. -->
        <mx:GridRow id="row2">
            <!-- Define a single cell to span three columns of Row 2. -->
            <mx:GridItem colSpan="3" horizontalAlign="center">
                <mx:Button label="Long-Named Button 4"/>
            </mx:GridItem>
        </mx:GridRow>
        <!-- Define Row 3. -->
        <mx:GridRow id="row3">
            <!-- Define an empty first cell of Row 3. -->
            <mx:GridItem/>
            <!-- Define a cell to span columns 2 and 3 of Row 3. -->
            <mx:GridItem colSpan="2" horizontalAlign="center">
                <mx:Button label="Button 5"/>
            </mx:GridItem>
        </mx:GridRow>
    </mx:Grid>
</s:Application>
```

Setting the row and column span

The `colSpan` and `rowSpan` properties of the GridItem container let you create grid items that occupy multiple grid rows and columns. Making an item span multiple rows or columns does not necessarily make its child control or container larger; you must size the child so it fits the space appropriately, as the following example shows.

The following image shows a modification to the example in Creating a Grid layout container, where Button 3a now spans two rows, Button 3b spans three rows, and Button 5 spans three columns:



The following code shows the changes that were made to produce these results:

```
<?xml version="1.0"?>
<!-- containers\layouts\GridRowSpan.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <mx:Grid id="myGrid">
        <!-- Define Row 1. -->
        <mx:GridRow id="row1" height="33%">
            <!-- Define the first cell of Row 1. -->
            <mx:GridItem>
                <mx:Button label="Button 1"/>
            </mx:GridItem>
            <mx:GridItem>
                <mx:Button label="2"/>
            </mx:GridItem>
            <mx:GridItem>
                <mx:Button label="Button 3"/>
            </mx:GridItem>
            <mx:GridItem rowSpan="2">
                <mx:Button label="Button 3a" height="100%"/>
            </mx:GridItem>
            <mx:GridItem rowSpan="3">
                <mx:Button label="Button 3b" height="100%"/>
            </mx:GridItem>
        </mx:GridRow>
        <!-- Define Row 2. -->
        <mx:GridRow id="row2" height="33%">
            <!-- Define a single cell to span three columns of Row 2. -->
            <mx:GridItem colSpan="3" horizontalAlign="center">
                <mx:Button label="Long-Named Button 4"/>
            </mx:GridItem>
        </mx:GridRow>
        <!-- Define Row 3. -->
        <mx:GridRow id="row3" height="33%">
            <!-- Define an empty first cell of Row 3. -->
            <mx:GridItem/>
            <!-- Define a cell to span columns 2 and 3 and 4 of Row 3. -->
            <mx:GridItem colSpan="3">
                <mx:Button
                    label="Button 5 expands across 3 columns"
                    width="75%"/>
            </mx:GridItem>
        </mx:GridRow>
    </mx:Grid>
</s:Application>
```

This example makes several changes with the following effects:

- It sets the height of each row to 33% of the grid, ensuring that the rows have equal heights.
- It sets the `rowSpan` properties of the items with Buttons 3a and 3b to make them span two and three rows, respectively.
- It sets the `height` properties of Buttons 3a and 3b to 100% to make these buttons fill all rows that they span. If you omit this property on these buttons, Flex sets the buttons to their default height, so they do not appear to span the rows.
- It sets Button 5 to span three rows and sets a percentage-based width of 75%. In this example, the text requires the button to fill the available width of the three columns, so Flex sizes the button to the default size that fits the text, not the requested 75%. If you omit the `width` property, the result is identical. To see the effect of the percentage width specification, keep the specification and shorten the label text; the button then spans three-quarters of the three columns, centered on the middle column.

  The resulting grid has the several additional characteristics. Although the second row definition specifies only a single `<mx:GridItem>` tag that defines a cell spanning three columns, Flex automatically creates two additional cells to allow Buttons 3a and 3b to expand into the row. The third row also has five cells. The first cell is defined by the empty `<mx:gridItem/>` tag. The second through fourth cells are defined by the `GridItem` that contains Button 5, which spans three columns. The fifth column is created because the last item in the first row spans all three rows.

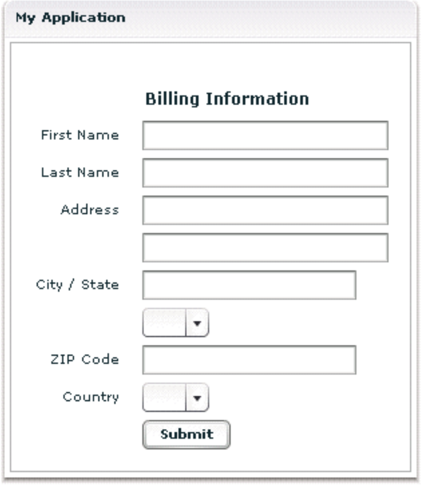
MX Panel layout container

A Panel layout container includes a title bar, a title, a status message area (in the title bar), a border, and a content area for its children. Typically, you use Panel containers to wrap self-contained application modules. For example, you could define several Panel containers in your application where one Panel container holds a form, a second holds a shopping cart, and a third holds a catalog.

***Note:** Adobe recommends that, when possible, you use the Spark Panel container instead of the MX Panel container. For more information, see "The Spark Panel container" on page 434.*

The Panel container has a `layout` property that lets you specify one of three types of layout: `horizontal`, `vertical` (default), or `absolute` layout. Horizontal and vertical layout use the Flex automatic layout rules to lay out children horizontally or vertically. Absolute layout requires you to specify each child's *x* and *y* position relative to the panel contents area, or to use constraint-based layout styles to anchor one or more sides or the container horizontal or vertical center relative to the panel content area. For examples of using absolute and constraint-based layout in a container, see "Creating and using a Canvas control" on page 574. For detailed information on using these layout techniques, see "Laying out components" on page 359.

The following example shows a Panel container with a Form container as its child:



For complete reference information, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Creating a Panel layout container

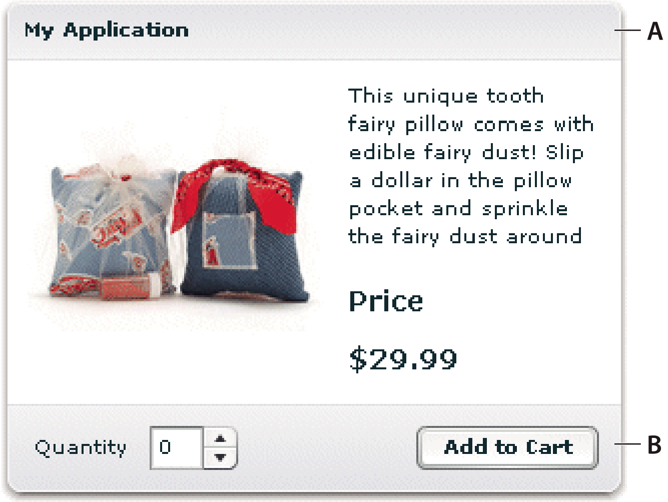
You define a Panel container in MXML by using the `<mx:Panel>` tag. Specify an `id` value if you intend to refer to a component elsewhere in your MXML, either in another tag or in an ActionScript block.

The following example defines a Panel container that contains a form as the top-level container in your application. In this example, the Panel container provides you with a mechanism for including a title bar, as in a standard GUI window.

```
<?xml version="1.0"?>
<!-- containers\layouts\PanelSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <mx:Panel id="myPanel" title="My Application">
        <mx:Form width="300">
            <mx:FormHeading label="Billing Information"/>
            <!-- Form contents goes here -->
        </mx:Form>
    </mx:Panel>
</s:Application>
```

Adding a ControlBar container to a Panel container

You can use the ControlBar container with a Panel container to hold components that can be shared by the other children in the Panel container. The RichTextEditor control, for example, consists of a Panel control with a TextArea control and a custom ControlBar for the text formatting controls. For a product catalog, the ControlBar container can hold the Flex controls to specify quantity and to add an item to a shopping cart, as the following example shows:



My Application
This unique tooth fairy pillow comes with edible fairy dust! Slip a dollar in the pillow pocket and sprinkle the fairy dust around
Price
$29.99
Quantity
0
Add to Cart
A
B

A. Panel container B. ControlBar container

You specify the `<mx:ControlBar>` tag as the last child tag of an `<mx:Panel>` tag, as the following example shows:

```
<?xml version="1.0"?>
<!-- containers\layouts\PanelCBar.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <mx:Panel title="My Application"
        paddingTop="10" paddingBottom="10"
        paddingLeft="10" paddingRight="10"
        width="300">

        <fx:Script>
            <![CDATA[
                private function addToCart():void {
                    // Handle event.
                }
            ]]>
        </fx:Script>

        <mx:HBox width="100%">
            <!-- Area for your catalog. -->
        </mx:HBox>

        <mx:ControlBar width="100%">
            <mx:Label text="Quantity"/>
            <mx:NumericStepper id="myNS"/>
            <!-- Use Spacer to push Button control to the right. -->
            <mx:Spacer width="100%"/>
            <mx:Button label="Add to Cart" click="addToCart();"/>
        </mx:ControlBar>
    </mx:Panel>
</s:Application>
```

For more information on the ControlBar container, see “MX ControlBar layout container” on page 581.

You can also add the ControlBar container dynamically to a Panel container, as the following example shows:

```
<?xml version="1.0"?>
<!-- containers\layouts\PanelCBarDynamicAdd.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <fx:Script>
        <![CDATA[
            import mx.containers.ControlBar;
            import mx.controls.*;
            import flash.events.MouseEvent;

            private var myCB:ControlBar=new ControlBar();
            private var myLabel:Label=new Label();
            private var myNS:NumericStepper=new NumericStepper();
            private var mySpacer:Spacer=new Spacer();
            private var myButton:Button=new Button();

            private var canAddChild:Boolean = true;

            private function addCBHandler():void {
                if (canAddChild) {
                    /* Create Controlbar control. */
                    myLabel.text="Quantity";
                    mySpacer.percentWidth=100;
                    myButton.label="Add to Cart";
                    myButton.addEventListener('click', addToCart);

                    myCB.percentWidth=100;
                    myCB.addChild(myLabel);
                    myCB.addChild(myNS);
                    myCB.addChild(mySpacer);
                    myCB.addChild(myButton);

                    /* Add the ControlBar as the last child of the
                       Panel container.
                       The ControlBar appears in the normal content area
                       of the Panel container. */
                    myPanel.addChildAt(myCB, myPanel.numChildren);

                    /* Call createComponentsFromDescriptors() to make the
                       ControlBar appear in the bottom border area
                       of the Panel container. The ControlBar must be the
                       last child in the Panel container. */
                    myPanel.createComponentsFromDescriptors();

                    /* Prevents more than one ControlBar control from being added. */
                    canAddChild = false;
                }
            }
            private function addToCart(event:MouseEvent):void {
                Alert.show("ControlBar Button clicked.");
            }
        ]]>
    </fx:Script>

    <mx:Panel id="myPanel"
        title="My Application"
        paddingTop="10" paddingBottom="10"
        paddingLeft="10" paddingRight="10"
        width="300">

        <mx:HBox width="100%">
            <!-- Area for your catalog. -->
        </mx:HBox>
        <mx:Button label="Add ControlBar"
            click="addCBHandler();"/>
    </mx:Panel>
</s:Application>
```

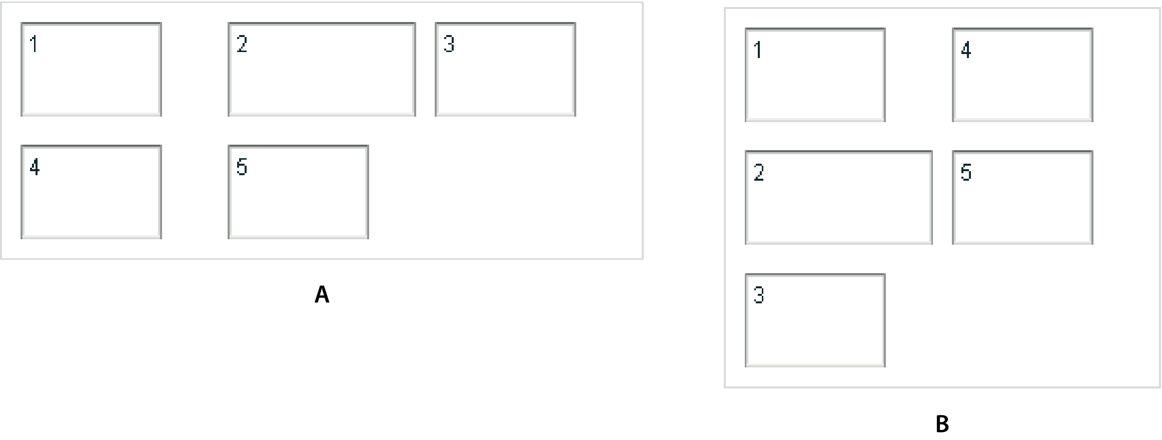
MX Tile layout container

A Tile layout container lays out its children in one or more vertical columns or horizontal rows, starting new rows or columns as necessary. The `direction` property determines the layout. The valid values for the `direction` property are `vertical` for a column layout and `horizontal` (default) for a row layout.

***Note:** Adobe recommends that, when possible, you use a Spark container with TileLayout instead of the MX Tile container. For more information, see "About Spark layouts" on page 420.*

All Tile container cells have the same size, unlike the cells of a Grid layout container (see “MX Grid layout container” on page 603). Flex arranges the cells of a Tile container in a square grid, where each cell holds a single child component. For example, if you define 16 children in a Tile layout container, Flex lays it out four cells wide and four cells high. If you define 13 children, Flex still lays it out four cells wide and four cells high, but leaves the last three cells in the fourth row empty.

The following image shows examples of horizontal and vertical Tile containers:



***A.** Horizontal (default)* ***B.** Vertical*

For complete reference information, see Tile in the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Creating a Tile layout container

You define a Tile container in MXML by using the `<mx:Tile>` tag. Specify an `id` value if you intend to refer to a component elsewhere in your MXML, either in another tag or in an ActionScript block. You can use the `tileHeight` and `tileWidth` properties to specify explicit tile dimensions.

The following example creates the horizontal Tile container shown in the image in “MX Tile layout container” on page 612. All cells have the height and width of the largest child, 50 pixels high and 100 pixels wide.

```
<?xml version="1.0"?>
<!-- containers\layouts\TileSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <mx:Tile id="myFlow"
        direction="horizontal"
        borderStyle="solid"
        paddingTop="10" paddingBottom="10"
        paddingRight="10" paddingLeft="10"
        verticalGap="15" horizontalGap="10">

        <mx:TextInput id="text1" text="1" height="50" width="75"/>
        <mx:TextInput id="text2" text="2" height="50" width="100"/>
        <mx:TextInput id="text3" text="3" height="50" width="75"/>
        <mx:TextInput id="text4" text="4" height="50" width="75"/>
        <mx:TextInput id="text5" text="5" height="50" width="75"/>
    </mx:Tile>
</s:Application>
```

Sizing and positioning a child in a Tile container

Flex sets the default size of each Tile cell to the height of the tallest child and the width of the widest child. All cells have the same default size. If the default size of a child is larger than the cell because, for example, you used the `tileHeight` and `tileWidth` properties to explicitly size the cells, Flex automatically sizes the child to fit inside the cell boundaries. This, in turn, may clip the content inside the control; for instance, the label of a button might be clipped even though the button itself fits into the cell. If you specify an explicit child dimension that is greater than the `tileHeight` or `tileWidth` property, Flex clips the child.

If the child's default width or default height is smaller than the cell, the default horizontal alignment of the child in the cell is `left` and the default vertical alignment is `top`. You can use the `horizontalAlign` and `verticalAlign` properties of the `<mx:Tile>` tag to control the positioning of the child.

If the child uses percentage-based sizing, the child is enlarged or shrunk to the specified percentage of the cell. In the example in "Creating a Tile layout container" on page 613, the TextInput control named `text2` has a width of 100 pixels; therefore, the default width of all Tile cells is 100 pixels, so most children are smaller than the cell size. If you want all child controls to increase in size to the full width of the cells, set the `width` property of each child to 100%, as the following example shows. The example also shows how to use the Tile control's `tileWidth` property to specify the width of the tiles:

```
<?xml version="1.0"?>
<!-- containers\layouts\TileSizing.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <mx:Tile id="myFlow"
        direction="horizontal"
        borderStyle="solid"
        paddingTop="10" paddingBottom="10"
        paddingRight="10" paddingLeft="10"
        verticalGap="15" horizontalGap="10"
        tileWidth="100">

        <mx:TextInput id="fname" text="1" height="50" width="100%"/>
        <mx:TextInput id="lname" text="2" height="50" width="100%"/>
        <mx:TextInput id="addr1" text="3" height="50" width="100%"/>
        <mx:TextInput id="addr2" text="4" height="50" width="100%"/>
        <mx:TextInput id="addr3" text="5" height="50" width="100%"/>
    </mx:Tile>
</s:Application>
```

***Note:** When you set the child's `width` and `height` properties to percentages, the percentage is based on the size of the tile cell, not on the size of the Tile container itself. Even though it isn't an explicitly defined container, the cell acts as the parent of the components in the Tile container.*

MX TitleWindow layout container

A TitleWindow layout container is a Panel container that is optimized for use as a pop-up window. The container consists of a title bar, a caption and status area in the title bar, a border, and a content area for its children. Unlike the Panel container, it can display a Close button, and is designed to work as a pop-up window that users can drag around the screen the application window.

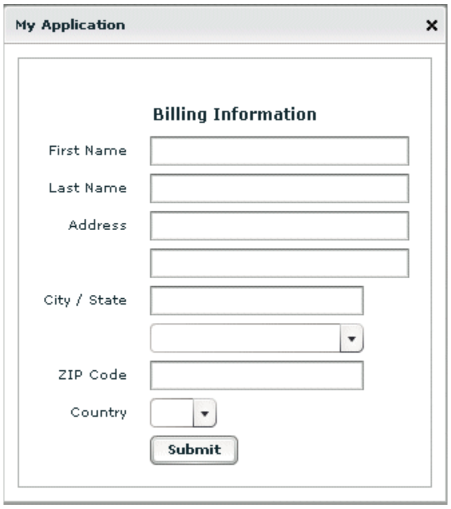
***Note:** Adobe recommends that, when possible, you use the Spark TitleWindow container instead of the MX TitleWindow container. For more information, see "The Spark TitleWindow container" on page 443.*

A pop-up TitleWindow container can be *modal*, which means that it takes all keyboard and mouse input until it is closed, or *nonmodal*, which means other windows can accept input while the pop-up window is still open.

One typical use for a TitleWindow container is to hold a form. When the user completes the form, you can close the TitleWindow container programmatically, or let the user request the application to close it by using the close icon (a box with an *x* inside it) in the upper-right corner of the window.

Because you pop up a Title window, you do not create it directly in MXML, as you do most controls; instead you use the PopUpManager.

The following example shows a TitleWindow container with a Form container as its child:



For complete reference information, see TitleWindow in the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Using the PopUpManager to create a TitleWindow container

To create and remove a pop-up TitleWindow container, you use methods of the PopUpManager. The PopUpManager is in the mx.managers package.

Creating a pop-up window

To create a pop-up window, use the PopUpManager`createPopUp()` method. The `createPopUp()` method has the following signature:

```
public static createPopUp(parent:DisplayObject, class:Class,
    modal:Boolean = false):IFlexDisplayObject
```

The method has the following arguments.

Argument	Description
`parent`	A reference to a window to pop-up over.
`class`	A reference to the class of object you want to create, typically a custom MXML component that implements a TitleWindow container.
`modal`	(Optional) A Boolean value that indicates whether the window is modal, and takes all mouse input until it is closed (`true`), or whether interaction is allowed with other controls while the window is displayed (`false`). The default value is `false`.

Note: *Flex continues executing code in the parent even after you create a modal pop-up window.*

You can also create a pop-up window by passing an instance of a TitleWindow class or custom component to the PopUpManager `addPopUp()` method. For more information, see “Using the addPopUp() method” on page 626.

Defining a custom TitleWindow component

One of the most common ways of creating a TitleWindow container is to define it as a custom MXML component.

- You define the TitleWindow container, its event handlers, and all of its children in the custom component.
- You use the PopUpManager `createPopUp()` and `removePopUp()` methods to create and remove the TitleWindow container.

The following example code defines a custom MyLoginForm TitleWindow component that is used as a pop-up window:

```
<?xml version="1.0"?>
<!-- containers\layouts\myComponents\MyLoginForm.mxml -->
<mx:TitleWindow xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <fx:Script>
        <![CDATA[
            import mx.managers.PopUpManager;

            private function processLogin():void {
                // Check credentials (not shown) then remove pop up.
                PopUpManager.removePopUp(this);
            }
        ]]>
    </fx:Script>
    <mx:Form>
        <mx:FormItem label="User Name">
            <mx:TextInput id="username" width="100%"/>
        </mx:FormItem>
        <mx:FormItem label="Password">
            <mx:TextInput id="password"
                displayAsPassword="true"
                width="100%"/>
        </mx:FormItem>
    </mx:Form>
    <mx:HBox>
        <mx:Button click="processLogin();" label="OK"/>
        <mx:Button
            label="Cancel"
            click="PopUpManager.removePopUp(this);"/>
    </mx:HBox>
</mx:TitleWindow>
```

This file, named MyLoginForm.mxml, defines a TitleWindow container by using the `<mx:TitleWindow>` tag. The TitleWindow container defines two TextInput controls, for user name and password, and two Button controls, for submitting the form and for closing the TitleWindow container. This example does not include the code for verifying the user name and password in the `submitForm()` event listener.

In this example, you process the form data in an event listener of the MyLoginForm.mxml component. To make this component more reusable, you can define the event listeners in your main application. This lets you create a generic form that leaves the data handling to the application that uses the form. For an example that defines the event listeners in the main application, see “Using TitleWindow and PopUpManager events” on page 620.

Using the PopUpManager to create the pop-up TitleWindow

To create a pop-up window, you call the PopUpManager `createPopUp()` method and pass it the parent, the name of the class that creates the pop-up, and the modal Boolean value. The following main application code creates the TitleWindow container defined in Defining a custom TitleWindow component:

```
<?xml version="1.0"?>
<!-- containers\layouts\MainMyLoginForm.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
            import mx.managers.PopUpManager;
            import mx.core.IFlexDisplayObject;
            import myComponents.MyLoginForm;
            private function showLogin():void {
                // Create a non-modal TitleWindow container.
                var helpWindow:IFlexDisplayObject =
                    PopUpManager.createPopUp(this, MyLoginForm, false);
            }
        ]]>
    </fx:Script>

    <mx:VBox width="300" height="300">
        <mx:Button click="showLogin();" label="Login"/>
    </mx:VBox>
</s:Application>
```

In this example, when the user selects the Login button, the event listener for the `click` event uses the `createPopUp()` method to create a TitleWindow container, passing to it the name of the MyLoginForm.mxml file as the class name.

Often, you cast the return value of the `createPopUp()` method to TitleWindow so that you can manipulate the properties of the pop-up TitleWindow container, as the following version of the `showLogin()` method from the preceding example shows:

```
<?xml version="1.0"?>
<!-- containers\layouts\MainMyLoginFormCast.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
          import mx.managers.PopUpManager;
          import mx.core.IFlexDisplayObject;
          import myComponents.MyLoginForm;
          // Additional import statement to use the TitleWindow container.
          import mx.containers.TitleWindow;
          private function showLogin():void {
            // Create the TitleWindow container.
            var helpWindow:TitleWindow =
          TitleWindow(PopUpManager.createPopUp(this, MyLoginForm, false));
            // Add title to the title bar.
            helpWindow.title="Enter Login Information";
            // Make title bar slightly transparent.
            helpWindow.setStyle("borderAlpha", 0.9);
            // Add a close button.
            // To close the container, your must also handle the close event.
            helpWindow.showCloseButton=true;
          }
        ]]>
    </fx:Script>

    <mx:VBox width="300" height="300">
        <mx:Button click="showLogin();" label="Login"/>
    </mx:VBox>
</s:Application>
```

Removing a pop-up window

To remove a pop-up TitleWindow, use the PopUpManager `removePopUp()` method. You pass the object created with the `PopUpManager.createPopUp()` method to the `removePopUp()` method. The following modification to the example from "Using the PopUpManager to create the pop-up TitleWindow" on page 617removes the pop-up when the user clicks the Done button:

```
<?xml version="1.0"?>
<!-- containers\layouts\MainMyLoginFormRemove.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
          import mx.managers.PopUpManager;
          import myComponents.MyLoginForm;
          import mx.core.IFlexDisplayObject;
          private var helpWindow:IFlexDisplayObject;
          private function showLogin():void {
            // Create the TitleWindow container.
            helpWindow = PopUpManager.createPopUp(this, MyLoginForm, false);
          }
          private function removeForm():void {
            PopUpManager.removePopUp(helpWindow);
          }
        ]]>
    </fx:Script>

    <mx:VBox width="300" height="300">
        <mx:Button click="showLogin();" label="Login"/>
        <mx:Button id="b2" label="Remove Form" click="removeForm();"/>
    </mx:VBox>
</s:Application>
```

You commonly call the `removePopUp()` method from a TitleWindow `close` event and the PopUpManager `mouseDownOutside` event, as described in “Passing data to and from a pop-up window” on page 622.

Centering a pop-up window

Call the `centerPopUp()` method of the PopUpManager to center the pop-up within another container. The following custom MXML component centers itself in its parent container:

```
<?xml version="1.0"?>
<!-- containers\layouts\myComponents\MyLoginFormCenter.mxml -->
<mx:TitleWindow xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="handleCreationComplete();">

    <fx:Script>
        <![CDATA[
            import mx.managers.PopUpManager;

            private function handleCreationComplete():void {
                // Center the TitleWindow container
                // over the control that created it.
                PopUpManager.centerPopUp(this);
            }

            private function processLogin():void {
                // Check credentials (not shown) then remove pop up.
                PopUpManager.removePopUp(this);
            }
        ]]>
    </fx:Script>
    <mx:Form>
        <mx:FormItem label="User Name">
            <mx:TextInput id="username" width="100%"/>
        </mx:FormItem>
        <mx:FormItem label="Password">
            <mx:TextInput id="password"
                width="100%"
                displayAsPassword="true"/>
        </mx:FormItem>
    </mx:Form>
    <mx:HBox>
        <mx:Button click="processLogin();" label="OK"/>
        <mx:Button
            label="Cancel"
            click="PopUpManager.removePopUp(this);"/>
    </mx:HBox>
</mx:TitleWindow>
```

Using TitleWindow and PopUpManager events

You can add a close icon (a small *x* in the upper-right corner of the TitleWindow title bar) to make it appear similar to dialog boxes in a GUI environment. You do this by setting the `showCloseButton` property to `true`, as the following example shows:

```
<mx:TitleWindow xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    showCloseButton="true">
```

The default value for `showCloseButton` is `false`.

The TitleWindow broadcasts a `close` event when the user clicks the close icon. You must create a handler for that event and close the TitleWindow from within that event handler. Flex does not close the window automatically.

In the simplest case, you can call the PopUpManager `removePopUp()` method directly in the TitleWindow `close` event property specify, as the following line shows:

```
<mx:TitleWindow xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    "showCloseButton="true"
    close="PopUpManager.removePopUp(this);">
```

If you need to clean up, before closing the TitleWindow control, create an event listener function for the close event and close the TitleWindow from within that handler, as the following example shows:

```
<?xml version="1.0"?>
<!-- containers\layouts\myComponents\MyLoginFormRemoveMe.mxml -->
<mx:TitleWindow xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    showCloseButton="true"
    close="removeMe();">
    <fx:Script>
        <![CDATA[
            import mx.managers.PopUpManager;
            private function removeMe():void {
                // Put any clean-up code here.
                PopUpManager.removePopUp(this);
            }
        ]]>
    </fx:Script>
</mx:TitleWindow>
```

You can also use the PopUpManager `mouseDownOutside` event to close the pop-up window when a user clicks the mouse outside the TitleWindow. To do this, you add an event listener to the TitleWindow instance for the `mouseDownOutside` event, as the following example shows:

```
<?xml version="1.0"?>
<!-- containers\layouts\MainMyLoginFormMouseDown.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
            import mx.managers.PopUpManager;
            import mx.containers.TitleWindow;
            import myComponents.MyLoginForm;
            import mx.events.FlexMouseEvent;
            private var helpWindow:TitleWindow;
            private function showLogin():void {
                // Create the TitleWindow container.
                helpWindow = TitleWindow(PopUpManager.createPopUp(this,
                    MyLoginForm, false));
                helpWindow.addEventListener("mouseDownOutside", removeForm);
            }
            private function removeForm(event:FlexMouseEvent):void {
                PopUpManager.removePopUp(helpWindow);
            }
        ]]>
    </fx:Script>

    <mx:VBox width="300" height="300">
        <mx:Button click="showLogin();" label="Login"/>
    </mx:VBox>
</s:Application>
```

You define the event listener in the main application, and then assign it to the pop-up window when you create it. This technique lets you use a generic pop-up window, defined by the component MyLoginForm.mxml, and then modify the behavior of the component by assigning event listeners to it from the main application.

Creating a modal pop-up window

The `createPopUp()` method takes an optional *modal* parameter. You can set this parameter to `true` to make the window modal. When a TitleWindow is modal, you cannot select any other component while the window is open. The default value of *modal* is `false`.

The following example creates a modal pop-up window:

```
var pop1:IFlexDisplayObject = PopUpManager.createPopUp(this, MyLoginForm,
    true);
```

Passing data to and from a pop-up window

To make your pop-up window more flexible, you might want to pass data to it or return data from it. To do this, use the following guidelines:

- Create a custom component to be your pop-up. In most circumstances, this component is a TitleWindow container.
- Declare variables in your pop-up that you will set in the application that creates the pop-up.
- Cast the pop-up to be the same type as your custom component.
- Pass a reference to that component to the pop-up window, if the pop-up window is to set a value on the application or one of the application's components.

For example, the following application populates a ComboBox in the pop-up window with an Array defined in the main application.

When creating the pop-up, the application casts the pop-up to be of type ArrayEntryForm, which is the name of the custom component that defines the pop-up window. If you do not do this, the application cannot access the properties that you create.

The application passes a reference to the TextInput component in the Application container to the pop-up window so that the pop-up can write its results back to the container. The application also passes the Array of file extensions for the pop-up ComboBox control's data provider, and sets the pop-up window's title. By setting these in the application, you can reuse the pop-up window in other parts of the application without modification, because it does not have to know the name of the component it is writing back to or the data that it is displaying, only that its data is in an Array and it is writing to a TextArea.

```
<?xml version="1.0"?>
<!-- containers\layouts\MainArrayEntryForm.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import mx.managers.PopUpManager;
            import myComponents.ArrayEntryForm;

            public var helpWindow:Object;

            public function displayForm():void {
                /* Array with data for the custom control ComboBox control. */
                var doctypes:Array = ["*.as", "*.mxml", "*.swc"]

                /* Create the pop-up and cast the
```

```
                  return value of the createPopUp()
                  method to the ArrayEntryForm custom component. */
               var pop1:ArrayEntryForm = ArrayEntryForm(
                   PopUpManager.createPopUp(this, ArrayEntryForm, true));

               /* Set TitleWindow properties. */
               pop1.title="Select File Type";
               pop1.showCloseButton=true;

               /* Set properties of the ArrayEntryForm custom component. */
               pop1.targetComponent = ti1;
               pop1.myArray = doctypes;
               PopUpManager.centerPopUp(pop1);
           }
       ]]>
    </fx:Script>
    <mx:TextInput id="ti1" text=""/>
    <mx:Button id="b1" label="Select File Type"
        click="displayForm();"/>
</s:Application>
```

The following custom component, ArrayEntryForm.mxml, declares two variables. The first one is for the Array that the parent application passes to the pop-up window. The second holds a reference to the parent application's TextInput control. The component uses that reference to update the parent application:

```
<?xml version="1.0"?>
<!-- containers\layouts\myComponents\ArrayEntryForm.mxml -->
<mx:TitleWindow xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
        showCloseButton="true"
        width="200" borderAlpha="1"
        close="removeMe();">

    <fx:Script>
        <![CDATA[
            import mx.controls.TextInput;
            import mx.managers.PopUpManager;

            // Variables whose values are set by the main application.
            // Data provider array for the component's ComboBox control.
            [Bindable]
            public var myArray:Array;
            // A reference to the TextInput control
            // in which to put the result.
            public var targetComponent:TextInput;
            // OK button click event listener.
            // Sets the target component in the application to the
            // selected ComboBox item value.
            private function submitData():void {
                targetComponent.text = String(cb1.selectedItem);
                removeMe();
            }
            // Cancel button click event listener.
            private function removeMe():void {
                PopUpManager.removePopUp(this);
            }
        ]]>
    </fx:Script>
    <mx:ComboBox id="cb1" dataProvider="{myArray}"/>
    <mx:HBox>
        <mx:Button label="OK" click="submitData();"/>
        <mx:Button label="Cancel" click="removeMe();"/>
    </mx:HBox>
</mx:TitleWindow>
```

From within a pop-up custom component, you can also access properties of the parent application by using the `parentApplication` property. For example, if the application has a Button control named b1, you can get the label of that Button control, as the following example shows:

```
myLabel = parentApplication.b1.label;
```

This technique, however, uses a hard-coded value in the pop-up component for both the target component id in the parent and the property in the component.

Passing data using events

The following example modifies the example from the previous section to use event listeners defined in the main application to handle the passing of data back from the pop-up window to the main application. This example shows the ArrayEntryFormEvents.mxml file with no event listeners defined within it.

```
<?xml version="1.0"?>
<!-- containers\layouts\myComponents\ArrayEntryFormEvents.mxml -->
<mx:TitleWindow xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    showCloseButton="true"
    width="200"
    borderAlpha="1">

    <fx:Script>
        <![CDATA[
            import mx.managers.PopUpManager;

            // Variables whose values are set by the main application.
            // Data provider array for the component's ComboBox control.
            [Bindable]
            public var myArray:Array;
        ]]>
    </fx:Script>
    <mx:ComboBox id="cb1" dataProvider="{myArray}"/>
    <mx:HBox>
        <mx:Button id="okButton" label="OK"/>
        <mx:Button id="cancelButton" label="Cancel"/>
    </mx:HBox>
</mx:TitleWindow>
```

The main application defines the event listeners and registers them with the controls defined within the pop-up window:

```
<?xml version="1.0"?>
<!-- containers\layouts\MainArrayEntryFormEvents.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import mx.managers.PopUpManager;
            import flash.events.Event;
            import myComponents.ArrayEntryFormEvents;

            public var pop1:ArrayEntryFormEvents;

            public function displayForm():void {
                // Array with data for the custom control ComboBox control.
                var doctypes:Array = ["*.as", "*.mxml", "*.swc"]

                // Create the pop-up and cast the return value
                // of the createPopUp()
                // method to the ArrayEntryFormEvents custom component.
                pop1 = ArrayEntryFormEvents(
              PopUpManager.createPopUp(this, ArrayEntryFormEvents, true));
                // Set TitleWindow properties.
                pop1.title="Select File Type";
                pop1.showCloseButton=true;
                // Set the event listeners for
                // the ArrayEntryFormEvents component.
                pop1.addEventListener("close", removeMe);
                pop1["cancelButton"].addEventListener("click", removeMe);
                pop1["okButton"].addEventListener("click", submitData);

                // Set properties of the ArrayEntryFormEvents custom control.
                pop1.myArray = doctypes;
                PopUpManager.centerPopUp(pop1);
            }

            // OK button click event listener.
            // Sets the target component in the application to the
            // selected ComboBox item value.
            private function submitData(event:Event):void {
                ti1.text = String(pop1.cb1.selectedItem);
                removeMe(event);
            }
            // Cancel button click event listener.
            private function removeMe(event:Event):void {
                PopUpManager.removePopUp(pop1);
            }
        ]]>
    </fx:Script>
    <mx:VBox>
        <mx:TextInput id="ti1" text=""/>
    </mx:VBox>
    <mx:Button id="b1" label="Select File Type" click="displayForm();"/>
</s:Application>
```

Using the addPopUp() method

You can use the `addPopUp()` method of the PopUpManager to create a pop-up window without defining a custom component. This method takes an instance of any class that implements IFlexDisplayObject. Because it takes a class instance, not a class, you can use ActionScript code in an `<fx:Script>` block to create the component instance to pop up, rather than as a separate custom component.

Using the `addPopUp()` method may be preferable to using the `createPopUp()` method if you have to pop up a simple dialog box that is never reused elsewhere. However, it is not the best coding practice if the pop-up is complex or cannot be reused elsewhere.

The following example creates a pop-up with `addPopUp()` method and adds a Button control to that window that closes the window when you click it:

```
<?xml version="1.0"?>
<!-- containers\layouts\MyPopUpButton.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    height="600" width="600" >
    <fx:Script>
        <![CDATA[
            import mx.containers.TitleWindow;
            import flash.events.*;
            import mx.managers.PopUpManager;
            import mx.controls.Button;
            import mx.core.IFlexDisplayObject;

            // The variable for the TitleWindow container
            public var myTitleWindow:TitleWindow = new TitleWindow();
            // Method to instantiate and display a TitleWindow container.
            // This is the initial Button control's click event handler.
            public function openWindow(event:MouseEvent):void {
                // Set the TitleWindow container properties.
                myTitleWindow = new TitleWindow();
                myTitleWindow.title = "My Window Title";
                myTitleWindow.width= 220;
                myTitleWindow.height= 150;
                // Call the method to add the Button control to the
                // TitleWindow container.
                populateWindow();
                // Use the PopUpManager to display the TitleWindow container.
                PopUpManager.addPopUp(myTitleWindow, this, true);
            }

            // The method to create and add the Button child control to the
            // TitleWindow container.
            public function populateWindow():void {
                var btn1:Button = new Button();
                btn1.label="close";
                btn1.addEventListener(MouseEvent.CLICK, closeTitleWindow);
                myTitleWindow.addChild(btn1);
            }

            // The method to close the TitleWindow container.
            public function closeTitleWindow(event:MouseEvent):void {
                PopUpManager.removePopUp(event.currentTarget.parent);
            }
        ]]>
    </fx:Script>
    <mx:Button label="Open Window" click="openWindow(event);"/>
</s:Application>
```

You can make any component pop up. The following example pops up a TextArea control. The example resizes the control, and listens for a Shift-click to determine when to close the TextArea. Whatever text you type in the TextArea is stored in a Label control in the application when the pop-up window is removed.

```
<?xml version="1.0"?>
<!-- containers\layouts\MyPopUpTextArea.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
            import mx.managers.PopUpManager;
            import mx.controls.TextArea;
            import mx.core.IFlexDisplayObject;

            public var myPopUp:TextArea

            public function openWindow(event:MouseEvent):void {
                myPopUp = new TextArea();
                myPopUp.width= 220;
                myPopUp.height= 150;
                myPopUp.text = "Hold down the Shift key, and " +
                    "click in the TextArea to close it.";
                myPopUp.addEventListener(MouseEvent.CLICK, closeWindow);
                PopUpManager.addPopUp(myPopUp, this, true);
                PopUpManager.centerPopUp(myPopUp);
            }

            public function closeWindow(event:MouseEvent):void {
                if (event.shiftKey) {
                    label1.text = myPopUp.text;
        PopUpManager.removePopUp(IFlexDisplayObject(event.currentTarget));
                }
            }
        ]]>
    </fx:Script>
    <mx:VBox>
        <mx:Button id="b1" label="Create TextArea Popup"
            click="openWindow(event);"/>
        <mx:Label id="label1"/>
    </mx:VBox>
</s:Application>
```

MX navigator containers

MX navigator containers control user movement, or navigation, among multiple children where the children are other MX containers. The individual child containers of the navigator container oversee the layout and positioning of their children; the navigator container does not oversee layout and positioning.

About MX navigator containers

An MX navigator container controls user movement through a group of child MX containers. For example, a TabNavigator container lets you select the visible child container by using a set of tabs.

***Note:** The direct children of an MX navigator container must be MX containers, either MX layout or MX navigator containers, or a Spark NavigatorContent container. You cannot directly nest a control or a Spark container other than the Spark NavigatorContent container in an MX navigator.*

Adobe® Flex® provides the following navigator containers:

- ViewStack
- TabNavigator
- Accordion

Using Spark containers in an MX navigator container

The children of a navigator container must be MX containers or a Spark NavigatorContent container. The following example uses the Spark NavigatorContent container as a child of an Accordion container:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- containers\spark\SparkNavContent.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <mx:Accordion>
        <s:NavigatorContent label="Pane 1"
            width="100" height="100">
            <s:layout>
                <s:VerticalLayout paddingTop="10" paddingLeft="5"/>
            </s:layout>
            <s:Label text="Text for Pane 1"/>
            <s:Button label="Button 1"/>
        </s:NavigatorContent>
        <s:NavigatorContent label="Pane 2"
            width="100" height="100">
            <s:layout>
                <s:VerticalLayout paddingTop="10" paddingLeft="5"/>
            </s:layout>
            <s:Label text="Text for Pane 2"/>
            <s:Button label="Button 2"/>
        </s:NavigatorContent>
        <s:NavigatorContent label="Pane 3"
            width="100" height="100">
            <s:layout>
                <s:VerticalLayout paddingTop="10" paddingLeft="5"/>
            </s:layout>
            <s:Label text="Text for Pane 3"/>
            <s:Button label="Button 3"/>
        </s:NavigatorContent>
    </mx:Accordion>
</s:Application>
```

For more information on the NavigatorContent container, see “The Spark NavigatorContent container” on page 433.

To use a Spark container other than the Spark NavigatorContent container as the child of a navigator, wrap it in an MX container or in the Spark NavigatorContent container. The following wraps a Spark SkinnableContainer container in an MX Box container:

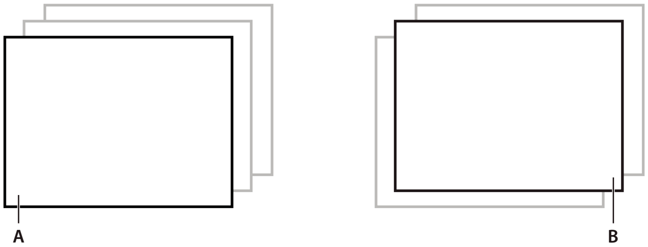
```
<?xml version="1.0"?>
<!-- containers\navigators\AccordionSimpleSpark.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <mx:Accordion id="accordion1" height="250">
        <mx:Box label="Accordion Panel 1">
            <s:SkinnableContainer>
                <s:TextInput text="Text 1"/>
            </s:SkinnableContainer>
        </mx:Box>
        <mx:Box label="Accordion Panel 2">
            <s:SkinnableContainer>
                <s:Button label="Button 2"/>
            </s:SkinnableContainer>
        </mx:Box>
        <mx:Box label="Accordion Panel 3">
            <s:SkinnableContainer>
                <s:CheckBox label="CheckBox 3"/>
            </s:SkinnableContainer>
        </mx:Box>
    </mx:Accordion>
</s:Application>
```

This scenario lets you take advantage of the new features of the Spark containers, such as skinning and styling, which still being able to use them in MX navigators.

MX ViewStack navigator container

A ViewStack navigator container is made up of a collection of child containers that are stacked on top of each other, with only one container visible, or active, at a time. The ViewStack container does not define a built-in mechanism for users to switch the currently active container; you must use a LinkBar, TabBar, ButtonBar, or ToggleButtonBar control or build the logic yourself in ActionScript to let users change the currently active child. For example, you can define a set of Button controls that switch among the child containers.

The following image shows the stacked child containers in a ViewStack container:



A. *Child container 1 active* ***B.*** *Child container 0 active*

On the left, you see a ViewStack container with the first child active. The index of a child in a ViewStack container is numbered from 0 to *n* - 1, where *n* is the number of child containers. The container on the right is a ViewStack container with the second child container active.

For complete reference information, see ViewStack in the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Creating a ViewStack container

You use the <mx:ViewStack> tag to define a ViewStack container, and you define the child containers in the tag body. You use the following properties of the ViewStack container to control the active child container:

`selectedIndex` The index of the currently active container if one or more child containers are defined. The value of this property is -1 if no child containers are defined. The index is numbered from 0 to `numChildren` - 1, where `numChildren` is the number of child containers in the ViewStack container. Set this property to the index of the container that you want active.

You can use the `selectedIndex` property of the `<mx:ViewStack>` tag to set the default active container when your application starts. The following example sets the index of the default active container to 1:

```
<mx:ViewStack id="myViewStack" selectedIndex="1">
```

The following example uses ActionScript to set the `selectedIndex` property so that the active child container is the second container in the stack:

```
myViewStack.selectedIndex=1;
```

`selectedChild` The currently active container if one or more child containers are defined. The value of this property is `null` if no child containers are defined. Set this property in ActionScript to the identifier of the container that you want active.

You can set this property only in an ActionScript statement, not in MXML.

The following example uses ActionScript to set the `selectedChild` property so that the active child container is the child container with an identifier of `search`:

```
myViewStack.selectedChild=search;
```

`numChildren` Contains the number of child containers in the ViewStack container.

The following example uses the `numChildren` property in an ActionScript statement to set the active child container to the last container in the stack:

```
myViewStack.selectedIndex=myViewStack.numChildren-1;
```

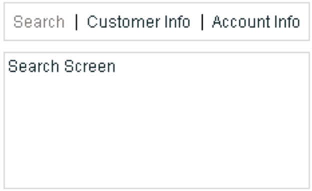
***Note:** The default creation policy for all containers, except the Application container, is the policy of the parent container. The default policy for the Application container is auto. In most cases, therefore, the View Stack control's children are not created until they are selected. You cannot set the `selectedChild` property to a child that is not yet created.*

The following example creates a ViewStack container with three child containers. The example also defines three Button controls that when clicked, select the active child container:

```
<?xml version="1.0"?>
<!-- containers\navigators\VSSimple.mxml  -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <!-- Create a VGroup container so the container for
        the buttons appears above the ViewStack container. -->
    <s:VGroup>
        <!-- Create an HBox container to hold the three buttons. -->
        <mx:HBox borderStyle="solid">
            <!-- Define the three buttons.
                Each uses the child container identifier
                to set the active child container. -->
            <s:Button id="searchButton"
                label="Search Screen"
                click="myViewStack.selectedChild=search;"/>
            <s:Button id="cInfoButton"
                label="Customer Info Screen"
                click="myViewStack.selectedChild=custInfo;"/>
            <s:Button id="aInfoButton"
                label="Account Info Screen"
                click="myViewStack.selectedChild=accountInfo;"/>
        </mx:HBox>
        <!-- Define the ViewStack and the three child containers and have it
            resize up to the size of the container for the buttons. -->
        <mx:ViewStack id="myViewStack"
            borderStyle="solid" width="100%">
            <mx:Canvas id="search" label="Search">
                <mx:Label text="Search Screen"/>
            </mx:Canvas>
            <mx:Canvas id="custInfo" label="Customer Info">
                <mx:Label text="Customer Info"/>
            </mx:Canvas>
            <mx:Canvas id="accountInfo" label="Account Info">
                <mx:Label text="Account Info"/>
            </mx:Canvas>
        </mx:ViewStack>
    </s:VGroup>
</s:Application>
```

When this example loads, the three Button controls appear, and the first child container defined in the ViewStack container is active. Select a Button control to change the active container.

You can also use an MX LinkBar, TabBar, ButtonBar, or ToggleButtonBar control or the Spark ButtonBar or TabBar control to set the active child of a ViewStack container. These controls can determine the number of child containers in a ViewStack container, and then create a horizontal or vertical set of links, tabs, or buttons that let the user select the active child, as the following image shows:



The items in the LinkBar control correspond to the values of the `label` property of each child of the ViewStack container, as the following example shows:

```
<?xml version="1.0"?>
<!-- containers\navigators\VSLinkBar.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:VGroup>
        <!-- Create a LinkBar control to navigate
            the ViewStack container. -->
        <mx:LinkBar dataProvider="{myViewStack}" borderStyle="solid"/>
        <!-- Define the ViewStack and the three child containers. -->
        <mx:ViewStack id="myViewStack"
            borderStyle="solid"
            width="100%">

            <mx:Canvas id="search" label="Search">
                <mx:Label text="Search Screen"/>
            </mx:Canvas>
            <mx:Canvas id="custInfo" label="Customer Info">
                <mx:Label text="Customer Info"/>
            </mx:Canvas>
            <mx:Canvas id="accountInfo" label="Account Info">
                <mx:Label text="Account Info"/>
            </mx:Canvas>
        </mx:ViewStack>
    </s:VGroup>
</s:Application>
```

You provide only a single property to the navigator bar control, `dataProvider`, to specify the name of the ViewStack container associated with it. For more information on the LinkBar control, see “LinkBar control” on page 693. For more information on the TabBar control, see “MX TabBar control” on page 720. For more information on the ButtonBar and ToggleButtonBar controls, see “MX ButtonBar and MX ToggleButtonBar controls” on page 656.

You can also use the Spark ButtonBar control to set the active child of a ViewStack container, as the following example shows:

```
<?xml version="1.0"?>
<!-- containers\navigators\VSSparkButtonBar.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:VGroup>
        <!-- Create a Spark ButtonBar control to navigate
            the ViewStack container. -->
        <s:ButtonBar dataProvider="{myViewStack}"/>
        <!-- Define the ViewStack and the three child containers. -->
        <mx:ViewStack id="myViewStack"
            borderStyle="solid"
            width="100%">

            <s:NavigatorContent id="search" label="Search">
                <s:Label text="Search Screen"/>
            </s:NavigatorContent>
            <s:NavigatorContent id="custInfo" label="Customer Info">
                <s:Label text="Customer Info"/>
            </s:NavigatorContent>
            <s:NavigatorContent id="accountInfo" label="Account Info">
                <s:Label text="Account Info"/>
            </s:NavigatorContent>
        </mx:ViewStack>
    </s:VGroup>
</s:Application>
```

For more information on the Spark ButtonBar control, see the “Spark ButtonBar and TabBar controls” on page 529.

Sizing the children of a ViewStack container

The default width and height of a ViewStack container is the width and height of the first child. A ViewStack container does not change size every time you change the active child.

You can use the following techniques to control the size of a ViewStack container so that it displays all the components inside its children:

- Set explicit `width` and `height` properties for all children to the same fixed values.
- Set percentage-based `width` and `height` properties for all children to the same fixed values.
- Set `width` and `height` properties for the ViewStack container to a fixed or percentage-based value.

  The technique that you use is based on your application and the content of your ViewStack container.

Applying effects to a ViewStack container

You can assign effects to the ViewStack container or to its children. For example, if you assign the WipeRight effect to the `creationCompleteEffect` property of the ViewStack control, Flex plays the effect once when the ViewStack first appears.

To specify the effects that run when the ViewStack changes children, use the children’s `hideEffect` and `showEffect` properties. The effect specified by the `hideEffect` property plays as a container is being hidden, and the effect specified by the `showEffect` property plays as the newly visible child appears. The ViewStack container waits for the completion of the effect specified by the `hideEffect` property for the container that is being hidden before it reveals the new child container.

The following example runs a WipeRight effect when the ViewStack container is first created, and runs a WipeDown effect when each child is hidden and a WipeUp effect when a new child appears.

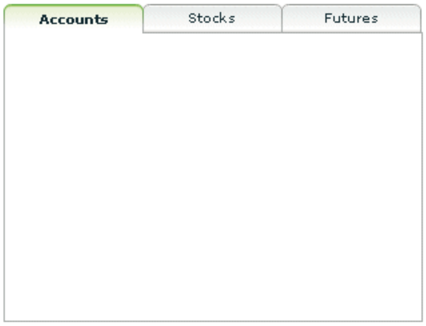
```
<?xml version="1.0"?>
<!-- containers\navigators\VSLinkEffects.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <fx:Declarations>
        <mx:WipeUp id="myWU" duration="300"/>
        <mx:WipeDown id="myWD" duration="300"/>
        <mx:WipeRight id="myWR" duration="300"/>
    </fx:Declarations>
    <s:VGroup>
        <mx:LinkBar dataProvider="{myViewStack}"
            borderStyle="solid"
            backgroundColor="#EEEEFF"/>
        <mx:ViewStack id="myViewStack"
            borderStyle="solid"
            width="100%"
            creationCompleteEffect="{myWR}">
            <mx:Canvas id="search"
                label="Search"
                hideEffect="{myWD}"
                showEffect="{myWU}">
                <mx:Label text="Search Screen"/>
            </mx:Canvas>
            <mx:Canvas id="custInfo"
                label="Customer Info"
                hideEffect="{myWD}"
                showEffect="{myWU}">
                <mx:Label text="Customer Info"/>
            </mx:Canvas>
            <mx:Canvas id="accountInfo"
                label="Account Info"
                hideEffect="{myWD}"
                showEffect="{myWU}">
                <mx:Label text="Account Info"/>
            </mx:Canvas>
        </mx:ViewStack>
    </s:VGroup>
</s:Application>
```

Notice that the `showEffect` property of a container is only triggered when the container's visibility changes from `false` to `true`. Therefore, you use the `creationCompleteEffect` property to trigger the effect when Flex first creates the component.

MX TabNavigator container

A TabNavigator container creates and manages a set of tabs, which you use to navigate among its children. The children of a TabNavigator container are other containers. The TabNavigator container creates one tab for each child. When the user selects a tab, the TabNavigator container displays the associated child, as the following image shows:



The TabNavigator container is a child class of the ViewStack container and inherits much of its functionality. For complete reference information, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Creating a TabNavigator container

You use the <mx:TabNavigator tag to define a TabNavigator container. Only one child of the TabNavigator container is visible at a time. Users can make any child the selected child by selecting its associated tab or by using keyboard navigation controls. Whenever the user changes the current child, the TabNavigator container broadcasts a `change` event.

The TabNavigator container automatically creates a tab for each of its children and determines the tab text from the `label` property of the child, and the tab icon from the `icon` property of the child. The tabs are arranged left to right in the order determined by the child indexes. All tabs are visible, unless they do not fit within the width of the TabNavigator container.

If you disable a child of a TabNavigator container by setting its `enabled` property to `false`, you also disable the associated tab.

The following code creates the TabNavigator container in the image in “MX TabNavigator container” on page 636:

```
<?xml version="1.0"?>
<!-- containers\navigators\TNSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <mx:TabNavigator borderStyle="solid" >
        <mx:VBox label="Accounts"
            width="300"
            height="150">
            <!-- Accounts view goes here. -->
        </mx:VBox>
        <mx:VBox label="Stocks"
            width="300"
            height="150">
            <!-- Stocks view goes here. -->
        </mx:VBox>
        <mx:VBox label="Futures"
            width="300"
            height="150">
            <!-- Futures view goes here. -->
        </mx:VBox>
    </mx:TabNavigator>
</s:Application>
```

You can also set the currently active child by using the `selectedChild` and `selectedIndex` properties inherited from the ViewStack container as follows:

- `numChildren` The index of the currently active container if one or more child containers are defined. The index is numbered from 0 to `numChildren` - 1, where `numChildren` is the number of child containers in the TabNavigator container. Set this property to the index of the container that you want active.
- `selectedChild` The currently active container, if one or more child containers are defined. This property is `null` if no child containers are defined. Set this property to the identifier of the container that you want active. You can set this property only in an ActionScript statement, not in MXML.

For more information on the `selectedChild` and `selectedIndex` properties, including examples, see “MX ViewStack navigator container” on page 630.

You use the `showEffect` and `hideEffect` properties of the children of a TabNavigator container to specify an effect to play when the user changes the currently active child. The following example plays the WipeRight effect each time the selected tab changes:

```
<?xml version="1.0"?>
<!-- containers\navigators\TNEffect.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Declarations>
        <mx:WipeRight id="myWR"/>
    </fx:Declarations>
    <mx:TabNavigator>
        <mx:VBox label="Accounts"
            width="300"
            height="150"
            showEffect="{myWR}">
            <!-- Accounts view goes here. -->
            <mx:Text text="This is a text control."/>
        </mx:VBox>
        <mx:VBox label="Stocks"
            width="300"
            height="150"
            showEffect="{myWR}">
            <!-- Stocks view goes here. -->
            <mx:Text text="This is a text control."/>
        </mx:VBox>
        <mx:VBox label="Futures"
            width="300"
            height="150"
            showEffect="{myWR}">
            <!-- Futures view goes here. -->
            <mx:Text text="This is a text control."/>
        </mx:VBox>
    </mx:TabNavigator>
</s:Application>
```

Sizing the children of a TabNavigator container

The default width and height of a TabNavigator container is the width and height of the first child. A TabNavigator container does not change size every time you change the active child.

You can use the following techniques to control the size of a TabNavigator container so that it displays all the components inside its children:

- Set explicit `width` and `height` properties for all children to the same fixed values.
- Set percentage-based `width` and `height` properties for all children to the same fixed values.
- Set explicit or percentage-based `width` and `height` properties for the TabNavigator container.

  The method that you use is based on your application and the content of your TabNavigator container.

TabNavigator container Keyboard navigation

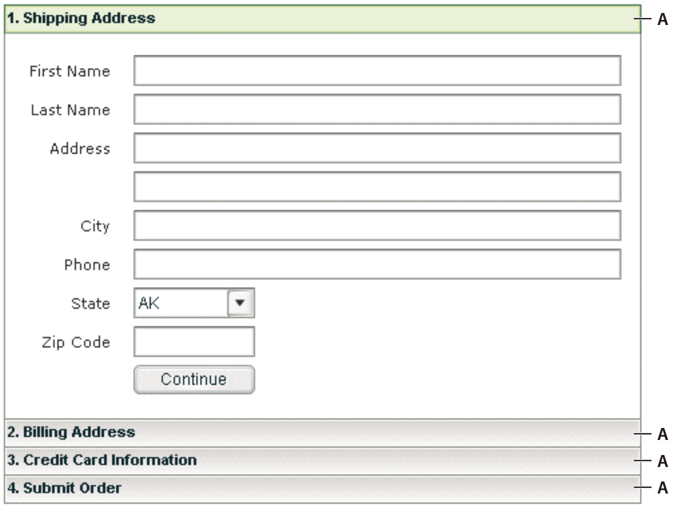
When a TabNavigator container has focus, Flex processes keystrokes as the following table describes:

Key	Action
Down Arrow Right Arrow	Gives focus to the next tab, wrapping from last to first, without changing the selected child.
Up Arrow Left Arrow	Gives focus to the previous tab, wrapping from first to last, without changing the selected child.
Page Down	Selects the next child, wrapping from last to first.
Page Up	Selects the previous child, wrapping from first to last.
Home	Selects the first child.
End	Selects the last child.
Enter Spacebar	Selects the child associated with the tab displaying focus.

MX Accordion navigator container

Forms are a basic component of many applications. However, users have difficulty navigating through complex forms, or moving back and forth through multipage forms. Sometimes, forms can be so large that they do not fit onto a single screen.

Flex includes the Accordion navigator container, which can greatly improve the look and navigation of a form. The Accordion container defines a sequence of child panels, but displays only one panel at a time. The following image shows an example of an Accordion container:



A. *Accordion container navigation button* *A.* *Accordion container navigation button*

To navigate a container, the user clicks the navigation button that corresponds to the child panel that they want to access. Accordion containers let users access the child panels in any order to move back and forth through the form. For example, when the user is in the Credit Card Information panel, they might decide to change the information in the Billing Address panel. To do so, they navigate to the Billing Address panel, edit the information, and then navigate back to the Credit Card Information panel.

In HTML, a form that contains shipping address, billing address, and credit card information is often implemented as three separate pages, which requires the user to submit each page to the server before moving on to the next. An Accordion container can organize the information on three child panels with a single Submit button. This architecture minimizes server traffic and lets the user maintain a better sense of progress and context.

***Note:** An empty Accordion container with no child panels cannot take focus.*

Although Accordion containers are useful for working with forms and Form containers, you can use any Flex component within a child panel of an Accordion container. For example, you could create a catalog of products in an Accordion container, where each panel contains a group of similar products.

For complete reference information, see Accordion in the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Creating an Accordion container

You use the `<mx:Accordion>` tag to define an Accordion container. In the Accordion container, you define one container for each child panel. For example, if the Accordion container has four child panels that the correspond to four parts of a form, you define each child panel by using the Form container, as the following example shows:

```
<?xml version="1.0"?>
<!-- containers\navigators\AccordionSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <mx:Accordion id="accordion1" height="250">
        <mx:Form id="shippingAddress" label="1. Shipping Address">
            <mx:FormItem id="sfirstNameItem" label="First Name">
                <mx:TextInput id="sfirstName"/>
            </mx:FormItem>
            <!-- Additional contents goes here. -->
        </mx:Form>
        <mx:Form id="billingAddress" label="2. Billing Address">
            <!-- Form contents goes here. -->
        </mx:Form>
        <mx:Form id="creditCardInfo" label="3. Credit Card Information">
            <!-- Form contents goes here. -->
        </mx:Form>
        <mx:Form id="submitOrder"   label="4. Submit Order">
            <!-- Form contents goes here. -->
        </mx:Form>
    </mx:Accordion>
</s:Application>
```

This example defines each child panel by using a Form container. However, you can use any container to define a child panel.

***Note:** You can use any container to define child panels. Some containers, such as an Accordion container, do not belong in child panels.*

Accordion container Keyboard navigation

When an Accordion container has focus, Flex processes keystrokes as the following table describes:

Key	Action
Down Arrow Right Arrow	Gives focus to the next button, wrapping from last to first, without changing the selected child.
Up Arrow Left Arrow	Gives focus to the previous button, wrapping from first to last, without changing the selected child.
Page Up	Moves to the previous child panel, wrapping from first to last.
Page Down	Moves to the next child panel, wrapping from last to first.
Home	Moves to the first child panel.
End	Moves to the last child panel.
Enter Spacebar	Selects the child associated with the tab displaying focus.

Using Button controls to navigate an Accordion container

The simplest way for users to navigate the panels of an Accordion container is to click the navigator button for the desired panel. However, you can create additional navigation Button controls, such as Back and Next, to make it easier for users to navigate.

Navigation Button controls use the following properties of the Accordion container to move among the child panels:

Property	Description
`numChildren`	Contains the total number of child panels defined in an Accordion container.
`selectedIndex`	The index of the currently active child panel. Child panels are numbered from 0 to `numChildren` - 1. Setting the `selectedIndex` property changes the currently active panel.
`selectedChild`	The currently active child container if one or more child containers are defined. This property is `null` if no child containers are defined. Set this property to the identifier of the container that you want active. You can set this property only in an ActionScript statement, not in MXML.

For more information on these properties, see “MX ViewStack navigator container” on page 630.

You can use the following two Button controls, for example, in the second panel of an Accordion container, panel number 1, to move back to panel number 0 or ahead to panel number 2:

```
<?xml version="1.0"?>
<!-- containers\navigators\AccordionButtonNav.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <mx:Accordion id="accordion1" height="250">
        <mx:Form id="shippingAddress" label="1. Shipping Address">
            <mx:FormItem id="sfirstNameItem" label="First Name">
                <s:TextInput id="sfirstName"/>
            </mx:FormItem>
        </mx:Form>
        <mx:Form id="billingAddress" label="2. Billing Address">
            <s:Button id="backButton"
                label="Back"
                click="accordion1.selectedIndex=0;"/>
            <s:Button id="nextButton"
                label="Next"
                click="accordion1.selectedIndex=2;"/>
        </mx:Form>
        <mx:Form id="creditCardInfo" label="3. Credit Card Information">
        </mx:Form>
    </mx:Accordion>
</s:Application>
```

You can also use relative location with navigation buttons. The following Button controls move forward and backward through Accordion container panels based on the current panel number:

```
<s:Button id="backButton" label="Back"
    click="accordion1.selectedIndex = accordion1.selectedIndex - 1;"/>
<s:Button id="nextButton" label="Next"
    click="accordion1.selectedIndex = accordion1.selectedIndex + 1;"/>
```

For the Next Button control, you also can use the `selectedChild` property to move to the next panel based on the value of the `id` property of the panel's container, as the following code shows:

```
<s:Button id="nextButton" label="Next"
    click="accordion1.selectedChild=creditCardInfo;"/>
```

The following Button control opens the last panel in the Accordion container:

```
<s:Button id="lastButton" label="Last"
    click="accordion1.selectedIndex = accordion1.numChildren - 1;"/>
```

Handling child button events

The Accordion container can recognize an event when the user changes the current panel. The Accordion container broadcasts a `change` event when the user changes the child panel, either by clicking a button or pressing a key, such as the Page Down key.

***Note:** A `change` event is not dispatched when the child panel changes programmatically; for example, the `change` event is not dispatched when you use the buttons in change panels (see "Using Button controls to navigate an Accordion container" on page 641). However, the `valueCommit` event is dispatched.*

You can register an event handler for the `change` event by using the `change` property of the `<mx:Accordion>` tag, or by registering the handler in ActionScript. The following example logs the change event to flashlog.txt each time the user changes panels:

```
<mx:Accordion id="accordion1" height="450" change="trace('change');">
```

Controlling the appearance of accordion buttons

The buttons on an Accordion container are rendered by the AccordionHeader class, which is a subclass of Button, and has the same style properties as the Button class.

To change the style of an Accordion button, call the Accordion class `getHeaderAt()` method to get a reference to a child container's button, and then call the button's `setStyle()` method to set the style. The following example uses this technique to set a different text color for each of the Accordion buttons:

```
<?xml version="1.0"?>
<!-- containers\navigators\AccordionStyling.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    width="600"
    height="600"
    creationComplete="setButtonStyles();">
    <fx:Script>
        <![CDATA[
            public function setButtonStyles():void {
                comp.getHeaderAt(0).setStyle('color', 0xAA0000);
                comp.getHeaderAt(1).setStyle('color', 0x00AA00);
            }
        ]]>
    </fx:Script>
    <mx:Accordion id="comp">
        <mx:VBox label="First VBox">
            <mx:TextInput/>
            <mx:Button label="Button 1"/>
        </mx:VBox>
        <mx:VBox label="Second VBox">
            <mx:TextInput/>
            <mx:Button label="Button 2"/>
        </mx:VBox>
    </mx:Accordion>
</s:Application>
```

You can also control the appearance of the buttons by using the `headerStyleName` style property of the Accordion class. For more information, see Accordion in the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

UI Controls

UI Controls are user-interface components such as Button, TextArea, and CheckBox controls. Adobe® Flex® has two types of controls: basic and data provider. For information on data provider controls, see "MX data-driven controls" on page 943.

About UI controls

UI controls are user-interface components, such as Button, TextArea, and CheckBox controls. You place UI controls in containers, which are user-interface components that provide a hierarchical structure for controls and other containers. Typically, you define a container, and then insert UI controls or other containers in it.

At the root of your MXML application is the `<s:Application>` tag. This tag represents a base container that covers the entire Adobe® Flash® Player or Adobe AIR™ drawing surface. You can place controls or containers directly under the `<s:Application>` tag or in other containers. For more information on containers, see “Introduction to containers” on page 326.

Flex provides a set of UI controls built for the Spark architecture. To take advantage of the skinning architecture in Spark, use the Spark controls whenever possible. The MX controls are also supported. You can use a combination of MX and Spark controls in an application.

To use Spark controls, include the Spark namespace (default prefix: `s`) in your Application tag. To use MX controls, include the MX namespace (default prefix: `mx`) in your Application tag.

```
xmlns:s = "library://ns.adobe.com/flex/spark"
xmlns:mx = "library://ns.adobe.com/flex/mx"
```

Most controls have the following characteristics:

- MXML API for declaring the control and the values of its properties and events
- ActionScript API for calling the control’s methods and setting its properties at run time
- Customizable appearance by using styles, skins, and fonts

The MXML and ActionScript APIs let you create and configure a control. The following MXML code example creates a TextInput control in a Form container:

```
<?xml version="1.0" encoding="utf-8"?>
<!--controls\TextInputInForm.mxml-->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:Form width="400" height="100">
        <s:FormItem label="Card Name">
            <s:TextInput id="cardName"/>
        </s:FormItem>
    </s:Form>

</s:Application>
```

Although you commonly use MXML as the language for building applications in Flex, you can also use ActionScript to configure controls. For example, the following code example populates a Spark DataGrid control by providing an Array of items as the value of the DataGrid control’s `dataProvider` property:

```
<?xml version="1.0" encoding="utf-8"?>
<!--controls\DataGridConfigAS.mxml-->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;

            private function myGrid_initialize():void {
              myGrid.dataProvider = new ArrayCollection([
                {Artist:'Steve Goodman', Album:'High and Outside', Price:8.99},
                {Artist:'Carole King', Album:'Tapestry', Price:11.99},
                {Artist:'The Beach Boys', Album:'Pet Sounds', Price:13.99},
                {Artist:'Original Cast', Album:'Camelot', Price:9.99} ]);
            }
        ]]>
    </fx:Script>

    <s:DataGrid id="myGrid"
        width="350" height="150"
        color="#7B0974"
        creationComplete="myGrid_initialize();"/>

</s:Application>
```

Text controls

Several Flex components display text or take text input, as the following table shows:

Type of text	Spark control	MX control
Editable, single-line text	TextInput	TextInput
Editable, multiline text	TextArea	TextArea
Noneditable, single-line text	Label	Label
Noneditable, multiline text	Label	Text
Noneditable, richly formatted text	RichText	n/a
Editable, richly formatted text	RichEditableText	n/a
Compound control that contains a multiline text field and controls that let you format text by selecting such characteristics as font, size, weight, and alignment	n/a	RichTextEditor

These controls can display plain text that all has the same appearance. The controls can also display rich text formatted by using a subset of the standard HTML formatting tags. For information on using text controls, see “MX text controls” on page 805.

Data provider controls

Several Flex components, such as the MX DataGrid and Tree controls, and the Spark ComboBox and List controls, take input data from a data provider. A *data provider* is a collection of objects, similar to an array. For example, a Tree control reads data from the data provider to define the structure of the tree and any associated data assigned to each tree node.

The data provider creates a level of abstraction between Flex components and the data that you use to populate them. You can populate multiple components from the same data provider, switch data providers for a component at runtime, and modify the data provider so that changes are reflected by all components that use the data provider.

Consider that the data provider is the model, and the components are the view onto the model. By separating the model from the view, you can change one without changing the other.

Menu controls

Several MX controls create or interact with menus, as the following table shows:

MX control (in mx.controls package)	Description
Menu	A visual menu that can have cascading submenus
MenuBar	A horizontal bar with multiple submenus
PopUpMenuButton	A Menu control that opens when you click a button

In Spark, you can create custom menu-type controls using the “PopUpAnchor control” on page 698.

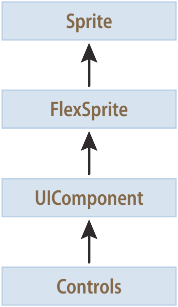
For information on menu controls, see “Menu-based controls” on page 985.

Working with controls

Controls share a common class hierarchy. Therefore, you use a similar procedure to configure all controls.

Class hierarchy of controls

Controls are ActionScript objects derived from the flash.display.Sprite, mx.core.FlexSprite, and mx.core.UIComponent classes, as the following diagram shows. Controls inherit the properties, methods, events, styles, skin parts, skin states, and effects of these superclasses:



Class hierarchy of controls

The Sprite, FlexSprite, and UIComponent classes are the base classes for all Flex components. Subclasses of the UIComponent class can have shape, draw themselves, and be invisible. Each subclass can participate in tabbing. Subclasses can accept low-level events like keyboard and mouse input. They can be disabled so that they do not receive mouse and keyboard input.

For information on the interfaces inherited by controls from the Sprite and UIComponent classes, see “Visual components” on page 280.

Sizing controls

All controls define rules for determining their size in an application. For example, a Button control sizes itself to fit its label text and optional icon image. An Image control sizes itself to the size of the imported image. Each control has a default height and a default width. The default size of each standard control is specified in the description of each control.

The default size of a control is not necessarily a fixed value. For example, for a Button control, the default size is large enough to fit its label text and optional icon image. At runtime, Flex calculates the default size of each control and, by default, does not resize a control from its default size.

Set the `height` and `width` attributes in MXML to percentages, such as 50%, or the `percentHeight` and `percentWidth` properties in ActionScript to percentage values, such as 50, to allow Flex to resize the control in the corresponding direction. Flex attempts to fit the control to the percentage of its parent container that you specify. If there isn't enough space available, the percentages are scaled, while retaining their relative values.

For example, you can set the width of a comments box to scale with its parent container as the parent container changes size:

```
<s:TextArea id="comments" width="100%" height ="20"/>
```

You can also specify explicit sizes for a control in MXML or ActionScript by setting the `height` and `width` properties to numeric pixel values. The following example sets the height and width of the `addr2` TextInput control to 20 pixels and 100 pixels, respectively:

```
<s:TextInput id="addr2" width="100" height ="20"/>
```

To resize a control at runtime, use ActionScript to set its `width` and `height` properties. For example, the click event listener for the following Button control increases the value of the `width` property of the `addr2` TextInput control by ten pixels:

```
<s:Button id="button1" label="Slide" height="20"
    click="addr2.width+=10;"/>
```

***Note:** The preceding technique works even if the `width` property was originally set as a percentage value. The stored values of the `width` and `height` properties are always in pixels.*

Many components have arbitrarily large maximum sizes, which means that Flex can make them as large as necessary to fit the requirements of your application. While some components have a defined nonzero minimum size, most have a minimum size of 0. You can use the `maxHeight`, `maxWidth`, `minHeight`, and `minWidth` properties to set explicit size ranges for each component.

For more information on sizing components, see "Laying out components" on page 359.

Positioning controls

You place controls inside containers. Most containers have predefined layout rules that automatically determine the position of their children. The Spark Group container positions children using BasicLayout, which is absolute positioning. The HGroup container positions children with a horizontal layout. The VGroup container positions children with a vertical layout. The MX Canvas container absolutely positions its children.

To absolutely position a control, you set its `x` and `y` properties to specific horizontal and vertical pixel coordinates within the container. These coordinates are relative to the upper-left corner of the container, where the upper-left corner is at coordinates (0,0). Values for `x` and `y` can be positive or negative integers. You can use negative values to place a control outside the visible area of the container. You can then use ActionScript to move the child to the visible area, possibly as a response to an event.

The following example places the TextInput control 150 pixels to the right and 150 pixels down from the upper-left corner of a Canvas container:

```
<s:TextInput id="addr2" width="100" height ="20" x="150" y="150"/>
```

To reposition a control within an absolutely-positioned container at runtime, you set its `x` and `y` properties. For example, the `click` event listener for the following Button control moves the TextInput control down ten pixels from its current position:

```
<s:Button id="button1" label="Slide" height="20" x="0" y="250"
    click="addr2.y = addr2.y+10;"/>
```

For detailed information about control positioning, including container-relative positioning, see "Laying out components" on page 359.

Changing the appearance of controls

Styles, skins, and fonts let you customize the appearance of controls. They describe aspects of components that you want components to have in common. Each control defines a set of styles, skins, and fonts that you can set. Some of these characteristics are specific to a particular type of control, and others are more general. In Spark, the skin controls all visual elements of a component, including layout. See "About Spark skins" on page 1602.

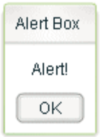
Flex provides several different ways for you to configure the appearance of your controls. For example, you can set styles for a specific control in the control's MXML tag, in CSS, or by using ActionScript. You can set styles globally for all instances of a specific control in an application by using the `<fx:Style>` tag.

A *theme* defines the appearance of an application. A theme can define something as simple as the color scheme or common font for an application. It can also be a complete reskinning of all the components. The current theme for your application defines the styles that you can set on the controls within it. That means some style properties might not always be settable. For more information, see "Styles and themes" on page 1492.

Alert control

The Alert control is part of the MX component set. There is no Spark equivalent.

All Flex components can call the static `show()` method of the Alert class to open a modal dialog box that contains a message and an optional title, buttons, and icons. The following example shows an Alert control pop-up dialog box:



The Alert control closes when you select a button in the control, or press the Escape key.

The `Alert.show()` method has the following syntax:

```
public static show(
    text:String,
    title:String=null,
    flags:uint=mx.controls.Alert.OK,
    parent:Sprite=null,
    clickListener:Function=null,
    iconClass:Class=null,
    defaultButton:uint=mx.controls.Alert.OK
):Alert
```

This method returns an Alert control object.

The following table describes the arguments of the `show()` method:

Argument	Description
`text`	(Required) Specifies the text message displayed in the dialog box.
`title`	Specifies the dialog box title. If omitted, displays a blank title bar.
`flags`	Specifies the buttons to display in the dialog box. The options are as follows: `mx.controls.Alert.OK` — OK button `mx.controls.Alert.YES` — Yes button `mx.controls.Alert.NO` — No button `mx.controls.Alert.CANCEL` — Cancel button Each option is a bit value and can be combined with other options by using the pipe '|' operator. The buttons appear in the order listed here regardless of the order specified in your code. The default value is `mx.controls.Alert.OK`.
`parent`	The parent object of the Alert control.
`clickListener`	Specifies the listener for click events from the buttons. The event object passed to this handler is an instance of the CloseEvent class. The event object contains the `detail` field, which is set to the button flag that was clicked (`mx.controls.Alert.OK`, `mx.controls.Alert.CANCEL`, `mx.controls.Alert.YES`, or `mx.controls.Alert.NO`).
`iconClass`	Specifies an icon to display to the left of the message text in the dialog box.
`defaultButton`	Specifies the default button by using one of the valid values for the `flags` argument. This is the button that is selected when the user presses the Enter key. The default value is `Alert.OK`. Pressing the Escape key triggers the Cancel or No button.

To use the Alert control, you first import the Alert class into your application, then call the `show()` method, as the following example shows:

```
<?xml version="1.0"?>
<!-- controls\alert\AlertSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
            import mx.controls.Alert;
        ]]>
    </fx:Script>
    <s:VGroup>
        <s:TextInput id="myInput"
                     width="150"
                     text=""/>
        <s:Button id="myButton"
                  label="Copy Text"
                  click="myText.text = myInput.text;
            Alert.show('Text Copied!', 'Alert Box', mx.controls.Alert.OK);"/>
        <s:TextInput id="myText"/>
    </s:VGroup>
</s:Application>
```

In this example, selecting the Button control copies text from the TextInput control to the TextArea control, and displays the Alert control.

You can also define an event listener for the Button control, as the following example shows:

```
<?xml version="1.0"?>
<!-- controls\alert\AlertSimpleEvent.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
            import mx.controls.Alert;
            private function alertListener():void {
                myText.text = myInput.text;
                Alert.show("Text Copied!", "Alert Box", Alert.OK);
            }
        ]]>
    </fx:Script>
    <s:VGroup>
        <s:TextInput id="myInput"
                     width="150"
                     text=""/>
        <s:Button id="myButton"
                  label="Copy Text"
                  click="alertListener();"/>
        <s:TextInput id="myText"/>
    </s:VGroup>
</s:Application>
```

***Note:** After the `show()` method creates the dialog box, Flex continues processing of your application; it does not wait for the user to close the dialog box.*

Sizing the Alert control

The Alert control automatically sizes itself to fit its text, buttons, and icon. You can explicitly size an Alert control by using the Alert object returned from the `show()` method, as the following example shows:

```
<?xml version="1.0"?>
<!-- controls\alert\AlertSize.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
            import mx.controls.Alert;
            import mx.events.CloseEvent;
            // Define variable to hold the Alert object.
            public var myAlert:Alert;
            private function openAlert():void {
                myAlert = Alert.show("Copy Text?", "Alert",
                    Alert.OK    | Alert.CANCEL);
                // Set the height and width of the Alert control.
                myAlert.height=250;
                myAlert.width=250;
            }
        ]]>
    </fx:Script>
    <s:VGroup>
        <s:TextInput id="myInput"
                     width="150"
                     text=""/>
        <s:Button id="myButton"
                  label="Copy Text"
                  click="openAlert();"/>
        <s:TextInput id="myText"/>
    </s:VGroup>
</s:Application>
```

In this example, you set the `height` and `width` properties of the Alert object to explicitly size the control.

Using event listeners with the Alert control

The next example adds an event listener to the Alert control dialog box. An event listener lets you perform processing when the user selects a button of the Alert control. The event object passed to the event listener is of type CloseEvent.

In the next example, you only copy the text when the user selects the OK button in the Alert control:

```
<?xml version="1.0"?>
<!-- controls\alert\AlertEvent.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
            import mx.controls.Alert;
            import mx.events.CloseEvent;
            private function alertListener(eventObj:CloseEvent):void {
                // Check to see if the OK button was pressed.
                if (eventObj.detail==Alert.OK) {
                    myText.text = myInput.text;
                }
            }
        ]]>
    </fx:Script>

    <s:VGroup>
        <s:TextInput id="myInput"
            width="150"
            text="" />
        <s:Button id="myButton"
            label="Copy Text"
            click='Alert.show("Copy Text?", "Alert",
            Alert.OK | Alert.CANCEL, this,
            alertListener, null, Alert.OK);'/>
        <s:TextInput id="myText"/>
    </s:VGroup>
</s:Application>
```

In this example, you define an event listener for the Alert control. Within the body of the event listener, you determine which button was pressed by examining the `detail` property of the event object. The event object is an instance of the CloseEvent class. If the user pressed the OK button, copy the text. If the user pressed any other button, or pressed the Escape key, do not copy the text.

Specifying an Alert control icon

You can include an icon in the Alert control that appears to the left of the Alert control text. This example modifies the example from the previous section to add the `Embed` metadata tag to import the icon. For more information on importing resources, see “Using ActionScript” on page 32.

```
<?xml version="1.0"?>
<!-- controls\alert\AlertIcon.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
            import mx.controls.Alert;
            import mx.events.CloseEvent;

            [Embed(source="assets/alertIcon.jpg")]
            [Bindable]
            public var iconSymbol:Class;
            private function alertListener(eventObj:CloseEvent):void {
                // Check to see if the OK button was pressed.
                if (eventObj.detail==Alert.OK) {
                    myText.text = myInput.text;
                }
            }
        ]]>
    </fx:Script>
    <s:VGroup>
        <s:TextInput id="myInput"
                     width="150"
                     text=""/>
        <s:Button id="myButton"
                  label="Copy Text"
                  click='Alert.show("Copy Text?", "Alert",
            Alert.OK | Alert.CANCEL, this,
                alertListener, iconSymbol,  Alert.OK );'/>
        <s:TextInput id="myText"/>
    </s:VGroup>
</s:Application>
```

Button and ToggleButton control

The Button and ToggleButton controls are part of both the MX and Spark component sets. While you can use the MX controls in your application, Adobe recommends that you use the Spark controls instead.

***Note:** In MX, you create a toggle button by setting the `toggle` property of the MX Button control to `true`. in Spark, the ToggleButton is a separate component.*

The Button control is a commonly used rectangular button. Button controls look like they can be pressed, and have a text label, an icon, or both on their face. You can optionally specify graphic skins for each of several Button states.

You can create a normal Button control or a ToggleButton control. A normal Button control stays in its pressed state for as long as the mouse button is down after you select it. A ToggleButton stays in the pressed state until you select it a second time. The ToggleButton control is available in Spark. In MX, the Button control contains a `toggle` property that provides similar functionality.

Buttons typically use event listeners to perform an action when the user selects the control. When a user clicks the mouse on a Button control, and the Button control is enabled, it dispatches a `click` event and a `buttonDown` event. A button always dispatches events such as the `mouseMove`, `mouseOver`, `mouseOut`, `rollOver`, `rollOut`, `mouseDown`, and `mouseUp` events whether enabled or disabled.

You can use customized graphic skins to customize your buttons to match your application’s look and functionality. You can give the Button and ToggleButton controls different skins. The control can change the image skins dynamically. The following table describes the skin states (Spark) and skin styles (MX) available for the Button and ToggleButton controls:

Spark Button skin states	Spark ToggleButton skin states	MX Button skin styles
disabled	disabled	disabledSkin
down	disabledAndSelected	downSkin
over	down	overSkin
up	downAndSelected	selectedDisabledSkin
---	over	selectedDownSkin
---	overAndSelected	selectedOverSkin
---	up	selectedUpSkin
---	upAndSelected	upSkin

Creating a Button control

You define a Button control in MXML by using the `<s:Button>` tag, as the following example shows. Specify an `id` value if you intend to refer to the button elsewhere in your MXML, either in another tag or in an ActionScript block. The following code creates a Button control with the label “Hello world!”:

```
<?xml version="1.0"?>
<!-- controls\button\ButtonLabel.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:Button id="button1"
        label="Hello world!"
        width="100"/>
</s:Application>
```

In Spark, all visual elements of a component, including layout, are controlled by the skin. For more information on skinning, see “About Spark skins” on page 1602.

In MX, a Button control’s icon, if specified, and label are centered within the bounds of the Button control. You can position the text label in relation to the icon by using the `labelPlacement` property, which accepts the values `right`, `left`, `bottom`, and `top`.

Sizing a Button control

By default, Flex stretches the Button control width to fit the size of its label, any icon, plus six pixels of padding around the icon. You can override this default width by explicitly setting the `width` property of the Button control to a specific value or to a percentage of its parent container. If you specify a percentage value, the button resizes between its minimum and maximum widths as the size of its parent container changes.

If you explicitly size a Button control so that it is not large enough to accommodate its label, the label is truncated and terminated by an ellipsis (...). The full label displays as a tooltip when you move the mouse over the Button control. If you have also set a tooltip by using the `toolTip` property, the tooltip is displayed rather than the label text. Text that is vertically larger than the Button control is also clipped.

If you explicitly size a Button control so that it is not large enough to accommodate its icon, icons larger than the Button control extend outside the Button control’s bounding box.

Button control user interaction

When a user clicks the mouse on a Button control, the Button control dispatches a `click` event, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- controls\button\ButtonClick.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
            import mx.controls.Alert;
            protected function myBtn_clickHandler(event:MouseEvent):void {
                Alert.show("Goodbye!");
            }
        ]]>
    </fx:Script>
    <s:Button id="myBtn"
        x="83" y="92"
        label="Hello World!"
        click="myBtn_clickHandler(event)"/>

</s:Application>
```

In this example, clicking the Button triggers an Alert control to appear with a message to the user.

If a Button control is enabled, it behaves as follows:

- When the user moves the pointer over the Button control, the Button control displays its rollover appearance.
- When the user clicks the Button control, focus moves to the control and the Button control displays its pressed appearance. When the user releases the mouse button, the Button control returns to its rollover appearance.
- If the user moves the pointer off the Button control while pressing the mouse button, the control's appearance returns to the rollover state and it retains focus.
- For MX controls, if the `toggle` property is set to `true`, the state of the Button control does not change until the user releases the mouse button over the control. For the Spark ToggleButton, this statement applies to the `selected` property.

If a Button control is disabled, it displays its disabled appearance, regardless of user interaction. In the disabled state, all mouse or keyboard interaction is ignored.

Embedding an icon in a Button control

The Button controls define a style property, `icon`, that you use to add an icon to the button. A button icon can be a GIF, JPEG, PNG, SVG, or SWF file.

***Note:** For the MX Button control, icons must be embedded at compile time. You cannot load the icon at runtime.*

Use the `@Embed` syntax in the `icon` property value to embed an icon file. Or you can bind to an image that you defined within a script block by using `[Embed]` metadata. If you must reference your button graphic at runtime, you can use an Image control instead of a Button control.

For more information on embedding resources, see "Embedding assets" on page 1699.

The following code example creates a Spark Button control with a label and icon.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- controls\button\ButtonLabelIconSpark.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
               xmlns:s="library://ns.adobe.com/flex/spark"
               xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Script>
        <![CDATA[
            import assets.*;
            import mx.controls.Alert;
            protected function myClickHandler():void{
                Alert.show("Thanks for submitting.")
            }
        ]]>
    </fx:Script>

    <s:Button id="iconButton"
              width="100" height="30"
              x="10" y="10"
              label="Submit to"
              icon="@Embed('assets/logo.jpg')"
              click="myClickHandler();"/>
</s:Application>
```

MX ButtonBar and MX ToggleButtonBar controls

The ButtonBar control is part of both the MX and Spark component sets. Spark does not define a separate ToggleButtonBar control. You can use the Spark ButtonBar control to replicate the functionality of the MX ToggleButtonBar control. While you can use the MX controls in your application, Adobe recommends that you use the Spark controls instead. For information on Spark ButtonBar, see "Spark ButtonBar and TabBar controls" on page 529.

The MX ButtonBar and ToggleButtonBar controls define a horizontal or vertical row of related buttons with a common appearance. The controls define a single event, the `itemClick` event, that is dispatched when any button in the control is selected.

The ButtonBar control defines group of buttons that do not retain a selected state. When you select a button in a ButtonBar control, the button changes its appearance to the selected state. When you release the button, it returns to the deselected state.

The ToggleButtonBar control defines a group of buttons that maintain their state, either selected or deselected. Only one button in the ToggleButtonBar control can be in the selected state. That means when you select a button in a ToggleButtonBar control, the button stays in the selected state until you select a different button.

If you set the `toggleOnClick` property of the ToggleButtonBar control to `true`, selecting the currently selected button deselects it. By default the `toggleOnClick` property is `false`.

Creating an MX ButtonBar control

You create a ButtonBar control in MXML by using the `<mx:ButtonBar>` tag, as the following example shows:

```
<?xml version="1.0"?>
<!-- controls\bar\BBarSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <mx:ButtonBar horizontalGap="5">
        <mx:dataProvider>
            <fx:String>Flash</fx:String>
            <fx:String>Director</fx:String>
            <fx:String>Dreamweaver</fx:String>
            <fx:String>ColdFusion</fx:String>
        </mx:dataProvider>
    </mx:ButtonBar>
</s:Application>
```

This example creates a row of four Button controls.

To create a ToggleButtonBar control, replace the `<mx:ButtonBar>` tag with the `<mx:ToggleButtonBar>` tag. For the ToggleButtonBar control, the `selectedIndex` property determines which button is selected when the control is created. The default value for `selectedIndex` is 0 and selects the leftmost button in the bar. Setting the `selectedIndex` property to -1 deselects all buttons in the bar. Otherwise, the syntax is the same for both controls.

The `dataProvider` property specifies the labels of the four buttons. You can also populate the `dataProvider` property with an Array of Objects, where each object can have up to three fields: `label`, `icon`, and `toolTip`.

In the following example, an Array of Objects specifies a label and icon for each button:

```
<?xml version="1.0"?>
<!-- controls\bar\BBarLogo.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <mx:ButtonBar horizontalGap="5">
        <mx:dataProvider>
            <fx:Object label="Flash"
                icon="@Embed(source='assets/Flashlogo.gif')"/>
            <fx:Object label="Director"
                icon="@Embed(source='assets/Dirlogo.gif')"/>
            <fx:Object label="Dreamweaver"
                icon="@Embed(source='assets/Dlogo.gif')"/>
            <fx:Object label="ColdFusion"
                icon="@Embed(source='assets/CFlogo.gif')"/>
        </mx:dataProvider>
    </mx:ButtonBar>
</s:Application>
```

A ButtonBar or ToggleButtonBar control creates Button controls based on the value of its `dataProvider` property. Even though ButtonBar and ToggleButtonBar are subclasses of Container, do not use the methods `Container.addChild()` and `Container.removeChild()` to add or remove Button controls. Instead, use methods `addItem()` and `removeItem()` to manipulate the `dataProvider` property. A ButtonBar or ToggleButtonBar control automatically adds or removes children based on changes to the `dataProvider` property.

Handling MX ButtonBar events

The MX ButtonBar and MX ToggleButtonBar controls dispatch an item`Click` event when you select a button. The event object passed to the event listener is of type ItemClickEvent. From within the event listener, you access properties of the event object to determine the index of the selected button and other information. The index of the first button is 0. For more information about the event object, see the description of the ItemClickEvent class in the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

The ToggleButtonBar control in the following example defines an event listener, named `clickHandler()`, for the `itemClick` event.

```
<?xml version="1.0"?>
<!-- controls\bar\BBarEvent.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Script>
        <![CDATA[
            import mx.events.ItemClickEvent;
            private var savedIndex:int = 99999;

            private function clickHandler(event:ItemClickEvent):void {
                if (event.index == savedIndex) {
                    myTA.text=""
                }
                else {
                    savedIndex = event.index;
                    myTA.text="Selected button index: " +
                    String(event.index) + "\n" +
                    "Selected button label: " +
                    event.label;
                }
            }
        ]]>
    </fx:Script>
    <s:VGroup>
        <mx:ToggleButtonBar
            horizontalGap="5"
            itemClick="clickHandler(event);"
            toggleOnClick="true"
            selectedIndex="-1">

        <mx:dataProvider>
            <fx:String>Flash</fx:String>
            <fx:String>Director</fx:String>
            <fx:String>Dreamweaver</fx:String>
            <fx:String>ColdFusion</fx:String>
        </mx:dataProvider>
        </mx:ToggleButtonBar>
        <s:TextArea id="myTA" width="250" height="100"/>
    </s:VGroup>
</s:Application>
```

In this example, the click handler displays the index and label of the selected button in a TextArea control in response to an `itemClick` event. If you press the selected button a second time, the button is deselected, and the sample click handler clears the text area.

CheckBox control

The CheckBox control is part of both the MX and Spark component sets. While you can use the MX CheckBox control in your application, Adobe recommends that you use the Spark CheckBox control instead.

The CheckBox control is a commonly used graphical control that can contain a check mark or not. You can use CheckBox controls to gather a set of `true` or `false` values that aren't mutually exclusive.

You can add a text label to a CheckBox control and place it to the left, right, top, or bottom. Flex clips the label of a CheckBox control to fit the boundaries of the control.

When a user clicks a CheckBox control or its associated text, the CheckBox control changes its state from checked to unchecked, or from unchecked to checked.

A CheckBox control can have one of two disabled states, checked or unchecked. By default, a disabled CheckBox control displays a different background and check mark color than an enabled CheckBox control.

Creating a CheckBox control

You use the `<s:CheckBox>` tag to define a CheckBox control in MXML, as the following example shows. Specify an `id` value if you intend to refer to a component elsewhere in your MXML, either in another tag or in an ActionScript block:

```
<?xml version="1.0"?>
<!-- controls\checkbox\CBSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <s:VGroup>
        <s:CheckBox width="100" label="Employee?"/>
    </s:VGroup>
</s:Application>
```

You can also use the `selected` property to generate a checkbox that is checked by default:

```
<?xml version="1.0"?>
<!-- controls\checkbox\CBSelected.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <s:VGroup>
        <s:CheckBox width="100" label="Employee?" selected="true"/>
    </s:VGroup>
</s:Application>
```

CheckBox control user interaction

When a CheckBox control is enabled and the user clicks it, the control receives focus. It displays its checked or unchecked appearance, depending on its initial state. The entire area of the CheckBox control is the click area. If the CheckBox control's text is larger than its icon, the clickable regions are above and below the icon.

If the user moves the pointer outside the area of the CheckBox control or its label while pressing the mouse button, the appearance of the CheckBox control returns to its original state and the control retains focus. The state of the CheckBox control does not change until the user releases the mouse button over the control.

Users cannot interact with a CheckBox control when it is disabled.

ColorPicker control

The ColorPicker control is part of the MX component set. There is no Spark equivalent.

The ColorPicker control lets users select a color from a drop-down swatch panel. It initially appears as a preview sample with the selected color. When a user selects the control, a color swatch panel appears. The panel includes a sample of the selected color and a color swatch panel. By default, the swatch panel displays the web-safe colors (216 colors, where each of the three primary colors has a value that is a multiple of 33, such as #CC0066).

For complete reference information, see ColorPicker in the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

About the ColorPicker control

When you open the ColorPicker control, the swatch panel expands over other controls on the application, and normally opens downwards. If the swatch panel would hit the lower boundary of the application, but could fit above color picker button, it opens upward.

If you set the `showTextField` property to `true` (the default), the panel includes a text box with a label for the selected color. If you display a text box and set the `editable` property to `true` (the default), the user can specify a color by entering a hexadecimal value.

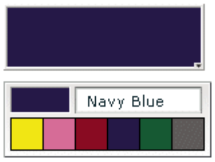
Flex populates the color swatch panel and the text box from a data provider. By default, the control uses a data provider that includes all the web-safe colors. If you use your own data provider you can specify the following:

The colors to display You *must* specify the colors if you use your own dataProvider.

Labels to display in the text box for the colors If you do not specify text labels, Flex uses the hexadecimal color values.

Additional information for each color This information can include any information that is of use to your application, such as IDs or descriptive comments.

The following image shows an expanded ColorPicker control that uses a custom data provider that includes color label values. It also uses styles to set the sizes of the display elements:



Creating a ColorPicker control

You use the `<mx:ColorPicker>` tag to define a ColorPicker control in MXML. Specify an `id` value if you intend to refer to a component elsewhere in your MXML, either in another tag or in an ActionScript block.

The ColorPicker control uses a list-based data provider for the colors. For more information on this type of data provider, see “Data providers and collections” on page 898. If you omit the data provider, the control uses a default data provider with the web-safe colors. The data provider can be an array of colors or an array of objects. The following example populates a ColorPicker with a simple array of colors.

```
<?xml version="1.0"?>
<!-- controls\colorpicker\CPSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Script>
        <![CDATA[
            [Bindable]
            public var simpleDP:Array = ['0x000000', '0xFF0000', '0xFF8800',
                '0xFFFF00', '0x88FF00', '0x00FF00', '0x00FF88', '0x00FFFF',
                '0x0088FF', '0x0000FF', '0x8800FF', '0xFF00FF', '0xFFFFFF'];
        ]]>
    </fx:Script>

    <mx:ColorPicker id="cp" dataProvider="{simpleDP}"/>
</s:Application>
```

You typically use events to handle user interaction with a ColorPicker control. The following example adds an event listener for a `change` event and an `open` event to the previous example ColorPicker control:

```
<?xml version="1.0"?>
<!-- controls\colorpicker\CPEvents.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Script>
        <![CDATA[
            //Import the event classes.
            import mx.events.DropdownEvent;
            import mx.events.ColorPickerEvent;
            [Bindable]
            public var simpleDP:Array = ['0x000000', '0xFF0000', '0xFF8800',
               '0xFFFF00', '0x88FF00', '0x00FF00', '0x00FF88', '0x00FFFF',
               '0x0088FF', '0x0000FF', '0x8800FF', '0xFF00FF', '0xFFFFFF'];

            public function openEvt(event:DropdownEvent):void {
                forChange.text="Opened";
            }
            public function changeEvt(event:ColorPickerEvent):void {
                forChange.text="Selected Item: "
                   + event.currentTarget.selectedItem + " Selected Index: "
                   + event.currentTarget.selectedIndex;
            }
        ]]>
    </fx:Script>
    <mx:VBox>
        <mx:TextArea id="forChange"
            width="150"/>
        <mx:ColorPicker id="cp"
            dataProvider="{simpleDP}"
            open="openEvt(event);"
            change="changeEvt(event);"/>
    </mx:VBox>
</s:Application>
```

The ColorPicker control dispatches open event when the swatch panel opens. It dispatches a change event when the value of the control changes due to user interaction. The currentTarget property of the object passed to the event listener contains a reference to the ColorPicker control. In this example, the event listeners use two properties of the ColorPicker control, selectedItem and selectedIndex. Every change event updates the TextArea control with the selected item and the item's index in the control, and an open event displays the word *Opened*.

If you populate the ColorPicker control from an array of color values, the target.selectedItem field contains the hexadecimal color value. If you populate it from an array of Objects, the target.selectedItem field contains a reference to the object that corresponds to the selected item.

The index of items in the ColorPicker control is zero-based, which means that values are 0, 1, 2, ... , *n* - 1, where *n* is the total number of items; therefore, the target.selectedIndex value is zero-based, and a value of 2 in the preceding example refers to the data provider entry with color 0xFF8800.

Using Objects to populate a ColorPicker control

You can populate a ColorPicker control with an Array of Objects. By default, the ColorPicker uses two fields in the Objects: one named color, and another named label. The label field value determines the text in the swatch panel's text field. If the Objects do not have a label field, the control uses the color field value in the text field. You can use the ColorPicker control's colorField and labelField properties to specify different names for the color and label fields. The Objects can have additional fields, such as a color description or an internal color ID, that you can use in ActionScript.

Example: ColorPicker control that uses Objects

The following example shows a ColorPicker that uses an Array of Objects with three fields: color, label, and descript:

```
<?xml version="1.0"?>
<!-- controls\colorpicker\CPObjects.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Script>
        <![CDATA[
            import mx.events.ColorPickerEvent;
            import mx.events.DropdownEvent;
            [Bindable]
            public var complexDPArray:Array = [
                {label:"Yellow", color:"0xFFFF00",
                    descript:"A bright, light color."},
                {label:"Hot Pink", color:"0xFF66CC",
                    descript:"It's HOT!"},
                {label:"Brick Red", color:"0x990000",
                    descript:"Goes well with warm colors."},
                {label:"Navy Blue", color:"0x000066",
                    descript:"The conservative favorite."},
                {label:"Forest Green", color:"0x006600",
                    descript:"Great outdoorsy look."},
                {label:"Grey", color:"0x666666",
                    descript:"An old reliable."}]
            public function openEvt(event:DropdownEvent):void {
                descriptBox.text="";
            }
            public function changeEvt(event:ColorPickerEvent):void {
                descriptBox.text=event.currentTarget.selectedItem.label
                    + ": " + event.currentTarget.selectedItem.descript;
            }
        ]]>
    </fx:Script>
    <fx:Style>
        .myStyle {
            swatchWidth:25;
            swatchHeight:25;
            textFieldWidth:95;
        }
    </fx:Style>

    <!-- Convert the Array to an ArrayCollection. Do this if
    you might change the colors in the panel dynamically. -->
    <fx:Declarations>
        <mx:ArrayCollection id="complexDP" source="{complexDPArray}"/>
    </fx:Declarations>
    <mx:VBox>
        <mx:TextArea id="descriptBox"
            width="150" height="50"/>
        <mx:ColorPicker id="cp"
            height="50" width="150"
            dataProvider="{complexDP}"
            change="changeEvt(event);"
            open="openEvt(event);"
            editable="false"/>
    </mx:VBox>
</s:Application>
```

In this example, the `selectedItem` property contains a reference to the object defining the selected item. The example uses `selectedItem.label` to access the object's `label` property (the color name), and `selectedItem.descript` to access the object's `descript` property (the color description). Every `change` event updates the `TextArea` control with the `label` property of the selected item and the item's description. The `open` event clears the current text in the `TextArea` control each time the user opens up the ColorPicker to display the swatch panel.

This example also uses several of the ColorPicker properties and styles to specify the control's behavior and appearance. The `editable` property prevents users from entering a value in the color label box (so they can only select the colors from the dataProvider). The `swatchWidth` and `swatchHeight` styles control the size of the color samples in the swatch panel. The `textFieldWidth` style ensures that the text field is long enough to accommodate the longest color name.

Using custom field names

In some cases, you might want to use custom names for the color and label fields. For example, you would use a custom name if the data comes from an external data source with custom column names. The following code changes the previous example to use custom color and label fields called cName and cVal. It also shows how to use an `<mx:dataProvider>` tag to populate the data provider:

```
<?xml version="1.0"?>
<!-- controls\colorpicker\CPCustomFieldNames.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
            import mx.events.ColorPickerEvent;
            import mx.events.DropdownEvent;
            public function openEvt(event:DropdownEvent):void {
                descriptBox.text="";
            }

            public function changeEvt(event:ColorPickerEvent):void {
                descriptBox.text=event.currentTarget.selectedItem.cName
                    + ": " + event.currentTarget.selectedItem.cDescript;
            }
        ]]>
    </fx:Script>

    <fx:Style>
        .myStyle {
            swatchWidth:25;
            swatchHeight:25;
            textFieldWidth:95;
        }
    </fx:Style>

    <mx:VBox>
        <mx:TextArea id="descriptBox"
            width="150" height="50"/>
        <mx:ColorPicker id="cp"
            height="50" width="150"
            labelField="cName"
            colorField="cVal"
            change="changeEvt(event)"
            open="openEvt(event)"
            swatchPanelStyleName="myStyle"
            editable="false">
            <mx:dataProvider>
```

```
                <mx:ArrayCollection>
                    <mx:source>
                        <fx:Object cName="Yellow" cVal="0xFFFF00"
                            cDescript="A bright, light color."/>
                        <fx:Object cName="Hot Pink" cVal="0xFF66CC"
                            cDescript="It's HOT!"/>
                        <fx:Object cName="Brick Red" cVal="0x990000"
                            cDescript="Goes well with warm colors."/>
                        <fx:Object cName="Navy Blue" cVal="0x000066"
                            cDescript="The conservative favorite."/>
                        <fx:Object cName="Forest Green" cVal="0x006600"
                            cDescript="Great outdoorsy look."/>
                        <fx:Object cName="Grey" cVal="0x666666"
                            cDescript="An old reliable."/>
                    </mx:source>
                </mx:ArrayCollection>
            </mx:dataProvider>
        </mx:ColorPicker>
    </mx:VBox>
</s:Application>
```

User interaction

A ColorPicker control can be editable or noneditable. In a noneditable ColorPicker control, the user must select a color from among the swatch panel options. In an editable ColorPicker control, a user can select swatch panel items or enter a hexadecimal color value directly into the label text field at the top of the swatch panel. Users can type numbers and uppercase or lowercase letters in the ranges a-f and A-F in the text box; it ignores all other non-numeric characters.

Mouse interaction

You can use the mouse to navigate and select from the control:

- Click the collapsed control to display or hide the swatch panel.
- Click any swatch in the swatch panel to select it and close the panel.
- Click outside the panel area to close the panel without making a selection.
- Click in the text field to move the text entry cursor.

Keyboard interaction

If the ColorPicker is editable and the swatch panel has the focus, alphabetic keys in the range A-F and a-f and numeric keys enter text in the color box. The Backspace and Delete keys remove text in the color text box. You can also use the following keystrokes to control the ColorPicker:

Key	Description
Control+Down Arrow	Opens the swatch panel and puts the focus on the selected swatch.
Control+Up Arrow	Closes the swatch panel, if open.
Home	Moves the selection to the first color in a row of the swatch panel. Has no effect if there is a single column.
End	Moves the selection to the last color in a row of the swatch panel. Has no effect if there is a single column.
Page Up	Moves the selection to the top color in a column of the swatch panel. Has no effect if there is a single row.
Page Down	Moves the selection to the bottom color in a column of the swatch panel. Has no effect if there is a single row.

Key	**Description**
Escape	Closes the swatch panel without changing the color in the color picker. Most Web browsers do not support using this key.
Enter	Selects the current color from the swatch panel and closes the swatch panel; equivalent to clicking a color swatch. If the focus is on the text field of an editable ColorPicker, selects the color specified by the field text.
Arrows	When the swatch panel is open, moves the focus to the next color left, right, up, and down in the swatch grid. On a single-row swatch panel, Up and Right Arrow keys are equivalent, and Down and Left Arrow keys are equivalent. On a multirow swatch panel, the selection wraps to the beginning or end of the next or previous line. On a single-row swatch panel, pressing the key past the beginning or end of the row loops around on the row. When the swatch panel is closed, but has the focus, pressing the Up and Down arrow keys has no effect. The Left and Right Arrow keys change the color picker selection, moving through the colors as if the panel were open.

***Note:** When the swatch panel is open, you cannot use the Tab and Shift+Tab keys to move the focus to another object.*

DateChooser and DateField controls

The DateChooser and DateField controls are part of the MX component set. There is no Spark equivalent.

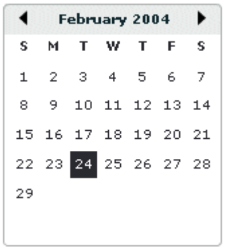
The DateChooser and DateField controls let users select dates from graphical calendars. The DateChooser control user interface is the calendar. The DateField control has a text field that uses a date chooser popup to select the date as a result. The DateField properties are a superset of the DateChooser properties.

For complete reference information, see DateChooser and DateField in the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

About the DateChooser control

The DateChooser control displays the name of a month, the year, and a grid of the days of the month. It contains columns labeled for the days of the week. This control is useful in applications where you want a continually visible calendar. The user can select a single date from the grid. The control contains forward and back arrow buttons to let you change the month and year. You can disable the selection of certain dates, and limit the display to a range of dates.

The following image shows a DateChooser control:



S	M	T	W	T	F	S
1	2	3	4	5	6	7
8	9	10	11	12	13	14
15	16	17	18	19	20	21
22	23	24	25	26	27	28
29						

Changing the displayed month does not change the selected date. Therefore, the currently selected date is not always visible. The DateChooser control resizes as necessary to accommodate the width of the weekday headings. Therefore, if you use day names, instead of letters, as headings, the calendar is wide enough to show the full day names.

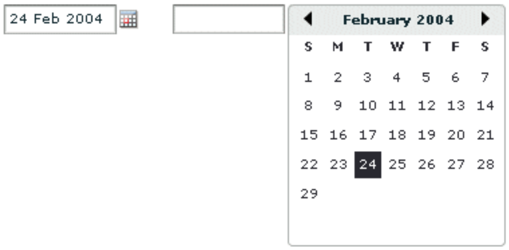
About the DateField control

The DateField control is a text field that displays the date with a calendar icon on its right side. When a user clicks anywhere inside the bounding box of the control, a date chooser that is identical to the DateChooser control pops up. If no date has been selected, the text field is blank and the current month is displayed in the date chooser.

When the date chooser is open, users can click the month scroll buttons to scroll through months and years, and select a date. When the user selects a date, the date chooser closes and the text field displays the selected date.

This control is useful in applications where you want a calendar selection tool, but want to minimize the space that the date information takes up.

The following example shows two images of a DateField control. On the left is the DateField control with the date chooser closed; the calendar icon appears on the right side of the text box. To the right is a DateField control with the date chooser open:



You can use the DateField control anywhere you want a user to select a date. For example, you can use a DateField control in a hotel reservation system, with certain dates selectable and others disabled. You can also use the DateField control in an application that displays current events, such as performances or meetings, when a user selects a date.

Creating a DateChooser or DateField control

You define a DateChooser control in MXML by using the `<mx:DateChooser>` tag. You define a DateField control in MXML by using the `<mx:DateField>` tag. Specify an `id` value if you intend to refer to a component elsewhere in your MXML, either in another tag or an ActionScript block.

The following example creates a DateChooser control; to create a DateField control, simply change `<mx:DateChooser>` to `<mx:DateField>`. The example uses the `change` event of the DateChooser control to display the selected date in several different formats.

```
<?xml version="1.0"?>
<!-- controls\date\DateChooserEvent.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
        import mx.events.CalendarLayoutChangeEvent;

        private function useDate(eventObj:CalendarLayoutChangeEvent):void {
            // Make sure selectedDate is not null.
            if (eventObj.currentTarget.selectedDate == null) {
                return
            }
            //Access the Date object from the event object.
            day.text=eventObj.currentTarget.selectedDate.getDay();
            date.text=eventObj.currentTarget.selectedDate.getDate();
            month.text=eventObj.currentTarget.selectedDate.getMonth() + 1;
            year.text=eventObj.currentTarget.selectedDate.getFullYear();

            wholeDate.text= (eventObj.currentTarget.selectedDate.getMonth() + 1) +
                "/" + (eventObj.currentTarget.selectedDate.getDate() +
                "/" + eventObj.currentTarget.selectedDate.getFullYear());
        }
        ]]>
    </fx:Script>
    <mx:DateChooser id="date1" change="useDate(event)"/>
    <s:Form x="200">
        <s:FormItem label="Day of week">
            <s:TextInput id="day" width="100"/>
        </s:FormItem>
        <s:FormItem label="Day of month">
            <s:TextInput id="date" width="100"/>
        </s:FormItem>
        <s:FormItem label="Month">
            <s:TextInput id="month" width="100"/>
        </s:FormItem>
        <s:FormItem label="Year">
            <s:TextInput id="year" width="100"/>
        </s:FormItem>
        <s:FormItem label="Date">
            <s:TextInput id="wholeDate" width="100"/>
        </s:FormItem>
    </s:Form>
</s:Application>
```

Notice that the first line of the event listener determines if the `selectedDate` property is null. This check is necessary because selecting the currently selected date while holding down the Control key deselects it, sets the `selectedDate` property to null, then dispatches the `change` event.

***Note:** The code that determines the value of the `wholeDate` field adds 1 to the month number because the DateChooser control uses a zero-based month system. In this system, January is month 0 and December is month 11.*

Using the Date class

The DateChooser and DateField controls use the `selectedDate` property to store the currently selected date, as an object of type Date. You can create Date objects to represent date and time values, or access the Date in the `selectedDate` property.

The Date class has many methods that you can use to manipulate a date. For more information on the Date class, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

In MXML, you can create and configure a Date object by using the `<mx:Date>` tag. This tag exposes the setter methods of the Date class as MXML properties so that you can initialize a Date object. For example, the following code creates a DateChooser control and sets the selected date to April 10, 2005. Notice that months are indexed starting at 0:

```
<mx:DateChooser id="date1">
        <mx:selectedDate>
            <fx:Date month="3" date="10" fullYear="2005"/>
        </mx:selectedDate>
</mx:DateChooser>
```

The following example uses inline ActionScript to set the initial selected date for a DateField control:

```
<mx:DateField id="date3" selectedDate="{new Date (2005, 3, 10)}"/>
```

You can also set the `selectedDate` property in a function, as the following example shows:

```
<fx:Script>
    <![CDATA[
        private function initDC():void {
            date2.selectedDate=new Date (2005, 3, 10);
        }
    ]]>
</fx:Script>

<mx:DateChooser id="date2" creationComplete="initDC();"/>
```

You can use property notation to access the ActionScript setter and getter methods of the `selectedDate` property Date object. For example, the following line displays the four-digit year of the selected date in a text box:

```
<s:TextInput text="{date1.selectedDate.fullYear}"/>
```

Specifying header, weekday, and today's day text styles

The following date chooser properties let you specify text styles for regions of the control:

- `headerStyleName`
- `weekDayStyleName`
- `todayStyleName`

These properties let you specify styles for the text in the header, weekday list, and today's date. You cannot use these properties to set non-text styles such as `todayColor`.

The following example defines a DateChooser control that has bold, blue header text in a 16-pixel Times New Roman font. The day-of-week headers are in bold, italic, green, 15-pixel Courier text, and today's date is bold, orange, 12-pixel Times New Roman text. Today's date background color is gray, and is set directly in the `<mx:DateChooser>` tag.

```
<?xml version="1.0"?>
<!-- controls\date\DateChooserStyles.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Style>
        .myHeaderStyle{
            color:#6666CC;
            font-family:Times New Roman, Times, serif;
            font-size:16px; font-weight:bold;}
        .myTodayStyle{
            color:#CC6633;
            font-family:Times New Roman, Times, serif;
            font-size:12px; font-weight:bold;}
        .myDayStyle{
            color:#006600;
            font-family:Courier New, Courier, mono;
            font-size:15px; font-style:italic; font-weight:bold;}
    </fx:Style>
    <mx:DateChooser
        headerStyleName="myHeaderStyle"
        todayStyleName="myTodayStyle"
        todayColor="#CCCCCC"
        weekDayStyleName="myDayStyle"/>
</s:Application>
```

Specifying selectable dates

The DateChooser control has the following properties that let you specify which dates a user can select:

Property	Description
`disabledDays`	An array of days of the week that the user cannot select. Often used to disable weekend days.
`disabledRange`	An array of dates that the user cannot select. The array can contain individual Date objects, objects specifying date ranges, or both.
`selectableRange`	A single range of dates that the user can select. The user can navigate only among the months that include this range; in these months any dates outside the range are disabled. Use the `disabledRange` property to disable dates within the selectable range.

The following example shows a DateChooser control that has the following characteristics:

- The `selectableRange` property limits users to selecting dates in the range January 1 - March 15, 2006. Users can only navigate among the months of January through March 2006.
- The `disabledRanges` property prevents users from selecting January 11 or any day in the range January 23 - February 10.
- The `disabledDays` property prevents users from selecting Saturdays or Sundays.

```
<?xml version="1.0"?>
<!-- controls\date\DateChooserSelectable.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

  <mx:DateChooser
    selectableRange="{{rangeStart: new Date(2006,0,1),
        rangeEnd: new Date(2006,2,15)}}"
    disabledRanges="{[new Date(2006,0,11),
        {rangeStart: new Date(2006,0,23), rangeEnd: new Date(2006,1,10)}]}"
    disabledDays="{[0,6]}"/>
</s:Application>
```

Setting DateChooser and DateField properties in ActionScript

Properties of the DateChooser and DateField controls take values that are scalars, Arrays, and Date objects. While you can set most of these properties in MXML, it can be easier to set some in ActionScript.

For example, the following code example uses an array to set the `disabledDays` property. Sunday (0) and Saturday (6) are disabled, which means that they cannot be selected in the calendar. This example sets the `disabledDays` property in two different ways, by using tags and by using tag attributes:

```
<?xml version="1.0"?>
<!-- controls\date\DateChooserDisabledOption.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <!-- Use tags.-->
    <mx:DateField>
            <mx:disabledDays>
                <fx:Number>0</fx:Number>
                <fx:Number>6</fx:Number>
            </mx:disabledDays>
    </mx:DateField>
    <!-- Use tag attributes.-->
    <mx:DateField disabledDays="[0,6]"/>
</s:Application>
```

The following example sets the `dayNames`, `firstDayOfWeek`, `headerColor`, and `selectableRange` properties of a DateChooser control by using an `initialize` event:

```
<?xml version="1.0"?>
<!-- controls\date\DateChooserInitializeEvent.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
            import mx.events.DateChooserEvent;
            private function dateChooser_init():void {
                myDC.dayNames=['Sun', 'Mon', 'Tue',
                    'Wed', 'Th', 'Fri', 'Sat'];
                myDC.firstDayOfWeek = 3;
                myDC.setStyle("headerColor", 0xff0000);
                myDC.selectableRange = {rangeStart: new Date(2009,0,1),
                    rangeEnd: new Date(2012,0,10)};
            }

            private function onScroll():void {
                myDC.setStyle("fontStyle", "italic");
            }
        ]]>
    </fx:Script>
    <mx:DateChooser id="myDC"
        width="200"
        creationComplete="dateChooser_init();"
        scroll="onScroll();"/>
</s:Application>
```

To set the `selectableRange` property, the code creates two Date objects that represent the first date and last date of the range. Users can only select dates within the specified range. This example also changes the `fontStyle` of the DateChooser control to `italics` after the first time the user scrolls it.

You can select multiple dates in a DateChooser control by using the `selectedRanges` property. This property contains an Array of objects. Each object in the Array contains two dates: a start date and an end date. By setting the dates within each object to the same date, you can select any number of individual dates in the DateChooser.

The following example uses an XML object to define the date for the DateChooser control. It then iterates over the XML object and creates an object for each date. These objects are then used to determine what dates to select in the DateChooser:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- controls\date\ProgrammaticDateChooserSelector.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    creationComplete="init()">
    <fx:Script>
        <![CDATA[
            private function init():void {
                dc1.displayedMonth = 1;
                dc1.displayedYear = 2008;
            }

            public function displayDates():void {
                var dateRanges:Array = [];
                for (var i:int=0; i<shows.show.length(); i++) {
                    var cDate:Date =
                        new Date(shows.show[i].showDate.toString());
                    var cDateObject:Object =
                        {rangeStart:cDate, rangeEnd:cDate};
                    dateRanges.push(cDateObject);
                }
                dc1.selectedRanges = dateRanges;
            }
        ]]>
    </fx:Script>
    <!-- Define the data for the DateChooser -->
    <fx:Declarations>
    <fx:XML id="shows" format="e4x">
        <data>
            <show>
               <showID>1</showID>
                <showDate>02/28/2008</showDate>
                <showTime>10:45am/11:15am</showTime>
            </show>
            <show>
                <showID>2</showID>
                <showDate>02/23/2008</showDate>
                <showTime>7:00pm</showTime>
            </show>
        </data>
    </fx:XML>
    </fx:Declarations>

    <mx:DateChooser id="dc1"
        showToday="false"
        creationComplete="displayDates();"/>

</s:Application>
```

Formatting dates with the DateField control

You can use the `formatString` property of the DateField control to format the string in the control’s text field. The `formatString` property can contain any combination of "MM", "DD", "YY", “YYYY”, delimiter, and punctuation characters. The default value is "MM/DD/YYYY".

In the following example, you select a value for the `formatString` property from the drop-down list:

```
<?xml version="1.0"?>
<!-- controls\date\DateFieldFormat.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <mx:HBox>
        <mx:ComboBox id="cb1">
            <mx:ArrayCollection>
                <fx:String>MM/DD/YY</fx:String>
                <fx:String>MM/DD/YYYY</fx:String>
                <fx:String>DD/MM/YY</fx:String>
                <fx:String>DD/MM/YYYY</fx:String>
                <fx:String>DD MM, YYYY</fx:String>
            </mx:ArrayCollection>
        </mx:ComboBox>

        <mx:DateField id="date2"
            editable="true"
            width="100"
            formatString="{cb1.selectedItem}"/>
    </mx:HBox>
</s:Application>
```

The DateField control also lets you specify a formatter function. A formatter function converts the date to a string in your preferred format for display in the control's text field. The DateField `labelFunction` property and the Spark DateTimeFormatter class help you format dates.

By default, the date in the DateField control text field is formatted in the form "MM/DD/YYYY". You use the `labelFunction` property of the DateField control to specify a function to format the date displayed in the text field and return a String containing the date. The function has the following signature:

```
public function formatDate(currentDate:Date):String {
    ...
    return dateString;
}
```

You can choose a different name for the function, but it must take a single argument of type Date and return the date as a String for display in the text field. The following example defines the function `formatDate()` to display the date in the form dd-mm-yyyy, such as 03-12-2011. This function uses a Spark DateTimeFormatter object to do the formatting:

```
<?xml version="1.0"?>
<!-- controls\date\DateChooserFormatter.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
            private function formatDateTime(date:Date):String {
                return dtf.format(date);
            }
        ]]>
    </fx:Script>
    <fx:Declarations>
        <s:DateTimeFormatter id="dtf" dateTimePattern="MM-dd-yyyy"/>
    </fx:Declarations>

    <mx:DateField id="df" labelFunction="formatDateTime" parseFunction="{null}"/>
</s:Application>
```

The `parseFunction` property specifies a function that parses the date entered as text in the text field of the DateField control and returns a Date object to the control. If you do not allow the user to enter a date in the text field, set the `parseFunction` property to `null` when you set the `labelFunction` property.

If you want to let the user enter a date in the control's text field, specify a function to the `parseFunction` property that converts the text string to a Date object for use by the DateField control. If you set the `parseFunction` property, it should typically perform the reverse of the function specified to the `labelFunction` property.

The function specified to the `parseFunction` property has the following signature:

```
public function parseDate(valueString:String, inputFormat:String):Date {
    ...
    return newDate
}
```

Where the `valueString` argument contains the text string entered by the user in the text field, and the `inputFormat` argument contains the format of the string. For example, if you only allow the user to enter a text string by using two characters for month, day, and year, then pass "MM/DD/YY" to the `inputFormat` argument.

User interaction

The date chooser includes arrow buttons that let users move between months. Users can select a date with the mouse by clicking the desired date.

Clicking a forward month arrow advances a month; clicking the back arrow displays the previous month. Clicking forward a month on December, or back on January, moves to the next (or previous) year. Clicking a date selects it. By default, the selected date is indicated by a green background around the date and the current day is indicated by a black background with the date in white. Clicking the currently selected date deselects it.

The following keystrokes let users navigate DateChooser and DateField controls:

Key	**Use**
Left Arrow	Moves the selected date to the previous enabled day in the month. Does not move to the previous month. Use the Shift key plus the Left Arrow key to access disabled days.
Right Arrow	Moves the selected date to the next enabled day in the month. Does not move to the next month. Use the Shift key plus the Right Arrow key to access disabled days.
Up Arrow	Moves the selected date up the current day of week column to the previous enabled day. Does not move to the previous month. Use the Shift key plus the Up Arrow key to access disabled days.
Down Arrow	Moves the selected date down the current day of week column to next enabled day. Does not move to the next month. Use the Shift key plus the Down Arrow key to access disabled days.
Page Up	Displays the calendar for the previous month.
Page Down	Displays the calendar for the next month.
Home	Moves the selection to the first enabled day of the month.
End	Moves the selection to the last enabled day of the month.
+	Move to the next year.
-	Move to the previous year.
Control+Down Arrow	DateField only: open the DateChooser control.
Control+Up Arrow	DateField only: close the DateChooser control.
Escape	DateField only: cancel operation.
Enter	DateField only: selects the date and closes the DateChooser control.

***Note:** The user must select the control before using navigation keystrokes. In a DateField control, all listed keystrokes work only when the date chooser is displayed.*

Image control

Adobe Flex supports several image formats, including GIF, JPEG, and PNG. You can import these images into your applications by using the Spark Image control or BitmapImage. To load SWF files, you use the SWFLoader control.

The Image control is part of both MX and Spark component sets. While you can use the MX Image control in your application, Adobe recommends that you use the Spark Image control instead.

Flex provides the following image controls:

Image control	**Use**
BimapImage	BitmapImage is a light-weight image control that can load both local and remote assets. You typically use the BitmapImage when you don't require a broken image icon or a preloader. The BitmapImage also supports runtime loading of images. However, when you load images at runtime, you should be aware of the security restrictions of Flash Player or AIR. For more information, see "Security" on page 117.
Spark Image	The Spark Image is a skinnable component that leverages a BitmapImage class as its main skin part. The Spark Image control provides a preloader as well as a broken image icon to indicate an invalid image state. The image loader and the broken-image icon are both customizable. For example, you can provide a broken image icon representing an invalid URL, or provide a progress bar as the image loads. The Spark Image control also provides customizable skinning for borders, frames, and loading states. For more information, see "Skinning the Spark Image control" on page 684. The Spark Image control lets you load local and trusted assets, as well as remote and untrusted assets. Security restrictions are applicable in case of untrusted assets. For more information, see "Loading images using a customizable load interface" on page 687.
SWFLoader	Flex also includes the SWFLoader control for loading applications built in Flex. You typically use the Image control for loading static graphic files, and use the SWFLoader control for loading SWF files and applications built in Flex. The Image control is also designed for use in custom item renderers and item editors. For more information on the SWFLoader control, see "SWFLoader control" on page 715.

The following example shows a BitmapImage embedded at compile time and a BitmapImage loaded at runtime:

```
<?xml version="1.0"?>
<!-- controls\image\ImageBitmapImageExample.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    width="700">

    <s:Panel title="BitmapImage Examples" width="600">
        <s:layout>
            <s:HorizontalLayout horizontalAlign="center"/>
        </s:layout>
        <s:BorderContainer width="50%" height="100%">
            <s:layout>
                <s:VerticalLayout
                   verticalAlign="middle"
                   horizontalAlign="center"/>
            </s:layout>
            <s:Label text="BitmapImage embedded at compile time"/>
            <s:BitmapImage id="embimg" source="@Embed(source='fblogo.jpg')"
               height="50" width="50"/>
        </s:BorderContainer>
        <s:BorderContainer width="50%" height="100%">
            <s:layout>
                <s:VerticalLayout
                   verticalAlign="middle"
                   horizontalAlign="center"/>
            </s:layout>
            <s:Label text="BitmapImage loaded at runtime"/>
            <s:BitmapImage id="runtimeimg" source="../assets/flexlogo.jpg"
               height="50" width="50"/>
        </s:BorderContainer>
    </s:Panel>
</s:Application>
```

For a video on using Spark Image and BitmapImage, see www.adobe.com/go/learn_flexsparkimagevideo_en

About loading images

Flex supports loading GIF, JPEG, and PNG files at runtime, and also embedding GIF, JPEG, and PNG files at compile time. The method you choose depends on the file types of your images and your application parameters.

Embedded images load immediately, because they are already part of the Flex SWF file. However, they add to the size of your application and slow down the application initialization process. Embedded images also require you to recompile your applications whenever your image files change. For an overview of resource embedding, see "Embedding assets" on page 1699.

The alternative to embedding a resource is to load the resource at runtime. You can load a resource from the local file system in which the SWF file runs. You can also access a remote resource, typically though an HTTP request over a network. These images are independent of your application built with Flex, so you can change them without causing a recompile operation as long as the names of the modified images remain the same. The referenced images add no additional overhead to an application's initial loading time. However, you can sometimes experience a delay when you use the images and load them into Adobe Flash Player or AIR.

A SWF file can access one type of external resource only, either local or over a network; it cannot access both types. You determine the type of access allowed by the SWF file by using the `use-network` flag when you compile your application. When `use-network` flag is set to `false`, you can access resources in the local file system, but not over the network. The default value is `true`, which allows you to access resources over the network, but not in the local file system.

For more information on the `use-network` flag, see "Flex compilers" on page 2164.

When you load images at runtime, you should be aware of the security restrictions of Flash Player or AIR. For example, you can reference an image by using a URL, but the default security settings only permit applications built in Flex to access resources stored on the same domain as your application. To access images on other servers, ensure that the domain that you are loading from uses a crossdomain.xml file.

For more information on application security, see "Security" on page 117.

Loading and embedding images with Spark Image and BitmapImage controls

The Spark Image control and BitmapImage support the following actions when you load an image:

Specifying the image path

The value of the `source` property of a Spark Image control or BitmapImage specifies a relative or absolute path, or URL to the imported image file. If the value is relative, it is relative to the directory that contains the file that uses the tag.

The `source` property has the following forms:

1 `source="@Embed(source='relativeOrAbsolutePath')"`

   The referenced image is packaged within the generated SWF file at compile time when Flex creates the SWF file for your application. You can embed GIF, JPEG, and PNG files. When embedding an image, the value of the `source` property must be a relative or absolute path to a file on the Flex developer's local file system; it cannot be a URL.

   The following example embeds a JPEG image into an application that is built in Flex:

```
<?xml version="1.0"?>
<!-- controls\image\ImageSimpleEmbed.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:Image id="loader1" source="@Embed(source='logo.jpg')"/>
</s:Application>
```

   In this example, the size of the image is the default size of the image file.

2 `source="relativeOrAbsolutePathOrURL"`

   Flex loads the referenced image file at runtime, typically from a location that is deployed on a web server; the image is not packaged as part of the generated SWF file. You can only reference GIF, JPEG, and PNG files.

   The following example accesses a JPEG image at runtime:

```
<?xml version="1.0"?>
<!-- controls\image\ImageSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <s:Image id="loader1" source="assets/flexlogo.jpg"/>
</s:Application>
```

Because you did not use @Embed in the source property, Flex loads the image at runtime. In this case, the location is the same directory as the page that embedded the SWF file.

When the use-network flag is set to false, you can access resources in the local file system, but not over the network. The default value is true, which allows you to access resources over the network, but not in the local file system.

In many applications, you create a directory to hold your application images. Commonly, that directory is a subdirectory of your main application directory. The source property supports relative paths to images, which let you specify the location of an image file relative to your application directory.

The following example stores all images in an assets subdirectory of the application directory:

```
<?xml version="1.0"?>
<!-- controls\image\ImageSimpleAssetsDir.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:Image id="loader1" source="@Embed(source='assets/logo.jpg')"/>
</s:Application>
```

The following example uses a relative path to reference an image in an assets directory at the same level as the application's root directory:

```
<?xml version="1.0"?>
<!-- controls\image\ImageSimpleAssetsDirTop.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:Image id="loader1" source="@Embed(source='../assets/logo.jpg')"/>
</s:Application>
```

You can also reference an image by using a URL, but the default security settings only permit applications to access resources stored on the same domain as your application. To access images on other servers, make sure that the domain that you are loading the image from uses a crossdomain.xml file that allows cross-domain access.

Cross-domain image loading is supported with restrictions. You can load local and trusted assets, as well as remote and untrusted assets. When you use untrusted assets, security restrictions are applicable. When a cross-domain image is loaded from an untrusted source, the security policy does not allow access to the image content. Then, the trustedSource property of the BimapImage and Spark Image is set to false, and the following image properties do not function:

- BitmapFillMode.REPEAT
- scaleGrid
- smooth
- smoothingQuality

Any advanced operations on the image data, such as, high-quality scaling or tiling, are not supported.

For more information, see "Security" on page 117.

The following example shows how to reference an image by using a URL:

```
<?xml version="1.0"?>
<!-- controls\image\ImageSimpleAssetsURL.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:Image id="image1"
        source="http://localhost:8100/flex/assets/logo.jpg"/>
</s:Application>
```

***Note:** You can use relative URLs for images hosted on the same web server as the application, but load these images over the Internet rather than access them locally.*

Using an image multiple times

You can use the same image multiple times in your application by using the normal image import syntax each time. Flex only loads the image once, and then references the loaded image as many times as necessary.

Sizing and scaling an image

You can size and scale images using both the Spark Image and BimapImage controls.

Sizing an image

Flex sets the height and width of an imported image to the height and width settings in the image file. By default, Flex does not resize the image.

To set an explicit height or width for an imported image, set its `height` and `width` properties of the image control. Setting the `height` or `width` property prevents the parent from resizing it. The `scaleContent` property has a default value of `true`; therefore, Flex scales the image as it resizes it to fit the specified height and width. The aspect ratio is maintained by default for a Spark Image, so the image may not completely fill the designated space. Set the `scaleContent` property to `false` to disable scaling.

When you resize a BitmapImage, the aspect ratio is not maintained, by default. To ensure that you maintain the aspect ratio, change the value of the `scaleMode` property from `stretch` to `letterbox` or `zoom`. For more information about image aspect ratios, see below.

One common use for resizing an image is to create image thumbnails. In the following example, the image has an original height and width of 100 by 100 pixels. By specifying a height and width of 20 by 20 pixels, you create a thumbnail of the image.

```
<?xml version="1.0"?>
<!-- controls\image\ImageSimpleThumbnail.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:BitmapImage id="image1"
        source="@Embed(source='logo.jpg')"
        width="20" height="20"
        smooth="true" smoothingQuality="high"/>
    <s:BitmapImage id="image2"
        source="@Embed(source='logo.jpg')"/>
</s:Application>
```

When you downscale a BimapImage, the default quality for scaled bitmaps, `BitmapSmoothingQuality.DEFAULT`, is used.

If you want to preserve the aspect ratio when creating image thumbnails, and achieve the best quality result when downscaling a BitmapImage, set the `smoothingQuality` property to `BitmapSmoothingQuality.HIGH`. The `smoothingQuality` property is applicable only when you set the `smooth` property of the BitmaImage to `true`. When you do so, a multi-bit-rate step algorithm is applied to the image, resulting in a much higher quality downscale than the default. This option is useful in creating high-quality image thumbnails.

To let Flex resize the image as part of laying out your application, set the `height` and `width` properties to a percentage value. Flex attempts to resize components with percentage values for these properties to the specified percentage of their parent container. You can also use the `maxHeight` and `maxWidth` and `minHeight` and `minWidth` properties to limit resizing. For more information on resizing, see "Introduction to containers" on page 326.

Maintaining aspect ratio when sizing

The aspect ratio of an image is the ratio of its width to its height. For example, a standard NTSC television set uses an aspect ratio of 4:3, and an HDTV set uses an aspect ratio of 16:9. A computer monitor with a resolution of 640 by 480 pixels also has an aspect ratio of 4:3. A square has an aspect ratio of 1:1.

All images have an inherent aspect ratio. When you use the `height` and `width` properties of the Image control to resize an image, Flex preserves the aspect ratio of the image, by default, so that it does not appear distorted.

By preserving the aspect ratio of the image, Flex might not draw the image to fill the entire height and width specified for the `<s:Image>` tag. For example, if your original image is a square 100 by 100 pixels, which means it has an aspect ratio of 1:1, and you use the following statement to load the image:

```
<s:Image source="myImage.jpg" height="200" width="200"/>
```

The image increases to four times its original size and fills the entire 200 x 200 pixel area.

The following example sets the height and width of the same image to 150 by 200 pixels, an aspect ratio of 3:4:

```
<s:Image source="myImage.jpg" height="150" width="200"/>
```

In this example, you do not specify a square area for the resized image. Flex maintains the aspect ratio of a Spark Image by default because the `scaleMode` property is set to `letterbox`. Therefore, Flex sizes the image to 150 by 150 pixels, the largest possible image that maintains the aspect ratio and conforms to the size constraints. The other 50 by 150 pixels remain empty. However, the `<s:Image>` tag reserves the empty pixels and makes them unavailable to other controls and layout elements.

To ensure that you maintain the aspect ratio when you resize a BitmapImage, change the value of the `scaleMode` property from `stretch` to `letterbox` or `zoom`.

When you resize an image, you can apply the required alignment properties. The Spark Image and BitmapImage both have `horizontalAlign` and `verticalAlign` properties that you can specify, as required.

By default, the `horizontalAlign` and `verticalAlign` properties are set to `center`. For example, when you resize an image that has an original height and width of 1024 by 768 to a height and width of 100 by 100, there is extra space at the top and bottom of the image. You can set the the `horizontalAlign` and `verticalAlign` properties as required to overcome the extra space.

You can also use a Resize effect to change the width and height of an image in response to a trigger. As part of configuring the Resize effect, you specify a new height and width for the image. Flex maintains the aspect ratio of the image by default, so it resizes the image as much as possible to conform to the new size, while maintaining the aspect ratio. For example, place your pointer over the image in this example to enlarge it, and then move the mouse off the image to shrink it to its original size:

```
<?xml version="1.0"?>
<!-- controls\image\ImageResize.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
            import mx.effects.Resize;
        ]]>
    </fx:Script>
    <fx:Declarations>
        <s:Resize id="resizeBig"
            widthFrom="22" widthTo="44"
            heightFrom="27" heightTo="54"/>
        <s:Resize id="resizeSmall"
            widthFrom="44" widthTo="22"
            heightFrom="54" heightTo="27"/>
    </fx:Declarations>
    <s:Image width="22" height="27"
        source="@Embed('logo.jpg')"
        rollOverEffect="{resizeBig}"
        rollOutEffect="{resizeSmall}"/>

</s:Application>
```

For more information on the Resize effect, see “Introduction to effects” on page 1784.

Scaling images using fillMode and scaleMode properties

You use the `fillMode` image property to determine how an image fills into a region.

You can use the `fillMode` property in a tag or in ActionScript, and set one of the following values:

- `scale`: scales the image to fill the bounding region.
- `clip`: displays the image in its original size. If the image is larger than the bounding region, the image is clipped to the size of the bounding region. If the image is smaller than the bounding region, an empty space is left.
- `repeat`: repeats or tiles the image and fills into the dimensions of the bounding region.

When you set the `fillMode` property to `scale` , you can set the `scaleMode` property to `stretch`, `letterbox`, or `zoom`.

When you use the `fillMode` property in ActionScript, you use `BitmapFillMode.CLIP`, `BitmapFillMode.REPEAT`, or `BitmapFillMode.SCALE`.

To stretch the image content to fit the bounding region, set the attribute value to `BitmapScaleMode.STRETCH`. If you set the value to `BitmapScaleMode.LETTERBOX`, the image content is sized to fit the region boundaries while maintaining the same aspect ratio as the original unscaled image. For `BitmapScaleMode.ZOOM`, the image content is scaled to fit with respect to the original unscaled image's aspect ratio. This results in cropping along one axis.

The following example shows the Flex logo scaled in the letterbox-mode and stretch-mode using the `fillMode` and `scaleMode` properties:

```
<?xml version="1.0"?>
<!-- controls\image\ImageScaling.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
               xmlns:s="library://ns.adobe.com/flex/spark"
               xmlns:mx="library://ns.adobe.com/flex/mx">

    <s:controlBarContent>
        <s:Form>
            <s:FormItem label="scaleMode:">
                <s:DropDownList id="ddl" selectedItem="letterbox">
                    <s:dataProvider>
                        <s:ArrayList source="[letterbox,scale]" />
                    </s:dataProvider>
                </s:DropDownList>
            </s:FormItem>
        </s:Form>
    </s:controlBarContent>

    <s:Image id="image"
       source="assets/flexlogo.jpg"
       height="20" width="20"
       fillMode="scale"
       scaleMode="{ddl.selectedItem}"
       left="20" right="20" top="20" bottom="20" />
</s:Application>
```

For more code examples, see Peter deHaan's blog.

Skinning the Spark Image control

The Spark Image control lets you customize the appearance of you image through skinning.

When you use the `<s:Image>` tag to import an image, a default skin class, ImageSkin, is created. The default skin provides a simple image skin that has a content loader with a generic progress bar and a broken image icon to reflect invalid content.

The ImageSkin class provides Spark and wireframe-themed skins that let you customize the content loader and the icon to identify images that failed to load. You also have customizable skinning for borders, frames, and loading states.

The ImageSkin class defines the following optional skin parts:

- `imageDisplay:BitmapImage`: Lets you specify the image to display for invalid content or loading error.
- `ProgressIndicator:Range`: Lets you specify the range, maximum, and minimum values of the progress bar. Use the `stepSize` property to specify the amount by which the value changes when the `changeValueByStep()` method is called.

For information about the different skin states, see the source code for the ImageSkin class.

For examples on customizing skins and icons for the Spark Image control, see Peter deHann’s blog post.

Caching and queuing of images

The ContentCache class supports caching and queuing of remote image assets, and can be associated with the BitmapImage or Spark Image controls.

You set the caching and queuing properties for the image content loader as follows:

```
<fx:Declarations>
    <s:ContentCache id="imgcache" enableCaching="true" enableQueueing="true"
    maxActiveRequests="1" maxCacheEntries="10"/>
</fx:Declarations>
```

To have a content loader with only queuing capabilities and no caching capabilities, set `enableCaching` to `false`.

The difference that you notice in image-loading when you use the caching-queuing mechanism can be significant, especially with large images. Without caching, large images can take several seconds to load. For example, you can use caching and queuing to prevent image-flickering in a scrolling list.

The ContentCache class provides the following methods and properties to manage caching and queuing:

Caching properties

Property name	**Description**
`maxCacheEntries`	Specifies the number of cache entries that can be stored at a given time. When the cache entries exceed the specified number, the least recent cache entries are automatically removed. The default value is 100.
`enableQueuing`	Enables queuing of images. The default value is `false`.
`enableCaching`	Enables caching of images. The default value is `true`.
`maxActiveRequests`	Specifies the number of pending load requests that can be active at a given time when image-queuing is enabled. The default value is 2.

Caching methods

Method name	**Description**
`load()`	Returns the requested image using the `ContentRequest` instance. If the image is still loading, `ContentRequest` returns a value of `false`. If the requested image is found in the cache, `ContentRequest` returns a value of `complete`.

`removeAllCacheEntries()`
`removeCacheEntry()`
	Removes cache entries.
	Use `removeCacheEntry()` to remove a single cache entry that's no longer needed. Use `removeAllCacheEntries()` to remove all the cached content.

`getCacheEntry()`	Checks for a pre-existing cache entry, and if found, obtains a reference to the cache entry.
`addCacheEntry()`	Adds a new cache entry. Use `addCacheEntry` to manually add a cache entry.

Queuing methods

Method	**Description**
`prioritize()`	Forces all pending requests of the specified contentLoaderGrouping to be moved to the top of the request list, when image-queuing is enabled. Any active URL requests at that time are canceled and requeued if their contentLoaderGrouping does not match the prioritized content grouping.
`removeAllQueueEntries()`	Cancels all the queued requests.

Example on caching and queuing images

The following example shows loading of images using the contentLoader. Caching and queuing are enabled and custom item renderers are used.

```
<?xml version="1.0"?>
<!-- controls\image\ImageCaching.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Style>
        @namespace s "library://ns.adobe.com/flex/spark";
        @namespace mx "library://ns.adobe.com/flex/mx";

        s|Image {
            enableLoadingState: true;
        }
    </fx:Style>

    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayList;

            protected var arrList:ArrayList = new ArrayList();

            protected function init():void {
                var rand:String = new Date().time.toString()
                var arr:Array = [];
                arr.push({src:"http://localhost:8100/flex/assets/fblogo.jpg?" + rand,
cache:ldr});
                arr.push({src:"http://localhost:8100/flex/assets/flexlogo.jpg?" + rand,
cache:ldr});

                arrList = new ArrayList(arr);
                dataGrp.dataProvider = arrList;
            }
        ]]>
    </fx:Script>

    <fx:Declarations>
        <s:ContentCache id="ldr" enableQueueing="true"
           maxActiveRequests="1" maxCacheEntries="10"/>
    </fx:Declarations>
    <s:Panel title="Loading images using the caching-queuing mechanism" x="20" y="20">
        <s:controlBarContent>
            <s:Button label="Load Images" click="init();"/>
        </s:controlBarContent>
        <s:DataGroup id="dataGrp">
            <s:layout>
                <s:TileLayout />
            </s:layout>
            <s:itemRenderer>
                <fx:Component>
                    <s:ItemRenderer dataChange="imageDisplay.source = data.src;">
                        <s:Image id="imageDisplay" contentLoaderGrouping="gr1"
                           contentLoader="{data.cache}" width="200" height="200" />
                    </s:ItemRenderer>
                </fx:Component>
            </s:itemRenderer>
        </s:DataGroup>
    </s:Panel>
</s:Application>
```

***Note:** You can replace the URLs in the example to access images over the Internet rather than access them locally.*

Loading images using a customizable load interface

Flex provides a customizable content loader, IContentLoader, to load images. The IContentLoader has a simple interface that contains a `load` method to manage the load requests. For a given source, which is usually a URL, the `load` method returns the requested resources using the `ContentRequest`instance. The `ContentRequest` instance provides the load progress information and also notifies any content validation errors.

The `load` method also provides a `contentLoaderGrouping` instance to manage multiple load requests as a group. For example, the ContentCache's queuing methods allows requests to be prioritized by `contentLoaderGrouping`.

HRule and VRule controls

The HRule and VRule controls are part of the MX component set. There is no Spark equivalent.

The HRule (Horizontal Rule) control creates a single horizontal line and the VRule (Vertical Rule) control creates a single vertical line. You typically use these controls to create dividing lines within a container.

Creating HRule and VRule controls

You define HRule and VRule controls in MXML by using the `<mx:HRule>` and `<mx:VRule>` tags, as the following example shows. Specify an `id` value if you intend to refer to a component elsewhere in your MXML, either in another tag or an ActionScript block.

```
<?xml version="1.0"?>
<!-- controls\rule\RuleSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
               xmlns:s="library://ns.adobe.com/flex/spark"
               xmlns:mx="library://ns.adobe.com/flex/mx">

    <s:VGroup>
        <mx:Label text="Above"/>
        <mx:HRule/>
        <mx:Label text="Below"/>
        <s:HGroup>
            <mx:Label text="Left"/>
            <mx:VRule/>
            <mx:Label text="Right"/>
        </s:HGroup>
    </s:VGroup>

</s:Application>
```

You can also use properties of the HRule and VRule controls to specify line width, stroke color, and shadow color, as the following example shows:

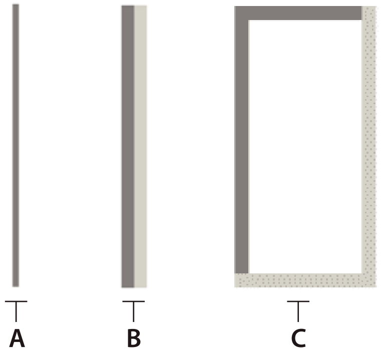
```
<?xml version="1.0"?>
<!-- controls\rule\RuleProps.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:VGroup>
        <mx:Label text="Above"/>
        <mx:HRule shadowColor="0xff0000"/>
        <mx:Label text="Below"/>
        <s:HGroup>
            <mx:Label text="Left"/>
            <mx:VRule strokeWidth="10" strokeColor="0x00ff00"/>
            <mx:Label text="Right"/>
        </s:HGroup>
    </s:VGroup>
</s:Application>
```

Sizing HRule and VRule controls

For the HRule and VRule controls, the `strokeWidth` property determines how Flex draws the line, as follows:

- If you set the `strokeWidth` property to 1, Flex draws a 1-pixel-wide line.
- If you set the `strokeWidth` property to 2, Flex draws the rule as two adjacent 1-pixel-wide lines, horizontal for an HRule control or vertical for a VRule control. This is the default value.
- If you set the `strokeWidth` property to a value greater than 2, Flex draws the rule as a hollow rectangle with 1-pixel-wide edges.

The following example shows all three options:



***A.** strokeWidth = 1* ***B.** default strokeWidth = 2* ***C.** strokeWidth = 10*

If you set the `height` property of an HRule control to a value greater than the `strokeWidth` property, Flex draws the rule within a rectangle of the specified height, and centers the rule vertically within the rectangle. The height of the rule is the height specified by the `strokeWidth` property.

If you set the `width` property of a VRule control to a value greater than the `strokeWidth` property, Flex draws the rule within a rectangle of the specified width, and centers the rule horizontally within the rectangle. The width of the rule is the width specified by the `strokeWidth` property.

If you set the `height` property of an HRule control or the `width` property of a VRule control to a value smaller than the `strokeWidth` property, the rule is drawn as if it had a `strokeWidth` property equal to the `height` or `width` property.

***Note:** If the `height` and `width` properties are specified as percentage values, the actual pixel values are calculated before the `height` and `width` properties are compared to the `strokeWidth` property.*

The `strokeColor` and `shadowColor` properties determine the colors of the HRule and VRule controls. The `strokeColor` property specifies the color of the line as follows:

- If you set the `strokeWidth` property to 1, specifies the color of the entire line.
- If you set the `strokeWidth` property to 2, specifies the color of the top line for an HRule control, or the left line for a VRule control.
- If you set the `strokeWidth` property to a value greater than 2, specifies the color of the top and left edges of the rectangle.

The `shadowColor` property specifies the shadow color of the line as follows:

- If you set the `strokeWidth` property to 1, does nothing.
- If you set the `strokeWidth` property to 2, specifies the color of the bottom line for an HRule control, or the right line for a VRule control.
- If you set the `strokeWidth` property to a value greater than 2, specifies the color of the bottom and right edges of the rectangle.

Setting style properties

The `strokeWidth`, `strokeColor`, and `shadowColor` properties are style properties. Therefore, you can set them in MXML as part of the tag definition, set them by using the `<fx:Style>` tag in MXML, or set them by using the `setStyle()` method in ActionScript.

The following example uses the `<fx:Style>` tag to set the default value of the `strokeColor` property of all HRule controls to `#00FF00` (lime green), and the default value of the `shadowColor` property to `#0000FF` (blue). This example also defines a class selector, called `thickRule`, with a `strokeWidth` of 5 that you can use with any instance of an HRule control or VRule control:

```
<?xml version="1.0"?>
<!-- controls\rule\RuleStyles.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Style>
        @namespace mx "library://ns.adobe.com/flex/mx";

        .thickRule {strokeWidth:5}
        mx|HRule {strokeColor:#00FF00; shadowColor:#0000FF}
    </fx:Style>
    <mx:HRule styleName="thickRule"/>
</s:Application>
```

HSlider and VSlider controls

The HSlider and VSlider controls are part of both the MX and Spark component sets. While you can use the MX HSlider and VSlider controls in your application, Adobe recommends that you use the Spark controls instead.

You can use the slider controls to select a value by moving a slider thumb between the end points of the slider track. The current value of the slider is determined by the relative location of the thumb between the end points of the slider. The slider end points correspond to the slider’s minimum and maximum values.

By default, the minimum value of a slider is 0 and the maximum value is 10. The current value of the slider can be any value in a continuous range between the minimum and maximum values. It can also be one of a set of discrete values, depending on how you configure the control.

About slider controls

Flex provides two slider controls: the HSlider (Horizontal Slider) control, which creates a horizontal slider, and the VSlider (Vertical Slider) control, which creates a vertical slider. The slider controls contain a track and a slider thumb. You can optionally show or hide tooltips and data tips, which show the data value as the user drags the slider thumb. The slider controls do not contain a label property, but you can add labels to the component skin.

The following code example shows a horizontal slider and a vertical slider with different properties set. In the horizontal slider, the values increment and decrement by a value of 0.25. In the vertical slider, the data tip is hidden but a tool tip is visible.

```
<?xml version="1.0"?>
<!-- controls\slider\HSliderSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <s:Group>
        <s:layout>
            <s:HorizontalLayout paddingTop="10"
                paddingLeft="10"/>
            </s:layout>
        <s:HSlider id="horizontalBar"
            snapInterval=".25"/>
        <s:VSlider id="volumeBar"
            showDataTip="false"
            toolTip="Volume"/>
    </s:Group>
</s:Application>
```

Creating a slider control

You define an HSlider control in MXML by using the `<s:HSlider>` tag. Define a VSlider control by using the `<s:VSlider>` tag. Specify an `id` value if you intend to refer to a component elsewhere, either in another tag or in an ActionScript block.

You can bind the `value` property of a slider to another control to display the current value of the slider. The following example binds the `value` property to a Label box. Because the `liveDragging` style property is set to `true`, the value in the text box updates as the slider moves. The `dataTipPrecision` property is set to 0 to show whole numbers.

```
<?xml version="1.0"?>
<!-- controls\slider\HSliderBinding.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:Group>
        <s:layout>
            <s:HorizontalLayout paddingTop="10"
                paddingLeft="10"/>
            </s:layout>
        <s:HSlider id="mySlider"
            liveDragging="true"
            dataTipPrecision="0"/>
        <s:Label text="The slider value is: {Math.round(mySlider.value)}"/>
    </s:Group>

</s:Application>
```

Using slider events

The slider controls let the user select a value by moving the slider thumb between the minimum and maximum values of the slider. You typically use events with the slider to recognize when the user has moved the thumb and to determine the current value associated with the slider.

The slider controls can dispatch the events described in the following table:

Event	Description
change	Dispatches when the user moves the thumb. If the liveDragging property is true, the event is dispatched continuously as the user moves the thumb. If liveDragging is false, the event is dispatched when the user releases the slider thumb.
thumbDrag	Dispatches when the user moves a thumb.
thumbPress	Dispatches when the user selects a thumb by using the pointer.
thumbRelease	Dispatches when the user releases the pointer after a thumbPress event occurs.

The following code example uses a change event to enable a Submit button when the user releases the slider thumb:

```
<?xml version="1.0"?>
<!-- controls\slider\HSliderEvent.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Script>
        <![CDATA[
            public function changeRB():void {
            myButton.enabled=true;
            }
        ]]>
    </fx:Script>
    <s:Group>
        <s:layout>
            <s:VerticalLayout paddingTop="10"
            paddingLeft="10"/>
        </s:layout>
        <s:HSlider id="mySlider"
            thumbRelease="changeRB()"/>
        <s:Button id="myButton" enabled="false" label="Submit"/>

    </s:Group>
</s:Application>
```

By default, the liveDragging property of the slider control is set to false. A value of false means that the control dispatches the change event when the user releases the slider thumb. If you set liveDragging to true, the control dispatches the change event continuously as the user moves the thumb, as shown in “Creating a slider control” on page 691.

Using data tips

By default, when you select a slider thumb, a data tip appears, showing the current value of the slider. As you move the selected thumb, the data tip shows the new slider value. You can disable data tips by setting the showDataTip property to false.

You can use the dataTipFormatFunction property to specify a callback function to format the data tip text. This function takes a single String argument containing the data tip text. It returns a String containing the new data tip text, as the following example shows:

```
<?xml version="1.0"?>
<!-- controls\slider\HSliderDataTip -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Script>
        <![CDATA[
            private function myDataTipFunc(val:String):String {
                return "Current value: " + String(val);
            }
        ]]>
    </fx:Script>
    <s:layout>
        <s:HorizontalLayout paddingTop="10"
            paddingLeft="10"/>
    </s:layout>
    <s:HSlider
        height="80"
        dataTipFormatFunction="myDataTipFunc"/>
</s:Application>
```

In this example, the data tip function prefixes the data tip text with the String "Current value:". You can modify this example to insert other characters, such as a dollar sign ($), on the data tip.

Keyboard navigation

The HSlider and VSlider controls have the following keyboard navigation features when the slider control has focus:

Key	Description
Left Arrow	Decrement the value of an HSlider control by one value interval or, if you do not specify a value interval, by one pixel.
Right Arrow	Increment the value of a HSlider control by one value interval or, if you do not specify a value interval, by one pixel.
Home	Moves the thumb of an HSlider control to its minimum value.
End	Moves the thumb of an HSlider control to its maximum value.
Up Arrow	Increment the value of an VSlider control by one value interval or, if you do not specify a value interval, by one pixel.
Down Arrow	Decrement the value of a VSlider control by one value interval or, if you do not specify a value interval, by one pixel.

LinkBar control

The LinkBar control is part of the MX component set. There is no Spark equivalent.

A LinkBar control defines a horizontal or vertical row of LinkButton controls that designate a series of link destinations. You typically use a LinkBar control to control the active child container of a ViewStack container, or to create a standalone set of links.

Creating a LinkBar control

One of the most common uses of a LinkBar control is to control the active child of a ViewStack container. For an example, see “MX ViewStack navigator container” on page 630.

You can also use a LinkBar control on its own to create a set of links in your application. In the following example, you define an itemClick handler for the LinkBar control to respond to user input, and use the `dataProvider` property of the LinkBar to specify its label text:

```
<?xml version="1.0"?>
<!-- controls\bar\LBarSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <mx:LinkBar borderStyle="solid"
        itemClick="navigateToURL(new URLRequest('http://www.adobe.com/' +
            String(event.label).toLowerCase()), '_blank');">
        <mx:dataProvider>
            <fx:String>Flash</fx:String>
            <fx:String>Director</fx:String>
            <fx:String>Dreamweaver</fx:String>
            <fx:String>ColdFusion</fx:String>
        </mx:dataProvider>
    </mx:LinkBar>
</s:Application>
```

In this example, you use the `<mx:dataProvider>` tag to define the label text. The event object passed to the `itemClick` handler contains the label selected by the user. The handler for the `itemClick` event constructs an HTTP request to the Adobe website based on the label, and opens that page in a new browser window.

You can also bind data to the `dataProvider` property to populate the LinkBar control, as the following example shows:

```
<?xml version="1.0"?>
<!-- controls\bar\LBarBinding.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;

            [Bindable]
            private var linkData:ArrayCollection = new ArrayCollection([
                {label:'Flash', url:'http://www.adobe.com/products/flash/'},
                {label:'Director', url:'http://www.adobe.com/products/director/'},
                {label:'Dreamweaver', url:'http://www.adobe.com/products/dreamweaver/'},
                {label:'ColdFusion', url:'http://www.adobe.com/products/coldfusion/'}]);
        ]]>
    </fx:Script>

    <mx:LinkBar
        dataProvider="{linkData}"
        horizontalAlign="right"
        borderStyle="solid"
        itemClick="navigateToURL(new URLRequest(event.item.url), '_blank');">
    </mx:LinkBar>
</s:Application>
```

A LinkBar control creates LinkButton controls based on the value of its `dataProvider` property. Even though LinkBar is a subclass of Container, do not use methods such as `Container.addChild()` and `Container.removeChild()` to add or remove LinkButton controls. Instead, use methods such as `addItem()` and `removeItem()` to manipulate the `dataProvider` property. A LinkBar control automatically adds or removes the necessary children based on changes to the `dataProvider` property.

LinkButton control

The LinkButton control is part of the MX component set. There is no Spark equivalent.

The LinkButton control creates a single-line hypertext link that supports an optional icon. You can use a LinkButton control to open a URL in a web browser.

Creating a LinkButton control

You define a LinkButton control in MXML by using the `<mx:LinkButton>` tag, as the following example shows. Specify an `id` value if you intend to refer to a component elsewhere in your MXML, either in another tag or in an ActionScript block:

```
<?xml version="1.0"?>
<!-- controls\button\LBSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <mx:HBox>
        <mx:LinkButton label="link1"/>
        <mx:LinkButton label="link2"/>
        <mx:LinkButton label="link3"/>
    </mx:HBox>
</s:Application>
```

The following code contains a single LinkButton control that opens a URL in a web browser window:

```
<?xml version="1.0"?>
<!-- controls\button\LBURL.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <mx:LinkButton label="ADBE"
        width="100"
        click="navigateToURL(new URLRequest('http://quote.yahoo.com/q?s=ADBE'), 'quote')"/>
</s:Application>
```

This example uses the `navigateToURL()` method to open the URL.

The LinkButton control automatically provides visual cues when you move your mouse pointer over or click the control. The previous code example contains no link handling logic but does change color when you move your mouse pointer over or click a link.

The following code example contains LinkButton controls for navigating in a ViewStack navigator container:

```
<?xml version="1.0"?>
<!-- controls\button\LBViewStack.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <mx:VBox>
        <!-- Put the links in an HBox container across the top. -->
        <mx:HBox>
            <mx:LinkButton label="Link1"
                click="viewStack.selectedIndex=0;"/>
            <mx:LinkButton label="Link2"
                click="viewStack.selectedIndex=1;"/>
            <mx:LinkButton label="Link3"
                click="viewStack.selectedIndex=2;"/>
        </mx:HBox>
        <!-- This ViewStack container has three children. -->
        <mx:ViewStack id="viewStack">
            <mx:VBox width="150">
                <mx:Label text="One"/>
            </mx:VBox>
            <mx:VBox width="150">
                <mx:Label text="Two"/>
            </mx:VBox>
            <mx:VBox width="150">
                <mx:Label text="Three"/>
            </mx:VBox>
        </mx:ViewStack>
    </mx:VBox>
</s:Application>
```

A LinkButton control's label is centered within the bounds of the LinkButton control. You can position the text label in relation to the icon by using the `labelPlacement` property, which accepts the values `right`, `left`, `bottom`, and `top`.

LinkButton control user interaction

When a user clicks a LinkButton control, the LinkButton control dispatches a `click` event. If a LinkButton control is enabled, the following happens:

- When the user moves the mouse pointer over the LinkButton control, the LinkButton control changes its rollover appearance.
- When the user clicks the LinkButton control, the input focus moves to the control and the LinkButton control displays its pressed appearance. When the user releases the mouse button, the LinkButton control returns to its rollover appearance.
- If the user moves the mouse pointer off the LinkButton control while pressing the mouse button, the control's appearance returns to its original state and the control retains input focus.
- If the toggle property is set to `true`, the state of the LinkButton control does not change until the mouse button is released over the control.

If a LinkButton control is disabled, it appears as disabled, regardless of user interaction. In the disabled state, the control ignores all mouse or keyboard interaction.

NumericStepper control

The NumericStepper control is part of both the MX and Spark component sets. While you can use the MX NumericStepper control in your application, Adobe recommends that you use the Spark control instead.

You can use the NumericStepper control to select a number from an ordered set. The NumericStepper control consists of a single-line input text field and a pair of arrow buttons for stepping through the valid values. You can use the Up Arrow and Down arrow keys to cycle through the values.

If the user clicks the up arrow, the value displayed increases by one unit of change. If the user holds down the arrow, the value increases or decreases until the user releases the mouse button. When the user clicks the arrow, it is highlighted to provide feedback to the user.

Users can also type a legal value directly into the text field. Although editable ComboBox controls provide similar functionality, NumericStepper controls are sometimes preferred because they do not require a drop-down list that can obscure important data.

NumericStepper control arrows always appear to the right of the text field.

Creating a NumericStepper control

You define a NumericStepper control in MXML by using the `<s:NumericStepper>` tag, as the following example shows. Specify an `id` value if you intend to refer to a component elsewhere in your MXML, either in another tag or in an ActionScript block:

```
<?xml version="1.0"?>
<!-- controls\numericstepper\NumStepSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:NumericStepper id="nstepper1"
        value="6"
        stepSize="2"
        maximum="100"/>

</s:Application>
```

Sizing a NumericStepper control

When the control is resized, the width of the Up and Down arrow buttons in the NumericStepper control do not change size. If the NumericStepper control is sized greater than the default height, the associated stepper buttons appear pinned to the top and the bottom of the control.

User interaction

If the user clicks the Up or Down arrow button, the value displayed increases by one unit of change. If the user presses either of the arrow buttons for more than 200 milliseconds, the value in the input field increases or decreases, based on step size, until the user releases the mouse button or the maximum or minimum value is reached.

Keyboard navigation

The NumericStepper control has the following keyboard navigation features:

Key	Description
Down Arrow	Value decreases by one unit.
Up Arrow	Value increases by one unit.
Left Arrow	Moves the insertion point to the left within the NumericStepper control's text field.
Right Arrow	Moves the insertion point to the right within the Numeric Stepper control's text field.

To use the keyboard to navigate through the stepper, it must have focus.

PopUpAnchor control

The PopUpAnchor control is part of the Spark component set. There is no MX equivalent.

The PopUpAnchor control displays a pop-up component in a layout. It has no visual appearance, but it has dimensions. The PopUpAnchor control is used in the DropDownList control. The PopUpAnchor displays the pop-up component by adding it to the PopUpManager, and then sizes and positions the pop-up component relative to itself. Because the pop-up component is managed by the PopUpManager, it appears above all other controls.

With the PopUpAnchor control, you can create various kinds of popup functionality, such as the following:

- Click a button and a form to submit feedback pops up
- Click a button, and a search field pops up
- Mouse over the top of an application and a menu drops down
- In a calendar tool, double-click an appointment block to open an Edit dialog

Creating a pop-up component with PopUpAnchor

Define a PopUpAnchor control in MXML by using the `<s:PopUpAnchor>` tag. as the following example shows. Specify an `id` value if you intend to refer to a component elsewhere in your MXML, either in another tag or in an ActionScript block.

Use the PopUpAnchor with two other components: the control that opens the popup, and the component that pops up (referred to as the pop-up component). The value of the `popUp` property is the pop-up component.

The following example creates an application with a button labeled Show slider. Click the button, and a VSlider component pops up. When you select a value using the slider, the `thumbRelease` event is triggered and the popup closes.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- controls\popup\PopUpSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:HGroup>
        <s:Button label="Show slider"
            click="slide.displayPopUp = true"/>
        <s:PopUpAnchor id="slide">
            <s:VSlider
                maxHeight="40"
                thumbRelease="slide.displayPopUp = false"/>
        </s:PopUpAnchor>
    </s:HGroup>
</s:Application>
```

Sizing and positioning a popup component

The PopUpAnchor control sizes and positions the component that pops up (the pop-up component) relative to itself. If the pop-up doesn't fit, it will flip the position. ABOVE -> BELOW, RIGHT -> LEFT, etc. If it still doesn't fit, it will go back to the original position and call the pop-up until it is fully on screen.

The width of the pop-up component is determined in the following order:

- If `popUpWidthMatchesAnchorWidth` is true, use the actual width of the PopUpAnchor
- Use the pop-up component's `explicitWidth` value, if specified
- Use the pop-up component's `measuredWidth` value

The height of the pop-up component is determined in the following order:

- If `popUpHeightMatchesAnchorHeight` is true, use the actual height of the PopUpAnchor control
- Use the popup's `explicitHeight` value, if specified
- Use the pop-up component's `measuredHeight` value

The `popUpPosition` property controls the position of the pop-up component. Valid values are static properties of the PopUpPosition class and are as follows:

Value	Description
`above`	The bottom of the popup is adjacent to the top of the PopUpAnchor control. The left edge of the popup is vertically aligned with the left edge of the PopUpAnchor control.
`below`	The top of the popup is adjacent to the bottom of the PopUpAnchor control. The left edge of the pop-up is vertically aligned with the left edge of the PopUpAnchor control.
`left`	The right edge of the popup is adjacent to the left edge of the PopUpAnchor control. The top edge of the popup is horizontally aligned with the top edge of the PopUpAnchor control.
`right`	The left edge of the popup is adjacent to the right edge of the PopUpAnchor control. The top edge of the popup is horizontally aligned with the top edge of the PopUpAnchor control.
`center`	The horizontal and vertical center of the popup is positioned at the horizontal and vertical center of the PopUpAnchor control.
`topLeft`	The popup is positioned at the same default top-left position as the PopUpAnchor control.

Transforming and animating a popup component

Transformations include scaling, rotation, and skewing. Transformations that are applied to the PopUpAnchor control or its ancestors before the pop-up component opens are always applied to the pop-up component when it opens. However, if such changes are applied while the pop-up is open, the changes are not applied to the pop-up until the next time the pop-up opens. To apply transformations to the pop-up while it is open, call the `updatePopUpTransform()` method.

You can apply effects to animate the showing and hiding of the pop-up. Because transformations made on the PopUpAnchor control apply to its pop-up, you can apply effects to either the PopUpAnchor control or its pop-up component.

Consider the following when deciding whether to apply an effect on the PopUpAnchor control or its pop-up component:

- Apply Move, Fade, Resize, and Zoom effects to the PopUpAnchor control. Applying these effects to the PopUpAnchor control allows the effect to respect some of the PopUpAnchor control's layout constraints.
- Apply Mask and Shader effects on the pop-up component directly. These effects require applying a mask to the target or taking a bitmap snapshot of the target.

- If the effect is applied to the PopUpAnchor or its ancestors while the pop-up component is open, call `updatePopUpTransform()`. Calling this method reapplies the effect to the popup while the effect plays.

The following example uses states to control the display of the popup component. It uses transitions to play animations between states. When you click the Email button, an e-mail form fades into the application. Click Send or Cancel, and the e-mail form fades out. By only including the PopUpAnchor in the emailOpen state (`includeIn="emailOpen"`), the form is only instantiated when it is displayed.

```
<?xml version="1.0" encoding="utf-8"?>
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx" >

    <s:layout>
        <s:HorizontalLayout/>
    </s:layout>

    <fx:Style>
    .popUpBox
    {
        backgroundColor : #e9e9e9;
        borderStyle : "solid";
        paddingTop : 2;
        paddingBottom : 2;
        paddingLeft : 2;
        paddingRight : 2;
    }
    </fx:Style>
    <s:states>
        <s:State name="normal" />
        <s:State name="emailOpen" />
    </s:states>
    <s:transitions>
        <mx:Transition fromState="*" toState="*">
            <mx:Sequence>
                <s:Fade target="{emailPopUp.popUp}"
                    duration="250"/>
            </mx:Sequence>
        </mx:Transition>
    </s:transitions>
    <s:Group x="60">
        <s:Button label="Send email"
            click="currentState = 'emailOpen'"/>
        <s:PopUpAnchor id="emailPopUp"
            left="0" bottom="0"
            popUpPosition="below"
            styleName="popUpBox"
            includeIn="emailOpen"
            displayPopUp.normal="false"
            displayPopUp.emailOpen="true">
            <mx:Form>
                <mx:FormItem label="From :">
                    <s:TextInput/>
                </mx:FormItem>
                <mx:FormItem label="To :">
```

```
                    <s:TextInput/>
                </mx:FormItem>
                <mx:FormItem label="Subject :">
                    <s:TextInput/>
                </mx:FormItem>
                <mx:FormItem label="Message :">
                    <s:TextArea width="100%"
                        height="100"
                        maxChars="120"/>
                </mx:FormItem>
                <mx:FormItem direction="horizontal">
                    <s:Button label="Send"
                        click="currentState = 'normal'"/>
                    <s:Button label="Cancel"
                        click="currentState = 'normal'" />
                </mx:FormItem>
            </mx:Form>
        </s:PopUpAnchor>
    </s:Group>
</s:Application>
```

You can also control when the PopUpAnchor is destroyed. See “Create and apply view states” on page 1850, particularly the sections on “Controlling when to create added children” on page 1856 and “Controlling caching of objects created in a view state” on page 1858. These sections discuss the `itemCreationPolicy` and `itemDestructionPolicy` properties.

The following example displays a Search button with an animated popup. Click the button, and a text input field and a Find now button pops up on the right. Click the Find button, and the text input field and Find now button are hidden. The animation plays directly on the popup components.

```
<?xml version="1.0" encoding="utf-8"?>
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
               xmlns:s="library://ns.adobe.com/flex/spark"
               xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Style>
        .popUpBox
        {
            backgroundColor : #e9e9e9;
            borderStyle : "solid";
            paddingTop : 2;
            paddingBottom : 2;
            paddingLeft : 2;
            paddingRight : 2;
        }
    </fx:Style>

    <fx:Declarations>
        <mx:Sequence id="hideSearch">
            <s:Scale target="{searchPopUp.popUp}"
                     scaleXFrom="1"
                     scaleXTo=".1"
                     duration="250"/>
            <mx:SetPropertyAction target="{searchPopUp}"
                                  name="displayPopUp"
                                  value="false"/>
        </mx:Sequence>
        <mx:Sequence id="showSearch">
            <mx:SetPropertyAction target="{searchPopUp}"
                                  name="displayPopUp"
                                  value="true"/>
            <s:Scale target="{searchPopUp.popUp}"
                     scaleXFrom=".1"
                     scaleXTo="1"
                     duration="200"/>
        </mx:Sequence>
    </fx:Declarations>

    <s:HGroup>
        <s:Button label="Search database" click="showSearch.play() "/>
        <s:PopUpAnchor id="searchPopUp"
                       left="0" right="0"
                       popUpPosition="right"
                       styleName="popUpBox">
            <s:HGroup>
                <s:TextInput id="searchField"
                             width="80" />
                <s:Button label="Find now"
                          click="hideSearch.play();"/>
            </s:HGroup>
        </s:PopUpAnchor>
    </s:HGroup>
</s:Application>
```

PopUpButton control

The PopUpButton control is part of the MX component set. There is no Spark equivalent.

The PopUpButton control consists of two horizontal buttons: a main button, and a smaller button called the pop-up button, which only has an icon. The main button is a Button control.

The pop-up button, when clicked, opens a second control called the pop-up control. Clicking anywhere outside the PopUpButton control, or in the pop-up control, closes the pop-up control

The PopUpButton control adds a flexible pop-up control interface to a Button control. One common use for the PopUpButton control is to have the pop-up button open a List control or a Menu control that changes the function and label of the main button.

The PopUpButton control is not limited to displaying menus; it can display any control as the pop-up control. A workflow application that lets users send a document for review, for example, could use a Tree control as a visual indication of departmental structure. The PopUpButton control's pop-up button would display the tree, from which the user could pick the message recipients.

The control that pops up does not have to affect the main button's appearance or action; it can have an independent action instead. You could create an undo PopUpButton control, for example, where the main button undoes only the last action, and the pop-up control is a List control that lets users undo multiple actions by selecting them.

The PopUpButton control is a subclass of the Button control and inherits all of its properties, styles, events, and methods, with the exception of the `toggle` property and the styles used for a selected button.

The control has the following characteristics:

- The `popUp` property specifies the pop-up control (for example, List or Menu).

- The `open()` and `close()` methods lets you open and close the pop-up control programmatically, rather than by using the pop-up button.
- The `open` and `close` events are dispatched when the pop-up control opens and closes.
- You use the `popUpSkin` and `arrowButtonWidth` style properties to define the PopUpButton control's appearance.

For detailed descriptions, see PopUpButton in *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Creating a PopUpButton control

You use the `<mx:PopUpButton>` tag to define a PopUpButton control in MXML. Specify an `id` value if you intend to refer to a component elsewhere in your MXML, either in another tag or in an ActionScript block.

In the following example, you use the PopUpButton control to open a Menu control. Once opened, the Menu control, or any pop-up control, functions just as it would normally. You define an event listener for the Menu control's change event to recognize when the user selects a menu item, as the following example shows:

```
<?xml version="1.0"?>
<!-- controls\button\PopUpButtonMenu.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    height="600" width="600">
    <fx:Script>
        <![CDATA[
            import mx.controls.*;
            import mx.events.*;
            private var myMenu:Menu;
            // Initialize the Menu control,
            // and specify it as the pop up object
            // of the PopUpButton control.
            private function initMenu():void {
                myMenu = new Menu();
                var dp:Object = [
                  {label: "New Folder"},
                  {label: "Sent Items"},
                  {label: "Inbox"}
                ];
                myMenu.dataProvider = dp;
                myMenu.addEventListener("itemClick", changeHandler);
                popB.popUp = myMenu;
            }
            // Define the event listener for the Menu control's change event.
            private function changeHandler(event:MenuEvent):void {
                var label:String = event.label;
                popTypeB.text=String("Moved to " + label);
                popB.label = "Put in: " + label;
                popB.close();
            }
        ]]>
    </fx:Script>
    <mx:VBox>
        <mx:Label text="Main button mimics the last selected menuItem."/>
        <mx:PopUpButton id="popB"
            label="Edit"
            width="135"
            creationComplete="initMenu();"/>

        <mx:Spacer height="50"/>
        <mx:TextInput id="popTypeB"/>
    </mx:VBox>
</s:Application>
```

User interaction

You navigate the PopUpButton control in the following ways:

- Moving the mouse over any part of the PopUpButton control highlights the button border and the main button or the pop-up button.
- Clicking the button dispatches the `click` event.
- Clicking the pop-up button pops up the pop-up control and dispatches an `open` event.
- Clicking anywhere outside the PopUpButton control, or in the pop-up control, closes the pop-up control and dispatches a `close` event.

The following keystrokes let users navigate the PopUpButton control:

Key	Use
Spacebar	Behaves like clicking the main button.
Control+Down Arrow	Opens the pop-up control and initiates an `open` event. The pop-up control’s keyboard handling takes effect.
Control+Up Arrow	Closes the pop-up control and initiates a `close` event.

***Note:** You cannot use the Tab key to leave an opened pop-up control; you must make a selection or close the control with the Control+Up Arrow key combination.*

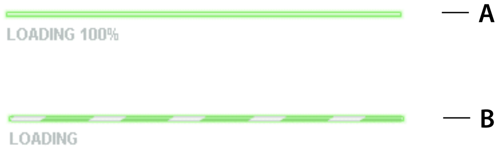
ProgressBar control

The ProgressBar control is part of the MX component set. There is no Spark equivalent.

The ProgressBar control provides a visual representation of the progress of a task over time. There are two types of ProgressBar controls: determinate and indeterminate. A *determinate* ProgressBar control is a linear representation of the progress of a task over time. You can use this when the user is required to wait for an extended period of time, and the scope of the task is known.

An *indeterminate* ProgressBar control represents time-based processes for which the scope is not yet known. As soon as you can determine the scope, you should use a determinate ProgressBar control.

The following example shows both types of ProgressBar controls:



Top. *Determinate ProgressBar control* ***Bottom.*** *Indeterminate ProgressBar control*

Use the ProgressBar control when the user is required to wait for completion of a process over an extended period of time. You can attach the ProgressBar control to any kind of loading content. A label can display the extent of loaded contents when enabled.

ProgressBar control modes

You use the `mode` property to specify the operating mode of the ProgressBar control. The ProgressBar control supports the following modes of operation:

event Use the `source` property to specify a loading process that emits `progress` and `complete` events. For example, the SWFLoader and Image controls emit these events as part of loading a file. You typically use a determinate ProgressBar in this mode. The ProgressBar control only updates if the value of the `source` property extends the EventDispatcher class. This is the default mode.

You also use this mode if you want to measure progress on multiple loads; for example, if you reload an image, or use the SWFLoader and Image controls to load multiple images.

polled Use the `source` property to specify a loading process that exposes the `bytesLoaded` and `bytesTotal` properties. For example, the SWFLoader and Image controls expose these properties. You typically use a determinate ProgressBar in this mode.

manual Set the `maximum`, `minimum`, and `indeterminate` properties along with calls to the `setProgress()` method. You typically use an indeterminate ProgressBar in this mode.

Creating a ProgressBar control

You use the `<mx:ProgressBar>` tag to define a ProgressBar control in MXML, as the following example shows. Specify an `id` value if you intend to refer to a component elsewhere in your MXML, either in another tag or in an ActionScript block.

The following example uses the default event mode to track the progress of loading an image by using the Image control:

```
<?xml version="1.0"?>
<!-- controls\pbar\PBarSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
            public function initImage():void {
              image1.load('../assets/DSC00034.JPG');
            }
        ]]>
    </fx:Script>
    <mx:VBox id="vbox0"
        width="600" height="600">
        <mx:Canvas>
            <mx:ProgressBar width="200" source="image1"/>
        </mx:Canvas>
        <s:Button id="myButton"
            label="Show"
            click="initImage();"/>
        <mx:Image id="image1"
            height="500" width="600"
            autoLoad="false"
            visible="true"/>
    </mx:VBox>
</s:Application>
```

After you run this example the first time, the large image will typically be stored in your browser's cache. Before running this example a second time, clear your browser's cache so that you can see the ProgressBar control complete. If you do not clear your browser's cache, Flash Player loads the image from the cache and the ProgressBar control might go from 0% to 100% too quickly to see it tracking any progress in between.

In this mode, the Image control issues `progress` events during the load, and a `complete` event when the load completes.

The `<mx:Image>` tag exposes the `bytesLoaded` and `bytesTotal` properties, so you could also use `polled` mode, as the following example shows:

```
<mx:ProgressBar width="200" source="image1" mode="polled"/>
```

In manual mode, `mode="manual"`, you use an indeterminate ProgressBar control with the `maximum` and `minimum` properties and the `setProgress()` method. The `setProgress()` method has the following method signature:

```
setProgress(Number completed, Number total)
```

`completed` Specifies the progress made in the task, and must be between the `maximum` and `minimum` values. For example, if you were tracking the number of bytes to load, this would be the number of bytes already loaded.

`total` Specifies the total task. For example, if you were tracking bytes loaded, this would be the total number of bytes to load. Typically, this is the same value as `maximum`.

To measure progress, you make explicit calls to the `setProgress()` method to update the ProgressBar control.

To measure progress, you make explicit calls to the `setProgress()` method to update the ProgressBar control.

Defining the label of a ProgressBar control

By default, the ProgressBar displays the label *LOADING xx%*, where *xx* is the percent of the image loaded. You use the `label` property to specify a different text string to display.

The `label` property lets you include the following special characters in the label text string:

%1 Corresponds to the current number of bytes loaded.

%2 Corresponds to the total number of bytes.

%3 Corresponds to the percent loaded.

%% Corresponds to the % sign.

For example, to define a label that displays as:

```
Loading Image 1500 out of 78000 bytes, 2%
```

use the following code:

```
<?xml version="1.0"?>
<!-- controls\pbar\PBarLabel.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
            public function initImage():void {
              image1.load('../assets/DSC00034.JPG');
            }
        ]]>
    </fx:Script>
    <mx:VBox id="vbox0"
        width="600" height="600">
        <mx:Canvas>
            <mx:ProgressBar
                width="300"
                source="image1"
                mode="polled"
                label="Loading Image %1 out of %2 bytes, %3%%"
                labelWidth="400"
            />
        </mx:Canvas>
        <s:Button id="myButton"
            label="Show"
            click="initImage();"
        />
        <mx:Image id="image1"
            height="500" width="600"
            autoLoad="false"
            visible="true"
        />
    </mx:VBox>
</s:Application>
```

As with the previous example, be sure to clear your browser's cache before running this example a second time.

RadioButton control

The RadioButton and RadioButtonGroup controls are part of both the MX and Spark component sets. While you can use the MX controls in your application, Adobe recommends that you use the Spark controls instead.

The RadioButton control is a single choice in a set of mutually exclusive choices. A RadioButton group is composed of two or more RadioButton controls with the same group name. Only one member of the group can be selected at any given time. Selecting an deselected group member deselects the currently selected RadioButton control in the group.

While grouping RadioButton instances in a RadioButtonGroup is optional, a group lets you do things like set a single event handler on a group of buttons, rather than on each individual button. The RadioButtonGroup tag goes in the `<fx:Declarations>` tag.

Creating a RadioButton control

You define a RadioButton control in MXML by using the `<s:RadioButton>` tag, as the following example shows. Specify an `id` value if you intend to refer to a component elsewhere in your MXML, either in another tag or in an ActionScript block.

```
<?xml version="1.0"?>
<!-- controls\button\RBSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:VGroup>
        <s:RadioButton groupName="cardtype"
            id="americanExpress"
            label="American Express"
            width="150"/>
        <s:RadioButton groupName="cardtype"
            id="masterCard"
            label="MasterCard"
            width="150"/>
        <s:RadioButton groupName="cardtype"
            id="visa"
            label="Visa"
            width="150"/>
    </s:VGroup>
</s:Application>
```

For each RadioButton control in the group, you can optionally define an event listener for each button's `click` event. When a user selects a RadioButton control, Flex calls the event handler associated with that button's `click` event, as the following code example shows:

```
<?xml version="1.0"?>
<!-- controls\button\RBEvent.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
            import flash.events.Event;
            private function handleAmEx(event:Event):void {
                // Handle event.
                myTA.text="Got Amex";
            }
            private function handleMC(event:Event):void {
                // Handle event.
                myTA.text="Got MasterCard";
            }
            private function handleVisa(event:Event):void {
                // Handle event.
                myTA.text="Got Visa";
            }
        ]]>
    </fx:Script>

    <s:VGroup>
        <s:RadioButton groupName="cardtype"
            id="americanExpress"
            label="American Express"
            width="150"
            click="handleAmEx(event);"/>
        <s:RadioButton groupName="cardtype"
            id="masterCard"
            label="MasterCard"
            width="150"
            click="handleMC(event);"/>
        <s:RadioButton groupName="cardtype"
            id="visa"
            label="Visa"
            width="150"
            click="handleVisa(event);"/>
        <s:TextArea id="myTA"/>
    </s:VGroup>
</s:Application>
```

Creating a group by using the <s:RadioButtonGroup> tag

The previous example created a RadioButton group by using the `groupName` property of each RadioButton control. To set functionality such as a single event handler on the group, use the `<s:RadioButtonGroup>` tag, as the following example shows:

```
<?xml version="1.0"?>
<!-- controls\button\RBGroupSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
            import mx.events.ItemClickEvent;
            private function handleCard(event:ItemClickEvent):void {
                //Print the value of the selected RadioButton in the Text Area
                var cardValue:Object = cardtype.selectedValue;
                myTA.text="You selected " + cardValue;
            }
        ]]>
    </fx:Script>

    <fx:Declarations>
        <s:RadioButtonGroup id="cardtype"
            itemClick="handleCard(event);"/>
    </fx:Declarations>

    <s:VGroup>
        <s:RadioButton group="{cardtype}"
            id="americanExpress"
            label="American Express"
            width="150"/>
        <s:RadioButton group="{cardtype}"
            id="masterCard"
            label="MasterCard"
            width="150"/>
        <s:RadioButton group="{cardtype}"
            id="visa"
            label="Visa"
            width="150"/>
        <s:TextArea id="myTA"/>
    </s:VGroup>
</s:Application>
```

In this example, the `id` property of the `<s:RadioButtonGroup>` tag defines the group name. use data binding to associate the group name with the `group` property of each RadioButton control.

The single `itemClick` event listener is defined for all buttons in the group. The `id` property is required when you use the `<s:RadioButtonGroup>` tag. The RadioButtonGroup is declared using the `<fx:Declarations>` tag.

The `itemClick` event listener for the group can take a different action depending on which button was selected, as the following example shows:

```
<?xml version="1.0"?>
<!-- controls\button\RBGroupEvent.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
            import mx.controls.Alert;
            import mx.events.ItemClickEvent;

            private function handleCard(event:ItemClickEvent):void {
                if (event.currentTarget.selectedValue == "AmEx") {
                    Alert.show("You selected American Express.");
                } else if (event.currentTarget.selectedValue == "MC") {
                        Alert.show("You selected MasterCard.");
                } else {
                    Alert.show("You selected Visa.");
                }
            }
        ]]>
    </fx:Script>

    <fx:Declarations>
        <s:RadioButtonGroup id="cardtype"
            itemClick="handleCard(event);"/>
    </fx:Declarations>

    <s:VGroup>
        <s:RadioButton group="{cardtype}"
            id="americanExpress"
            value="AmEx"
            label="American Express"
            width="150"/>
        <s:RadioButton group="{cardtype}"
            id="masterCard"
            value="MC"
            label="MasterCard"
            width="150"/>
        <s:RadioButton group="{cardtype}"
            id="visa"
            value="Visa"
            label="Visa"
            width="150"/>
    </s:VGroup>
</s:Application>
```

In the `itemClick` event listener, the `selectedValue` property of the RadioButtonGroup control in the event object is set to the value of the `value` property of the selected RadioButton control. If you omit the `value` property, Flex sets the `selectedValue` property to the value of the `label` property.

You can still define a `click` event listener for the individual buttons, even though you also define one for the group.

RadioButton user interaction

If a RadioButton control is enabled, when the user moves the pointer over an deselected RadioButton control, the button displays its rollover appearance. When the user clicks an deselected RadioButton control, the input focus moves to the control and the button displays its false pressed appearance. When the mouse button is released, the button displays the true state appearance. The previously selected RadioButton control in the group returns to its false state appearance.

If the user moves the pointer off the RadioButton control while pressing the mouse button, the control's appearance returns to the false pressed state. The control retains input focus.

If a RadioButton control is not enabled, the RadioButton control and RadioButton group display the disabled appearance, regardless of user interaction. In the disabled state, all mouse or keyboard interaction is ignored.

The RadioButton and RadioButtonGroup controls have the following keyboard navigation features:

Key	Action
Control+arrow keys	Move focus among the buttons without selecting a button.
Spacebar	Select a button.

HScrollBar and VScrollBar controls

The HScrollBar and VScrollBar controls are part of both the MX and Spark component sets. While you can use the MX controls in your application, Adobe recommends that you use the Spark controls instead.

The VScrollBar (vertical ScrollBar) control and HScrollBar (horizontal ScrollBar) controls let the user control the portion of data that is displayed when there is too much data to fit in the display area.

Although you can use the VScrollBar control and HScrollBar control as stand-alone controls, they are usually combined with other components as part of a custom component to provide scrolling functionality.

Scrollbar controls consists of four parts: two arrow buttons, a track, and a thumb. The position of the thumb and display of the buttons depends on the current state of the control. The width of the control is equal to the largest width of its subcomponents (arrow buttons, track, and thumb). Every subcomponent is centered in the scroll bar.

The ScrollBarBase control uses four parameters to calculate its display state:

- Minimum range value
- Maximum range value
- Current position value; must be within the minimum and maximum range values
- Viewport size; represents the number of items in the range that can be displayed at once and must be equal to or less than the range

For more information on using these controls with Spark containers, see "Scrolling Spark containers" on page 338.

Creating a scrollbar control

Define a scrollbar control in MXML by using the `<s:VScrollBar>` tag for a vertical scrollbar or the `<s:HScrollBar>` tag for a horizontal scrollbar, as the following example shows. Specify an `id` value if you intend to refer to a component elsewhere in your MXML, either in another tag or in an ActionScript block.

```
<?xml version="1.0"?>
<!-- controls\bar\SBarSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
     <fx:Script>
        <![CDATA[

            import mx.events.ScrollEvent;

            // Event handler function to display the scroll location.
            private function myScroll():void {
                showPosition.text = "VScrollBar properties summary:" + '\n' +
                    "------------------------------------" + '\n' +
                    "Current scroll position: " +
                    bar.value  + '\n' +
                    "The maximum scroll position: " +
                    bar.maximum + '\n' +
                    "The minimum scroll position: " +
                    bar.minimum;
            }
        ]]>
    </fx:Script>
    <s:VGroup>
        <s:Label
            width="100%"
            text="Click on the ScrollBar control to view its properties."/>

    <s:VScrollBar id="bar"
                   height="100%"
                   minimum="0"
                   maximum="{this.width - 20}"
                   stepSize="50"
                   pageSize="100"
                   repeatDelay="1000"
                   repeatInterval="500"
                   change="myScroll();"/>

    <s:TextArea id="showPosition"
                 height="100%"
                 width="100%" />
    </s:VGroup>
</s:Application>
```

Sizing a scrollbar control

The scrollbar control does not display correctly if it is sized smaller than the height of the Up arrow and Down arrow buttons. There is no error checking for this condition. Adobe recommends that you hide the scrollbar control in such a condition. If there is not enough room for the thumb, the thumb is made invisible.

User interaction

Use the mouse to click the various portions of the scrollbar control, which dispatches events to listeners. The object listening to the scrollbar control is responsible for updating the portion of data displayed. The scrollbar control updates itself to represent the new state after the action has taken place.

Scroller control

The Scroller control is part of the Spark component set. There is no MX equivalent.

The Scroller control contains a pair of scroll bars and a viewport. A viewport displays a rectangular subset of the area of a component, rather than displaying the entire component. You can use the Scroller control to make any container that implements the IViewport interface, such as Group, scrollable.

The scroll bars control the viewport's vertical and horizontal scroll position. They reflect the viewport's actual size and content size. Scroll bars are displayed according to the Scroller's vertical and horizontal scroll policy properties. By default, the policy is set to `"auto"`. This value indicates that scroll bars are displayed when the content within a viewport is larger than the actual size of the viewport.

For more information on using this control with Spark containers, see “Scrolling Spark containers” on page 338.

Creating a Scroller control

You define a Scroller control in MXML by using the `<s:Scroller>` tag. Specify an `id` value if you intend to refer to a component elsewhere in your MXML, either in another tag or in an ActionScript block.

In the following example, the Group container `myGroup` is the viewport for this scroller. The content in the viewport is the loaded image. The layout of the application is controlled by the VGroup container.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- controls\Scroller\ScrollerImage.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    width="450" height="450">
    <s:VGroup paddingLeft="10" paddingTop="10">
        <s:Scroller width="400" height="400">
            <s:Group id="myGroup" >
                <s:Image id="loader1"
                          source="@Embed(source='../assets/strawberries.jpg')"/>
            </s:Group>
        </s:Scroller>
        <s:Label
            fontSize="14" fontFamily="Arial"
            text= "Scroll to see fresh summer strawberries"/>
    </s:VGroup>
</s:Application>
```

Sizing a Scroller control

You can size the width and height of the Scroller control directly or size the viewport container. The VScrollBar and HScrollBar classes bind to the viewport's scroll position and actual and content sizes.

Skinning a Scroller control

The Scroller skin provides scroll bars and manages layout according to the verticalScrollPolicy and horizontalScrollPolicy properties in the Scroller class.

The Scroller skin layout cannot be changed because it must handle the vertical and horizontal scroll policies. Scroller skins can only provide replacement scroll bars.

Spinner control

The Spinner control is part of the Spark component set. There is no MX equivalent.

The Spinner control lets users step through an allowed set of values and select a value by clicking up or down buttons. It is a base class for the NumericStepper control. You could use Spinner to create controls with a different input or display than the standard text input field used in NumericStepper. Another possibility is to use a Spinner control to control tabs or a menu by assigning different values to tabs or menu items.

Creating a Spinner control

You define a Spinner control in MXML by using the `<s:Spinner>` tag. Specify an `id` value if you intend to refer to a component elsewhere in your MXML, either in another tag or in an ActionScript block.

The following example shows a Spinner control that allows wrapping back to the minimum value once the maximum value is reached. The `allowValueWrap` property is false by default. The `snapInterval` property is set to 2. When you click the up (or increment) button for the first time, the value of the Spinner control is set to 4.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- \controls\spinner\SpinnerSimple.mxml-->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
               xmlns:s="library://ns.adobe.com/flex/spark"
               xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
            private function onClickHandler(event:Event):void {
                message.text += "You selected "+ mySpinner.value + "\n";
                }
        ]]>
    </fx:Script>

    <s:VGroup paddingTop="10" paddingLeft="10">
        <s:HGroup>
            <s:Label text="Use the arrows to change value"/>
            <s:Spinner id="mySpinner"
                       click="onClickHandler(event);"
                       minimum="2"
                       maximum="20"
                       snapInterval="2"
                       allowValueWrap="true"/>
        </s:HGroup>
        <s:TextArea id="message"/>
    </s:VGroup>
</s:Application>
```

SWFLoader control

The SWFLoader control is part of the MX component set. There is no Spark equivalent of this control.

The SWFLoader control lets you load one Flex application into another Flex application as a SWF file. It has properties that let you scale its contents. It can also resize itself to fit the size of its contents. By default, content is scaled to fit the size of the SWFLoader control. The SWFLoader control can also load content on demand programmatically, and monitor the progress of a load operation.

When loading an applications into a main application, you should be aware of the following factors:

Versioning SWF files produced with earlier versions of Flex or ActionScript may not work properly when loaded with the SWFLoader control. You can use the `loadForCompatibility` property of the SWFLoader control to ensure that applications loaded into a main application works, even if the applications were compiled with a different version of the compiler.

Security When loading applications, especially ones that were created by a third-party, you should consider loading them into their own SecurityDomain. While this places additional limitations on the level of interoperability between the main application and the application, it ensures that the content is safe from attack.

For more information about creating and loading applications, see “Developing and loading sub-applications” on page 176.

The SWFLoader control also lets you load the contents of a GIF, JPEG, PNG, SVG, or SWF file into your application, where the SWF file does not contain a Flex application, or a ByteArray representing a SWF, GIF, JPEG, or PNG.

For more information, see “Image control” on page 676. For more information on using the SWFLoader control to load a Flex application, see “Externalizing application classes” on page 719.

***Note:** Flex also includes the Image control for loading GIF, JPEG, PNG, SVG, or SWF files. You typically use the Image control for loading static graphic files and SWF files, and use the SWFLoader control for loading Flex applications as SWF files. The Image control is also designed to be used in custom cell renderers and item editors.*

A SWFLoader control cannot receive focus. However, content loaded into the SWFLoader control can accept focus and have its own focus interactions.

Creating a SWFLoader control

You define a SWFLoader control in MXML by using the `<mx:SWFLoader>` tag, as the following example shows. Specify an `id` value if you intend to refer to a component elsewhere in your MXML, either in another tag or in an ActionScript block:

```
<?xml version="1.0"?>
<!-- controls\swfloader\SWFLoaderSimple.mxml-->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:VGroup>
        <mx:SWFLoader id="loader1" source="FlexApp.swf"/>
    </s:VGroup>

</s:Application>
```

Like the Image control, you can also use the Embed statement with the SWFLoader control to embed the image in your application, as the following example shows:

```
<?xml version="1.0"?>
<!-- controls\swfloader\SWFLoaderSimpleEmbed.mxml-->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <mx:SWFLoader id="loader1" source="@Embed(source='FlexApp.swf')"/>

</s:Application>
```

When using the SWFLoader control with an SVG file, you can only load it by using an Embed statement; you cannot load an SVG file at run time. For more information about embedding resources, see the description for the Image control at “Image control” on page 676, and “Embedding assets” on page 1699.

This technique works well with SWF files that add graphics or animations to an application but are not intended to have a large amount of user interaction. If you import SWF files that require a large amount of user interaction, you should build them as custom components.

Interacting with a loaded Flex application

The following example, in the file FlexApp.mxml, shows a simple Flex application that defines two Label controls, a variable, and a method to modify the variable:

```
<?xml version="1.0"?>
<!-- controls\swfloader\FlexApp.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    height="100" width="200">
    <fx:Script>
        <![CDATA[
            [Bindable]
            public var varOne:String = "This is a public variable.";
            public function setVarOne(newText:String):void {
                varOne=newText;
            }
        ]]>
    </fx:Script>
    <s:VGroup>
        <s:Label id="lblOne" text="I am here."/>
        <s:Label text="{varOne}"/>
        <s:Button label="Nested Button" click="setVarOne('Nested button pressed.');"/>
    </s:VGroup>
</s:Application>
```

You compile this example into the file FlexApp.SWF, and then use the SWFLoader control to load it into another Flex application, as the following example shows:

```
<?xml version="1.0"?>
<!-- controls\swfloader\SWFLoaderInteract.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    backgroundColor="gray"
    height="200">
    <fx:Script>
        <![CDATA[
            import mx.managers.SystemManager;

            [Bindable]
            public var loadedSM:SystemManager;
            // Initialize variables with information from
            // the loaded application.
            private function initNestedAppProps():void {
                loadedSM = SystemManager(myLoader.content);

                // Enable the buttons after the application loads.
                b1.enabled = true;
                b2.enabled = true;
                b3.enabled = true;
            }
            // Update the Label control in the outer application
            // from the Label control in the loaded application.
            public function updateLabel():void {
                lbl.text=loadedSM.application["lblOne"].text;
            }
            // Write to the Label control in the loaded application.
            public function updateNestedLabels():void {
                loadedSM.application["lblOne"].text = "I was just updated.";
                loadedSM.application["varOne"] = "I was just updated.";
            }

            // Write to the varOne variable in the loaded application
            // using the setVarOne() method of the loaded application.
            public function updateNestedVarOne():void {
                loadedSM.application["setVarOne"]("Updated varOne!");
            }
        ]]>
    </fx:Script>
    <s:VGroup>
        <s:Label id="lbl"/>
        <mx:SWFLoader id="myLoader" width="300"
            source="FlexApp.swf"
            complete="initNestedAppProps();"/>
        <s:Button id="b1" label="Update Label Control in Outer Application"
            click="updateLabel();"
            enabled="false"/>
        <s:Button id="b2" label="Update Nested Controls"
            click="updateNestedLabels();"
            enabled="false"/>
        <s:Button id="b3" label="Update Nested varOne"
            click="updateNestedVarOne();"
            enabled="false"/>
    </s:VGroup>
</s:Application>
```

In this example, the FlexApp.swf file is in the same directory as the main application. Modify the path to the file appropriately for your application.

Notice that this application loads the SWF file at run time; it does not embed it. For information on embedding a Flex application by using the SWFLoader tag, see “Embedding assets” on page 1699.

You use the `complete` event of the SWFLoader control to initialize a variable with a reference to the SystemManager object for the loaded Flex application.

When a user clicks the first Button control in the outer application, Flex copies the text from the Label control in the loaded application to the Label control in the outer application.

When a user clicks the second Button control, Flex writes the text to the Label control and to the *varOne* variable defined in the loaded application.

When a user clicks the third Button control, the *setVarOne()* method of the loaded application writes to the *varOne* variable defined in the loaded application.

Note: *When working with loaded SWF files, consider using modules rather than the SWFLoader control. For more information on creating modular applications, see “Modular applications” on page 138.*

The level of interoperability between a main application and a loaded application depends on the type of loaded application:

Sandboxed Sandboxed applications are loaded into their own security domains, and can be multi-versioned. Using sandboxed applications is the recommended practice for third-party applications. In addition, if your loaded applications use RPC or DataServices-related functionality, you should load them as sandboxed. For more information, see “Developing sandboxed applications” on page 205.

Multi-versioned Multi-versioned applications are those that can be compiled with different versions of the Flex framework than the main application that loads them. Their interoperability with the main application and other loaded applications is more limited than single-versioned applications. For more information, see "Developing multi-versioned applications" on page 213.

Single-versioned Single-versioned applications are applications that are guaranteed to have been compiled with the same version of the compiler as the main application. They have the greatest level of interoperability with the main application, but they also require that you have complete control over the source of the loaded applications. For more information, see "Creating and loading sub-applications" on page 191.

Externalizing application classes

To reduce the size of the applications that you load by using the SWFLoader control, you can instruct the loaded application to externalize framework classes that are also included by the loading application. The result is that the loaded application is smaller because it only includes the classes it requires, while the framework code and other dependencies are included in the loading application.

To externalize framework classes, you generate a linker report from the loading application by using `link-report` option to the mxmlc command. You then use the `load-externs` option to the mxmlc compiler to specify this report when you compile the loaded application.

Externalize framework classes

1 Generate the linker report for the loading application:

```
mxmlc -link-report=report.xml MyApplication.mxml
```

2 Compile the loaded application by using the link report:

```
mxmlc -load-externs=report.xml MyLoadedApplication.mxml
```

3 Compile the loading application:

```
mxmlc MyApplication.mxml
```

***Note:** If you externalize the loaded application's dependencies by using the `load-externs` option, your loaded application might not be compatible with future versions of Adobe Flex. Therefore, you might be required to recompile the application. To ensure that a future Flex application can load your application, compile that module with all the classes it requires.*

For more information, see "Flex compilers" on page 2164.

Sizing a SWFLoader control

You use the SWFLoader control's `scaleContent` property to control the sizing behavior of the SWFLoader control. When the `scaleContent` property is set to `true`, Flex scales the content to fit within the bounds of the control. However, images will still retain their aspect ratio by default.

Styling loaded applications

When you use the SWFLoader control to load a loaded application, the loaded application uses the same rules for applying styles as modules.

For more information, see "Using styles with modules" on page 143.

MX TabBar control

The TabBar control is part of both the MX and Spark component sets. While you can still use the MX control in your application, Adobe recommends that you use the Spark control instead. For information on Spark TabBar, see "Spark ButtonBar and TabBar controls" on page 529.

A TabBar control defines a horizontal or vertical row of tabs. The following shows an example of a TabBar control:

As with the LinkBar control, you can use a TabBar control to control the active child container of a ViewStack container. The syntax for using a TabBar control to control the active child of a ViewStack container is the same as for a LinkBar control. For an example, see "MX ViewStack navigator container" on page 630.

While a TabBar control is similar to a TabNavigator container, it does not have any children. For example, you use the tabs of a TabNavigator container to select its visible child container. You can use a TabBar control to set the visible contents of a single container to make that container's children visible or invisible based on the selected tab.

Creating an MX TabBar control

You use the `<mx:TabBar>` tag to define a TabBar control in MXML. Specify an `id` value if you intend to refer to a component elsewhere in your MXML, either in another tag or in an ActionScript block.

You specify the data for the TabBar control by using the `<mx:dataProvider>` child tag of the `<mx:TabBar>` tag. The `<mx:dataProvider>` tag lets you specify data in several different ways. In the simplest case for creating a TabBar control, you use the `<mx:dataProvider>` and `<fx:String>` tags to specify the text for each tab, as the following example shows:

```
<?xml version="1.0"?>
<!-- controls\bar\TBarSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <mx:TabBar>
        <mx:dataProvider>
            <fx:String>Alabama</fx:String>
            <fx:String>Alaska</fx:String>
            <fx:String>Arkansas</fx:String>
        </mx:dataProvider>
    </mx:TabBar>
</s:Application>
```

The `<fx:String>` tags define the text for each tab in the TabBar control.

You can also use the `<fx:Object>` tag to define the entries as an array of objects, where each object contains a `label` property and an associated data value, as the following example shows:

```
<?xml version="1.0"?>
<!-- controls\bar\TBarObject.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <mx:TabBar>
        <mx:dataProvider>
            <fx:Object label="Alabama" data="Montgomery"/>
            <fx:Object label="Alaska" data="Juneau"/>
            <fx:Object label="Arkansas" data="Little Rock"/>
        </mx:dataProvider>
    </mx:TabBar>
</s:Application>
```

The `label` property contains the state name and the `data` property contains the name of its capital. The `data` property lets you associate a data value with the text label. For example, the `label` text could be the name of a color, and the associated data value could be the numeric representation of that color.

By default, Flex uses the value of the `label` property to define the tab text. If the object does not contain a `label` property, you can use the `labelField` property of the TabBar control to specify the property name containing the tab text, as the following example shows:

```
<?xml version="1.0"?>
<!-- controls\bar\TBarLabel.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <mx:TabBar labelField="state">
        <mx:dataProvider>
            <fx:Object state="Alabama" data="Montgomery"/>
            <fx:Object state="Alaska" data="Juneau"/>
            <fx:Object state="Arkansas" data="Little Rock"/>
        </mx:dataProvider>
    </mx:TabBar>
</s:Application>
```

Passing data to an MX TabBar control

Flex lets you populate a TabBar control from an ActionScript variable definition or from a Flex data model. When you use a variable, you can define it to contain one of the following:

- A label (string)
- A label (string) paired with data (scalar value or object)

The following example populates a TabBar control from a variable:

```
<?xml version="1.0"?>
<!-- controls\bar\TBarVar.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;

            [Bindable]
            private var STATE_ARRAY:ArrayCollection = new ArrayCollection([
                {label:"Alabama", data:"Montgomery"},
                {label:"Alaska", data:"Juneau"},
                {label:"Arkansas", data:"LittleRock"}
            ]);
        ]]>
    </fx:Script>
    <mx:TabBar >
        <mx:dataProvider>
            {STATE_ARRAY}
        </mx:dataProvider>
    </mx:TabBar>
</s:Application>
```

You can also bind a Flex data model to the `dataProvider` property. For more information on using data models, see "Storing data" on page 889.

Handling MX TabBar control events

The TabBar control defines an item`Click` event that is broadcast when a user selects a tab. The event object contains the following properties:

- `label` String containing the label of the selected tab.
- `index` Number containing the index of the selected tab. Indexes are numbered from 0 to *n* - 1, where *n* is the total number of tabs. The default value is 0, corresponding to the first tab.

The following example code shows a handler for the `itemClick` event for this TabBar control:

```
<?xml version="1.0"?>
<!-- controls\bar\TBarEvent.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
            import mx.events.ItemClickEvent;
            import mx.controls.TabBar;
            import mx.collections.ArrayCollection;

            [Bindable]
            private var STATE_ARRAY:ArrayCollection = new ArrayCollection([
                {label:"Alabama", data:"Montgomery"},
                {label:"Alaska", data:"Juneau"},
                {label:"Arkansas", data:"LittleRock"}
            ]);
            private function clickEvt(event:ItemClickEvent):void {
                // Access target TabBar control.
                var targetComp:TabBar = TabBar(event.currentTarget);
                forClick.text="label is: " + event.label + "\nindex is: " +
                    event.index + "\ncapital is: " +
                    targetComp.dataProvider[event.index].data;
            }
        ]]>
    </fx:Script>
    <s:VGroup>
        <mx:TabBar id="myTB" itemClick="clickEvt(event);">
            <mx:dataProvider>
                {STATE_ARRAY}
            </mx:dataProvider>
        </mx:TabBar>

        <s:TextArea id="forClick" width="250" height="100"/>
    </s:VGroup>
</s:Application>
```

In this example, every `itemClick` event updates the TextArea control with the tab label, selected index, and the selected data from the TabBar control's `dataProvider` Array.

MX VideoDisplay control

The VideoDisplay control is part of both the MX and Spark component sets. While you can still use the MX control in your application, Adobe recommends that you use the Spark control instead. Continue to use the MX VideoDisplay control to work with cue points or stream live video from a local camera using the `attachCamera()` method of the Camera class.

Flex supports the VideoDisplay control to incorporate streaming media into Flex applications. Flex supports the Flash Video File (FLV) file format with this control.

Using media in Flex

Media, such as movie and audio clips, are used more and more to provide information to web users. As a result, you need to provide users with a way to stream the media, and then control it. The following examples are usage scenarios for media controls:

- Showing a video message from the CEO of your company
- Streaming movies or movie previews
- Streaming songs or song snippets
- Providing learning material in the form of media

The streaming VideoDisplay control makes it easy to incorporate streaming media into Flash presentations. Flex supports the Flash Video File (FLV) file format with this control. You can use this control with video and audio data. When you use the VideoDisplay control by itself, your application provides no mechanism for its users to control the media files.

***Note:** The VideoDisplay control does not support scan forward and scan backward functionality. Also, the VideoDisplay control does not support accessibility or styles.*

About the MX VideoDisplay control

Flex creates an MX VideoDisplay control with no visible user interface. It is simply a control to hold and play media.

***Note:** The user cannot see anything unless some video media is playing.*

The `playheadTime` property of the control holds the current position of the playhead in the video file, measured in seconds. Most events dispatched by the control include the playhead position in the associated event object. One use of the playhead position is to dispatch an event when the video file reaches a specific position. For more information, see “Adding a cue point to the MX VideoDisplay control” on page 725.

The VideoDisplay control also supports the `volume` property. This property takes a value from 0.0 to 1.00; 0.0 is mute and 1.00 is the maximum volume. The default value is 0.75.

Setting the size of the MX VideoDisplay control

The appearance of any video media playing in a VideoDisplay control is affected by the following properties:

- `maintainAspectRatio`
- `height`
- `width`

When you set `maintainAspectRatio` to `true` (the default), the control adjusts the size of the playing media after the control size has been set. The size of the media is set to maintain its aspect ratio.

If you omit both `width` and `height` properties for the control, Flex makes the control the size of the playing media. If you specify only one property, and the `maintainAspectRatio` property is `false`, the size of the playing media determines the value of the other property. If the `maintainAspectRatio` property is `true`, the media retains its aspect ratio when resizing.

The following example creates a VideoDisplay control:

```
<?xml version="1.0"?>
<!-- controls\videodisplay\VideoDisplaySimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <mx:VBox>
        <mx:VideoDisplay
            source="../assets/MyVideo.flv"
            height="250"
            width="250"
        />
    </mx:VBox>
</s:Application>
```

By default, Flex sizes the VideoDisplay control to the size of the media. If you specify the `width` or `height` property of the control, and either is smaller than the media's dimensions, Flex does not change the size of the component. Instead, Flex sizes the media to fit within the component. If the control's playback area is smaller than the default size of the media, Flex shrinks the media to fit inside the control.

Using methods of the MX VideoDisplay control

You can use the following methods of the VideoDisplay control in your application: `close()`, `load()`, `pause()`, `play()`, and `stop()`. The following example uses the `pause()` and `play()` methods in event listener for two Button controls to pause or play an FLV file:

```
<?xml version="1.0"?>
<!-- controls\videodisplay\VideoDisplayStopPlay.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    creationComplete="myVid.pause();">
    <mx:VBox>
        <mx:VideoDisplay id="myVid"
            source="../assets/MyVideo.flv"
            height="250"
            width="250"
        />
        <mx:HBox>
            <mx:Button label="||" click="myVid.pause();"/>
            <mx:Button label="&gt;" click="myVid.play();"/>
        </mx:HBox>
    </mx:VBox>
</s:Application>
```

Adding a cue point to the MX VideoDisplay control

You can use cue points to trigger events when the playback of your media reaches a specified location. To use cue points, you set the `cuePointManagerClass` property to mx.controls.videoClasses.CuePointManager to enable cue point management, and then pass an Array of cue points to the `cuePoints` property of the VideoDisplay control. Each element of the Array contains two fields. The `name` field contains an arbitrary name of the cue point. The `time` field contains the playhead location, in seconds, of the VideoDisplay control with which the cue point is associated.

When the playhead of the VideoDisplay control reaches a cue point, it dispatches a `cuePoint` event, as the following example shows:

```
<?xml version="1.0"?>
<!-- controls\videodisplay\VideoDisplayCP.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    height="450"
    creationComplete="myVid.pause();">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import mx.events.CuePointEvent;
            import mx.controls.videoClasses.CuePointManager;
            private function cpHandler(event:CuePointEvent):void {
                cp.text+="Got to " + event.cuePointName + " cuepoint @ " +
                    String(event.cuePointTime) + " seconds in.\n";
            }
        ]]>
    </fx:Script>
    <mx:VBox>
        <mx:VideoDisplay id="myVid"
            source="../assets/MyVideo.flv"
            cuePointManagerClass="mx.controls.videoClasses.CuePointManager"
            cuePoint="cpHandler(event);"
            height="250"
            width="250"
        >
            <mx:cuePoints>
                <fx:Object name="first" time="5"/>
                <fx:Object name="second" time="10"/>
            </mx:cuePoints>
        </mx:VideoDisplay>
        <mx:Label text="{myVid.playheadTime}"/>
        <mx:TextArea id="cp" height="100" width="250"/>
    </mx:VBox>
    <mx:HBox>
        <mx:Button label="||" click="myVid.pause();"/>
        <mx:Button label="&gt;" click="myVid.play();"/>
    </mx:HBox>
</s:Application>
```

In this example, the event listener writes a String to the TextArea control when the control reaches a cue point. The String contains the name and time of the cue point.

Adding a cue point by using the CuePointManager class

You can set cue points for the VideoDisplay control by using the `cuePointManager` property. This property is of type CuePointManager, where the CuePointManager class defines methods that you use to programmatically manipulate cue points, as the following example shows:

```
<?xml version="1.0"?>
<!-- controls\videodisplay\VideoDisplayCPManager.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    height="450"
    creationComplete="myVid.pause();">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            import mx.events.CuePointEvent;
            [Bindable]
            private var myCuePoints:Array = [
                { name: "first", time: 5},
                { name: "second", time: 10}
            ];

            // Set cue points using methods of the CuePointManager class.
            private function initCP():void {
                myVid.cuePointManager.setCuePoints(myCuePoints);
            }
            private var currentCP:Object=new Object();
            private function cpHandler(event:CuePointEvent):void {
                cp.text += "Got to " + event.cuePointName + " cuepoint @ " +
                    String(event.cuePointTime) + " seconds in.\n";
                // Remove cue point.
                currentCP.name=event.cuePointName;
                currentCP.time=event.cuePointTime;
                myVid.cuePointManager.removeCuePoint(currentCP);
                // Display the number of remaining cue points.
                cp.text += "# cue points remaining: " +
                    String(myVid.cuePointManager.getCuePoints().length) + ".\n";
            }
        ]]>
    </fx:Script>
    <mx:VBox>
        <mx:VideoDisplay id="myVid"
            cuePointManagerClass="mx.controls.videoClasses.CuePointManager"
            source="../assets/MyVideo.flv"
            cuePoint="cpHandler(event);"
            height="250"
            width="250"
        />
        <mx:Label text="{myVid.playheadTime}"/>
        <mx:TextArea id="cp" height="100" width="250"/>
    </mx:VBox>
    <mx:HBox>
        <mx:Button label="&gt;" click="cp.text='';initCP();myVid.play();"/>
    </mx:HBox>
</s:Application>
```

Streaming video from a camera to the MX VideoDisplay control

You can use the `VideoDisplay.attachCamera()` method to configure the control to display a video stream from a camera, as the following example shows:

```
<?xml version="1.0"?>
<!-- controls\videodisplay\VideoDisplayCamera.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[

            // Define a variable of type Camera.
            import flash.media.Camera;
            public var cam:Camera;
            public function initCamera():void {
                // Initialize the variable.
                cam = Camera.getCamera();
                myVid.attachCamera(cam)
            }
        ]]>
    </fx:Script>

    <mx:VideoDisplay id="myVid"
        width="320" height="240"
        creationComplete="initCamera();"/>
</s:Application>
```

In this example, you create a Camera object in the event handler for the `creationComplete` event of the VideoDisplay control, then pass the Camera object as the argument to the `attachCamera()` method.

Using the MX VideoDisplay control with Flash Media Server

You can use the VideoDisplay control to play a media stream from Adobe® Flash® Media Server, without needing to register the Flex application with the server. The following code shows a simple example that uses the video-on-demand (vod) service that is available in Flash Media Server 3.5 and later:

```
<?xml version="1.0"?>
<!-- controls\videodisplay\VideoDisplayFMS.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:HorizontalLayout/>
    </s:layout>

    <s:Label text="RTMP FMS 3.5"/>
    <mx:VideoDisplay
            source="rtmp://fmsexamples.adobe.com/vod/edge_codeJam.flv"/>
</s:Application>
```

Spark VideoPlayer and VideoDisplay controls

The VideoPlayer control lets you play progressively downloaded or streaming video. It supports multi-bit rate streaming and live video when used with a server that supports these features, such as Flash Media Server 3.5 or later.

The VideoPlayer control contains a full UI to let users control playback of video. It contains a play/pause toggle button; a scrub bar to let users seek through video; a volume bar; a timer; and a button to toggle in and out of fullscreen mode.

Flex also offers the Spark VideoDisplay control, which plays video without any chrome, skin, or UI. The Spark VideoDisplay has the same methods and properties as the Spark VideoPlayer control. It is useful when you do not want the user to interact with the control, or when you want to fully customize the interactivity but not reskin the VideoPlayer control.

Both VideoPlayer and VideoDisplay support playback of FLV and F4V file formats, as well as MP4-based container formats.

About OSMF

The underlying implementation of the Spark VideoDisplay and VideoPlayer classes rely on the Open Source Media Framework (OSMF) classes.

You can use the OSMF classes to extend the VideoPlayer and VideoDisplay classes. For example, you can use OSMF to incorporate advertising, reporting, cue points, and DVR functionality.

You can also use OSMF classes to implement your own player. For an example of this, see OSMF + Flex Example.

For more information about OSMF, see Open Source Media Framework

Spark VideoPlayer events

The VideoPlayer control dispatches several different types of events that you can use to monitor and control playback. The event objects associated with each event dispatched by the VideoPlayer control is defined by a class in the org.osmf.events.* package.

The following example handles the `complete` and `mediaPlayerStateChange` events dispatched by the VideoPlayer control:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- controls\videoplayer\VideoPlayerEvent.mxml-->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            import org.osmf.events.MediaPlayerStateChangeEvent;
            import org.osmf.events.TimeEvent;
            protected function vpCompleteHandler(event:TimeEvent):void {
                myTA.text = "Video complete - restarting."
            }
            protected function
vpMediaPlayerStateChangeHandler(event:MediaPlayerStateChangeEvent):void {
                if (event.state == "loading")
                    myTA.text = "loading ...";
                if (event.state == "playing")
                    myTA.text = "playing ...";
            }
        ]]>
    </fx:Script>

    <s:VideoPlayer
        source="rtmp://fmsexamples.adobe.com/vod/mp4:_cs4promo_1000.f4v"
        width="350" height="250"
        loop="true"
        complete="vpCompleteHandler(event);"
        mediaPlayerStateChange="vpMediaPlayerStateChangeHandler(event);"/>
    <s:TextArea id="myTA" width="350" height="25"/>
</s:Application>
```

The VideoPlayer control dispatches the `complete` event when the video completes. The event object for the complete event is of type org.osmf.events.TimeEvent.

The VideoPlayer control dispatches the `mediaPlayerStateChange` event when the state of the control changes. The control has several states, including the `buffering`, `loading`, `playing`, and `ready` states. The event object for the `mediaPlayerStateChange` event is of org.osmf.events.MediaPlayerStateChangeEvent. The event handler for the `mediaPlayerStateChange` event uses the `state` property of the event object to determine the new state of the control.

Setting the video source for the Spark VideoPlayer control

The VideoPlayer component supports playback of local media, streaming media, and progressively downloaded media. You can play back both live and recorded media.

To play back a single media file, use the `source` attribute. The correct value for the `source` attribute is the path to the file. Use the correct syntax in the URL: HTTP for progressive download and RTMP for streaming from Flash Media Server. If using Flash Media Server, use the correct prefixes or extensions.

The following code plays a local FLV file, phone.flv, that resides in the assets folder in the same project folder as the SWF file:

```
<s:VideoPlayer source="assets/phone.flv"/>
```

The following code plays a single F4V file from Flash Media Server, using the video-on-demand service that Flash Media Server 3.5 and later provides. The use of the MP4 prefix and the F4V file extension are required. The MP4 prefix is always required; the F4V file extension is required when the name of the file to be loaded contains a file extension.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- controls\videoplayer\VideoPlayerSimple.mxml-->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <s:VideoPlayer
        source="rtmp://fmsexamples.adobe.com/vod/mp4:_cs4promo_1000.f4v"
        width="350" height="250"
        loop="true"/>
</s:Application>
```

Using dynamic streaming

The Spark VideoPlayer and VideoDisplay components support dynamic streaming (also known as *multi-bitrate streaming* or *adaptive streaming*) for on-demand and live content. To use dynamic streaming, you encode a stream at several different bit rates. During playback, Flash Player dynamically switches among the streams based on connection quality and other metrics to provide the best experience.

You can do dynamic streaming over RTMP and HTTP. On-demand and live dynamic streaming over RTMP require Flash Media Server. RTMP streaming has the following benefits over HTTP streaming:

- RTMPe for lightweight content protection
- RTMP quality of service
- Absolute timecodes
- Enhanced buffering

Live HTTP Dynamic Streaming requires Flash Media Server. On-demand HTTP Dynamic Streaming requires an Apache HTTP Server Origin Module and a File Packager tool. These tools are available as free downloads from http://www.adobe.com/products/httpdynamicstreaming/.

Dynamic streaming over HTTP

To use live and on-demand dynamic streaming over HTTP, point the `source` property of the VideoDisplay or VideoPlayer class to an *.f4m file:

```
<s:VideoPlayer source="http://mysite.com/dynamic_Streaming.f4m" autoPlay="false"/>
```

HTTP Dynamic Streaming is not designed to be used with the DynamicStreamingVideoSource or the DynamicStreamingVideoItem classes. Use those classes to stream media over RTMP with Flash Media Server.

Before your can dynamically stream your video content over HTTP, use the File Packager to package the file. The File Packager converts the media file to fragments and creates an F4M manifest file to point to the pieces of the package. You must also install the Apache HTTP Origin Module on your web server to serve the streams.

For more information about HTTP Dynamic Streaming, see Adobe HTTP Dynamic Streaming.

Dynamic streaming over RTMP

Flash Media Server 3.5 and later supports live and on-demand dynamic streaming over RTMP. To perform dynamic streaming with Flash Media Server, use the DynamicStreamingVideoSource class.

The DynamicStreamingVideoSource object contains multiple stream items, each of which represents the same video stream encoded at a different bitrate.

The following example uses the DynamicStreamingVideoSource object to define streams of different qualities:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- controls\VideoPlayer\VideoPlayerFMS.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx" >
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <s:VideoPlayer id="myPlayer"
        width="500" height="300">
        <s:source>
            <s:DynamicStreamingVideoSource id="mySVS"
                host="rtmp://fmsexamples.adobe.com/vod/">
                <s:DynamicStreamingVideoItem id="dreamgirl150"
                    streamName="MP4:_PS_dreamgirl_150.f4v"
                    bitrate="150" />
                <s:DynamicStreamingVideoItem id="dreamgirl500"
                    streamName="MP4:_PS_dreamgirl_500.f4v"
                    bitrate="500" />
                <s:DynamicStreamingVideoItem id="dreamgirl1000"
                    streamName="MP4:_PS_dreamgirl_1000.f4v"
                    bitrate="1000" />
            </s:DynamicStreamingVideoSource>
        </s:source>
    </s:VideoPlayer>
    <s:TextArea width="500" height="50"
        text="Please wait while the video loads..."/>
</s:Application>
```

Dynamic streaming (Flash Media Server documentation)

Adobe HTTP Dynamic Streaming

Playing back live video with the Spark VideoPlayer control

To play back live video, use a DynamicStreamingVideoSource object and set the `streamType` attribute to `live`:

```
<s:VideoPlayer>
    <s:DynamicStreamingVideoSource host="rtmp://localhost/live/" streamType="live">
        <s:DynamicStreamingVideoItem streamName="myStream.flv"/>
    </s:DynamicStreamingVideoSource>
</s:VideoPlayer>
```

The VideoPlayer is the client application that plays back video. To capture and stream the live video, you can use a tool like Flash Media Live Encoder, which captures and streams live video to Flash Media Server. If you don’t use Flash Media Live Encoder, you’ll need to create a custom publishing application. For information on creating a custom video capture application, see the Flash Media Server documentation.

Setting the size of the Spark VideoPlayer control

The appearance of any video media playing in a VideoPlayer control is affected by the following properties:

- `scaleMode`
- `height`
- `width`

The `scaleMode` property only works when you set the `height` or `width` property. It adjusts the size of the playing media after the control size has been set. Possible values are `none`, `stretch`, `letterbox`, and `zoom`.

If you omit both `width` and `height` properties for the control, Flex sizes the control to fit the size of the playing media. If you specify only one property, and set the `scaleMode` property, the size of the playing media determines the value of the other property. If you do not set the `scaleMode` property, the media retains its aspect ratio when resizing.

If you explicitly set the `width` and `height` properties, be sure the values are appropriate for the size of video that plays.

By default, Flex sizes the VideoPlayer control to the size of the media. If you specify the `width` or `height` property of the control, and either is smaller than the media's dimensions, Flex does not change the size of the component. Instead, Flex sizes the media to fit within the component. If the control's playback area is smaller than the default size of the media, Flex shrinks the media to fit inside the control.

The sample video used here is larger than the specified component size, but the width and height ratio are still appropriate to the video size. If you were to remove the width and height properties from the code, however, you would see that the VideoPlayer component is automatically sized to the size of the video.

Using the Spark VideoDisplay control

The Spark VideoDisplay control is the same as the Spark VideoPlayer control, except that it does not have a UI associated with it. You must manually create controls that perform functions such as play, stop, and pause.

The following example uses a Spark VideoDisplay control, and exposes the `play()` and `pause()` methods with Button controls:

```
<?xml version="1.0"?>
<!-- controls\videodisplay\SparkVideoDisplayStopPlay.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    creationComplete="myVid.pause();">
    <s:VGroup>
        <s:VideoDisplay id="myVid"
            source="../assets/MyVideo.flv"
            height="250"
            width="250"
        />
        <s:HGroup>
            <s:Button label="||" click="myVid.pause();"/>
            <s:Button label="&gt;" click="myVid.play();"/>
        </s:HGroup>
    </s:VGroup>
</s:Application>
```

Spark text controls

Text controls in an Adobe® Flex® application can display text, let the user enter text, or do both.

About the Spark text controls

You use Flex text-based controls to display text and to let users enter text into your application.

The following table lists the primary Flex text-based controls:

Control	Component set	Superclass	Multi Line	Editable	textFlow/text/textDisplay
Label	Spark	UIComponent	Y	N	text
RichEditableText	Spark	UIComponent	Y	Y	textFlow/text
RichText	Spark	UIComponent	Y	N	textFlow/text
TextArea	Spark	UIComponent	Y	Y	textFlow/text
TextInput	Spark	UIComponent	N	Y	text/textDisplay (textFlow)

Comparing Spark and MX text controls

This section describes the Spark text controls. For information on the MX text controls, see “MX text controls” on page 805.

How much control you have over the formatting of the text in the control depends on the type of control. The MX controls support a small set of formatting options with their style properties and the `htmlText` property. The Spark controls support a richer set of formatting options because they are based on Flash Text Engine (FTE) and Text Layout Framework (TLF).

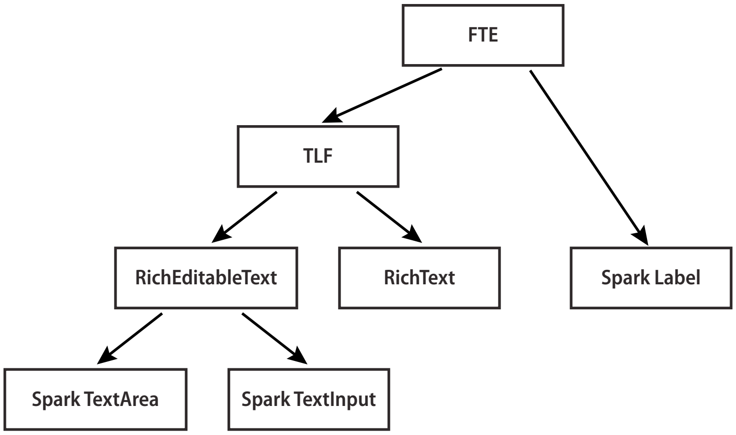
Some MX controls can also use limited functionality of FTE and TLF. For more information, see “Using FTE in MX controls” on page 1594.

When building Flex 4 applications, you should use the Spark text controls where possible. This is especially true if you plan on using TLF or embedded fonts. In some cases, there are both MX and Spark versions of the same text-based control. For example, there are MX and Spark versions of the Label, TextArea, and TextInput controls. The MX versions are in the mx.controls package.*. The Spark versions are in the spark.components.* package.

Spark text control feature overview

The primary Spark controls for displaying text are Label, RichText, and RichEditableText. The Label control has the least amount of functionality, but is also the most lightweight. The RichEditableText control has the most functionality, but also uses the most system resources.

The following image shows the relationship among the Spark text controls and FTE/TLE:



Relationship of the Spark text controls to FTE/TLF

The following table shows more information about these Spark text primitives:

Feature	Spark Label	RichText	RichEditableText
Extends	UIComponent	UIComponent	UIComponent
Uses	FTE	TLF	TLF
Advanced typography	Y	Y	Y
Alpha	Y	Y	Y
Rotation	Y	Y	Y
Bi-directional text	Y	Y	Y
Default formatting with CSS styles	Y	Y	Y
Multiple lines	Y	Y	Y
Multiple formats	N	Y	Y
Multiple paragraphs	N	Y	Y
Text object model	N	Y	Y
Markup language	N	Y	Y
Clickable HTML links	N	N	Y
Inline graphics	N	Y	Y
Hyperlinks	N	N	Y
Scrolling	N	N	Y
Selection	N	N	Y
Editing	N	N	Y

Styling text controls

The default styles for Spark text control are set in CSS. The easiest way to customize your text controls is to use CSS to change style properties. For example, you can adjust the font size and color by using the fontSize and color style properties as the following example shows:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/SimpleStyleExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Style>
        @namespace s "library://ns.adobe.com/flex/spark";
        s|RichText {
            color: #33CC66;
            fontStyle: italic;
            fontSize: 24;
        }
    </fx:Style>

    <s:RichText id="myRET">
        This is the text.
    </s:RichText>
</s:Application>
```

CSS lets you adjust the styles of all controls of a certain type (using a type selector) or any controls that match a certain class (using a class selector).

Spark text controls have a much richer set of style properties than standard CSS because they support TLF. These style properties include paragraph spacing, line spacing, and margins. The following example sets the line height and space after each paragraph:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/AnotherStyleExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Style>
        @namespace s "library://ns.adobe.com/flex/spark";
        s|RichText {
            fontSize: 18;
            lineHeight:16;
            paragraphSpaceAfter: 10;
        }
    </fx:Style>

    <s:RichText id="myRET" width="200">
        <s:p>This is my text. There are many others like it, but this one is mine.</s:p>
        <s:p>My text is my best friend.</s:p>
        <s:p>It is my life. I must master it as I must master my life.</s:p>
        <s:p>Without me, my text is useless.</s:p>
    </s:RichText>
</s:Application>
```

With TLF, you can also manipulate the appearance of text within the TextFlow at compile time or run-time. For more information, see “Styling TLF-based text controls” on page 785.

When styling the TextInput and TextArea controls, you should keep in mind that the text is rendered by a RichEditableText subcomponent. You access properties of this subcomponent with the `textDisplay` property. For more information, see “Subcomponent styles” on page 1527.

Label control

The Label control displays noneditable text. It is the lightest weight of the text controls. The Label control has the following characteristics:

- The user cannot change the text, but the application can modify it.
- You can control the alignment and sizing.
- The control’s background is transparent, so the background of the component’s container shows through.
- The control has no borders, so the label appears as text written directly on its background.
- The control cannot take the focus.
- The control can display multiple lines.
- The control cannot be made selectable.

For complete reference information, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

To create user-editable text fields, use the TextInput or TextArea controls. For more information, see “TextInput control” on page 740 and “TextArea control” on page 737.

Creating a Label control

You define a Label control in MXML by using the `<s:Label>` tag, as the following example shows. Specify an `id` value if you intend to refer to a component elsewhere in your MXML, either in another tag or an ActionScript block.

```
<?xml version="1.0"?>
<!-- sparktextcontrols/SparkLabelControl.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    width="150" height="80">
  <s:Label text="Label1"/>
</s:Application>
```

Sizing a Label control

If you do not specify a width, the Label control automatically resizes when you change the value of the `text` property.

If you explicitly size a Label control so that it is not large enough to accommodate its text, the text is truncated and terminated by an ellipsis (...). The full text displays as a tooltip when you move the mouse over the Label control. If you also set a tooltip by using the `tooltip` property, the tooltip is displayed rather than the text.

TextArea control

The TextArea control is a multiline, editable text field with a border and optional scroll bars. The TextArea control supports the rich text rendering capabilities of Flash Player and AIR. The TextArea control dispatches `change` and `textInput` events.

The TextArea control supports TLF. The text is rendered by a RichEditableText subcomponent that is defined in the TextArea control's skin class.

For complete reference information, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

To create a single-line, editable text field, use the TextInput control. For more information, see "TextInput control" on page 740. To create noneditable text fields, use the Label control. For more information, see "Label control" on page 737.

To change the disabled color for the TextArea control, you must edit the TextAreaSkin class.

You can set a TextArea control's `editable` property to `false` to prevent editing of the text. You can set a TextArea control's `displayAsPassword` property to conceal input text by displaying characters as asterisks.

Creating a TextArea control

You define a TextArea control in MXML by using the `<s:TextArea>` tag, as the following example shows:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/SparkTextAreaControl.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:TextArea id="textConfirm"
        width="300" height="100"
        text="Please enter your thoughts here."/>
</s:Application>
```

Using large amounts of text in the TLF-based TextArea control can cause a degradation in performance. As a result, in some cases, you should use the MX TextArea control. For more information, see "MX TextArea control" on page 827.

Sizing the TextArea control

The TextArea control does not resize to fit the text that it contains.

If the new text exceeds the capacity of a TextArea control and the `horizontalScrollPolicy property` is set to `true` (the default value), the control adds a scrollbar.

Using TLF with the TextArea control

The TextArea control supports the advanced text formatting and manipulation of TLF. You add TLF content to the TextArea control by using either the `textFlow` or `content` properties.

The following example adds a block of TLF-formatted text to the TextArea control:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- sparktextcontrols/TextAreaTLF.mxml -->
<s:Application name="RichEditableTextExample"
        xmlns:fx="http://ns.adobe.com/mxml/2009"
        xmlns:s="library://ns.adobe.com/flex/spark"
        xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:Panel title="TextArea TLF"
            width="90%" height="90%"
            horizontalCenter="0" verticalCenter="0">
            <s:TextArea id="ta1" textAlign="left" percentWidth="90">
                <s:textFlow>
                    <s:TextFlow>
                        <s:p fontSize="24">TextArea with TLF block</s:p>
                       <s:p>1) Lorem ipsum dolor sit amet, consectetur adipiscing elit.</s:p>
                       <s:p>2) Cras posuere posuere sem, <s:span fontWeight="bold">eu congue
orci mattis quis</s:span>.</s:p>
                        <s:p>3) Curabitur <s:span textDecoration="underline">pulvinar
tellus</s:span> venenatis ipsum tempus lobortis.<s:br/>
                          <s:span color="0x6600CC">Vestibulum eros velit</s:span>, bibendum
at aliquet ut.
                        </s:p>
                    </s:TextFlow>
                </s:textFlow>
            </s:TextArea>
    </s:Panel>
</s:Application>
```

For more information about using TLF with Spark text controls, see “Using Text Layout Framework” on page 758.

Styling the TextArea control

The TextArea control uses a RichEditableText control as a subcomponent to render the text. You can set the values of inheritable style properties on the TextArea contorl, and those properties are inherited by the RichEditableText subcomponent.

To access the RichEditableText control, you use the `textDisplay` property. You can access this property to set style properties that are noninheritable; for example, the `columnCount` and `columnGap` properties.

There are some exceptions to noninheritable styles. For example, the `verticalAlign`, `lineBreak`, and `paddingBottom/Left/Right/Top` style properties are noninheritable. You can set these properties, which are defined on the RichEditableText control, directly on the TextArea control because the TextAreaSkin class passes them through to the subcomponent.

The following example sets styles on the RichEditableText subcomponent with the `textDisplay` property, and also sets the values of some noninheriting style properties that are not normally accessible. You must cast the `textDisplay` property as a RichEditableText object before you can call methods such as `setStyle()` on it.

```
<?xml version="1.0"?>
<!-- sparktextcontrols/SparkTextAreaStyles.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    creationComplete="initApp()">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            /*
            Non-inheriting styles you must set on textDisplay:
                columnCount
                columnGap
                columnWidth

            Non-inheriting styles that you can set on TextArea because
            they are passed to the subcomponent through the TextAreaSkin class:
                lineBreak
                paddingTop/Bottom/Left/Right
                verticalAlign
            */

            import spark.components.RichEditableText;

            private function initApp():void {
                RichEditableText(ta1.textDisplay).setStyle("columnCount", 3);
                RichEditableText(ta1.textDisplay).setStyle("columnWidth", 100);
                RichEditableText(ta1.textDisplay).setStyle("columnGap", 15);
            }
        ]]>
    </fx:Script>
    <s:TextArea id="ta1" height="100" width="400" verticalAlign="bottom" paddingBottom="20">
       This is a text area control. Because the text rendering is done by a RichEditableText
subcontrol,
      you have to use the textDisplay property to set the values of some non-inheriting styles.
       Other non-inheriting styles are defined in the skin class and are passed through to the
        subcomponent.
        For inheriting styles, they are inherited by the RichEditableText subcontrol.
    </s:TextArea>
</s:Application>
```

TextInput control

The Spark TextInput control is a single-line text field that is optionally editable. This control supports TLF. The text is rendered by a RichEditableText subcomponent in its skin class.

For complete reference information, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

To create a multiline, editable text field, use a TextArea control. For more information, see “TextArea control” on page 737. To create noneditable text fields, use the Label or RichText controls. For more information, see “Label control” on page 737 and “RichText control” on page 743.

The TextInput control does not include a label, but you can add one by using a Label control or by nesting the TextInput control in a FormItem container in a Form layout container.

To change the disabled color for the Spark TextInput control, you must edit the TextInputSkin class. The following example shows the differences between the enabled and disabled versions of the Spark and MX TextInput controls:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/TextInputDisabledColors.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:VGroup>
        <mx:TextInput enabled="false" text="disabled MX"/>
        <mx:TextInput enabled="true" text="enabled MX"/>
        <s:TextInput enabled="false" text="disabled Spark"/>
        <s:TextInput enabled="true" text="enabled Spark"/>
    </s:VGroup>
</s:Application>
```

You can set a TextInput control's `editable` property to `false` to prevent users from editing the text. You can set a TextInput control's `displayAsPassword` property to conceal the input text by displaying characters as asterisks.

Creating a TextInput control

You define a TextInput control in MXML by using the `<s:TextInput>` tag, as the following example shows. Specify an `id` value if you intend to refer to a control elsewhere in your MXML, either in another tag or in an ActionScript block.

```
<?xml version="1.0"?>
<!-- sparktextcontrols/SparkTextInputControl.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
  <s:TextInput id="text1" width="100"/>
</s:Application>
```

You can use the `text` property to specify a string of raw text in the TextInput control.

Sizing a TextInput control

If you do not specify a width, the TextInput control is automatically sized when the application first completes loading. The size of the TextInput control does not change in response to user input or programmatic text input.

The TextInput control determines the value of its `measuredWidth` property by using a `widthInChars` property rather than measuring the text assigned to it, because the text frequently starts out empty. This property is calculated based on the current font size and style.

The value of its `measuredHeight` property is determined by the height of the current font. If you change the font style or size, then the TextInput control resizes to accomodate the new settings, even if there is no text in the control at the time of the resizing.

Binding to a TextInput control

In some cases, you might want to bind a variable to the `text` property of a TextInput control so that the control represents a variable value, as the following example shows:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/SparkBoundTextInputControl.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
  <fx:Script><![CDATA[
     [Bindable]
     public var myProp:String="This is the initial String myProp.";
  ]]></fx:Script>
  <s:TextInput text="{myProp}"/>
</s:Application>
```

In this example, the TextInput control displays the value of the `myProp` variable. Remember that you must use the `[Bindable]` metadata tag if the variable changes value and the control must track the changed values; also, the compiler generates warnings if you do not use this metadata tag.

Using TLF with the TextInput control

You can use TLF with a TextInput control by accessing the `textDisplay` property and casting it as a RichEditableText object. This property points to the underlying RichEditableText object that renders the text in the TextInput control. The RichEditableText object is a subcomponent that is defined in the TextInput control's skin class.

The following example defines a TextFlow as XML, and assigns that to the TextInput control's `textDisplay`:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/TextInputTLF.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp()">
    <fx:Declarations>
        <fx:XML id="myXML">
            <div>
                <p>Hello <span fontWeight='bold'>world</span>!</p>
            </div>
        </fx:XML>
    </fx:Declarations>
    <fx:Script>
        import spark.utils.TextFlowUtil;
        import spark.components.RichEditableText;
        private function initApp():void {
            RichEditableText(text1.textDisplay).textFlow = TextFlowUtil.importFromXML(myXML);
        }

    </fx:Script>
    <s:TextInput id="text1" width="100"/>
</s:Application>
```

For more information about using TLF with Spark text controls, see "Using Text Layout Framework" on page 758.

RichText control

The RichText control is a middleweight Spark text control. It can display richly-formatted text, with multiple character and paragraph formats. However, it is non-interactive: it does not support hyperlinks, scrolling, selection, or editing. If you want a control that supports formatted text plus scrolling, selection, and editing, you can use the RichEditableText control.

For specifying the text, the RichText control supports the `textFlow`, `text`, and `content` properties. If you set the `text` property, the contents are read in as a String; tags such as `<p>` and `<img>` are ignored. If you set the `textFlow` or `content` properties, then the contents are parsed by TLF and stored as a TextFlow object. Tags such as `<p>` and `<img>` are mapped to instances of the ParagraphElement and InlineGraphicElement classes.

To create a RichText control, you use the `<s:RichText>` tag in MXML, as the following example shows:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/RichTextExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <!-- You can display simple text with the text property. -->
    <s:RichText text="Hello World!"/>
    <!-- Or the text child tag. -->
    <s:RichText>
        <s:text>
            Hello World!
        </s:text>
    </s:RichText>
    <!-- You can display formatted text with the default property. -->
    <s:RichText>
        Hello <s:span fontSize='16'>BIG NEW</s:span> World!
    </s:RichText>
    <!-- Or the TextFlow child tag. -->
    <s:RichText>
        <s:textFlow>
            <s:TextFlow>
                Hello <s:span fontSize='16'>BIG NEW</s:span> World!
            </s:TextFlow>
        </s:textFlow>
    </s:RichText>
</s:Application>
```

The text in a RichText control can be horizontally and vertically aligned but it cannot be scrolled. The contents of the control wraps at the right edge of the control's bounds. If the content extends below the bottom, it is clipped. It is also clipped if you turn off wrapping by setting the `lineBreak` style property to `explicit` and add content that extends past the right edge of the control.

The contents of a RichText control can be exported to XML using the `export()` method, which produces XML. For an example of using the `export()` method, see http://blog.flexexamples.com/2009/07/25/exporting-a-textflow-object-in-flex-4/.

For more information about using TLF with Spark text controls, see "Using Text Layout Framework" on page 758.

RichEditableText control

The RichEditableText is similar to the RichText control in that it can display richly-formatted text, with multiple character and paragraph formats. In addition, the RichEditableText control is interactive: it supports hyperlinks, scrolling, selection, and editing.

The RichEditableText class is similar to the TextArea control, except that it does not have a border, scroll bars, or focus glow.

Creating a RichEditableText control

To create a RichEditableText control in MXML, you use the `<s:RichEditableText>` tag, as the following example shows:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/RichEditableTextExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <s:RichEditableText height="100" width="200">
        <s:text>
            Hello World!
        </s:text>
    </s:RichEditableText>
</s:Application>
```

For specifying the text, the RichEditableText control supports the `textFlow`, `text`, and `content` properties. If you set the `text` property, the contents are read in as a String; tags such as `<p>` and `<img>` are ignored. If you set the `textFlow` or `content` properties, then the contents are parsed by TLF and stored in a TextFlow object. Tags such as `<p>` and `<img>` are mapped to instances of the ParagraphElement and InlineGraphicElement classes.

Inserting and appending text

The RichEditableText control also supports the `insertText()` and `appendText()` methods. These methods let you add text to the contents of the control as if you had typed it. The `insertText()` method either replaces a selection (if there is one) or adds the new text at the current insertion point. The `appendText()` adds the text to the end of the contents. New text added with these methods is not parsed by the TLF parser; it is read in as a literal string.

The `insertText()` method does not insert text unless the RichEditableText control has focus. The `appendText()` appends text even if the RichEditableText control does not have the focus. If the RichEditableText control gets focus by pressing the Tab key, the `insertText()` method inserts the text before any existing text. If the control gets focus by clicking within the control, the text is inserted at the insertion point.

The following example lets you append or insert new text to the RichEditableText control:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/AddTextExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <fx:Script>
    <![CDATA[
        [Bindable]
        private var newText:String = "<p>This is the new text.</p>";

        private function insertNewText():void {
            myRET.insertText(newText);
        }

        private function appendNewText():void {
            myRET.appendText(newText);
        }
      ]]>
  </fx:Script>

    <s:RichEditableText id="myRET" height="100" width="200">
        <s:textFlow>
            <s:TextFlow>
                <s:p>This is paragraph 1.</s:p>
                <s:p>This is paragraph 2.</s:p>
            </s:TextFlow>
        </s:textFlow>
    </s:RichEditableText>
    <s:HGroup>
        <s:Button label="Insert New Text" click="insertNewText()"/>
        <s:Button label="Append New Text" click="appendNewText()"/>
    </s:HGroup>
    <s:Label text="New text to add: '{newText}'"/>
</s:Application>
```

The contents of a RichEditableText control can be exported to XML using the `export()` method, which produces XML. For an example of using the `export()` method, see http://blog.flexexamples.com/2009/07/25/exporting-a-textflow-object-in-flex-4/.

Making content selectable and editable

You can make the content of the RichEditableText control selectable by setting the `selectable` property to `true`. You can make the content of the RichEditableText control editable by setting the `editable` property to `true`.

The following example makes the RichEditableText content both selectable and editable:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/RETEditableAndSelectable.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <s:RichEditableText height="100" width="200"
        editable="true"
        selectable="true">
        <s:text>
            This text is editable and selectable!
        </s:text>
    </s:RichEditableText>
</s:Application>
```

You can read the selection range with the read-only `selectionAnchorPosition` and `selectionActivePosition` properties. You can set the selection with the `selectRange()` method. For examples of using the `selectRange()` method, see "Selecting text" on page 754.

Using the getFormatOfRange() and setFormatOfRange() methods

To determine the text formatting on the selection, use the `getFormatOfRange()` method. This method returns a TextLayoutFormat object. This returns the computed value of every property on the control, including defaults.

You can set the format of the selection with the `setFormatOfRange()` method. In general, you should not use `getFormatOfRange()` method to get the TextLayoutFormat and then set properties on that. This overwrites custom properties you might have already set on the text control with the default values. The following example is not a best practice, as it overwrites any custom properties:

```
var tf:TextLayoutFormat = myTextControl.getFormatOfRange(null,0,0);
tf.fontSize = 16;
tf.fontWeight = FontWeight.BOLD;
myTextControl.setFormatOfRange(tf,0,0);
```

The following example uses the `setFormatOfRange()` method to apply properties without overwriting other custom properties with the defaults:

```
var tf:TextLayoutFormat = new TextLayoutFormat();
tf.fontSize = 16;
tf.fontWeight = FontWeight.BOLD;
myTextControl.setFormatOfRange(tf,0,0);
```

Clipping content

You can clip contents of the RichEditableText control and let users scroll it by setting the `clipAndEnableScrolling` property to `true`, as the following example shows:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/RETClipAndScroll.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:RichEditableText height="100" width="200" clipAndEnableScrolling="true">
        <s:text>
            Hello World!
            Hello World!
            Hello World!
            Hello World!
            Hello World!
            Hello World!
            Hello World!
            Hello World!
            Hello World!
            Hello World!
            Hello World!
            Hello World!
            Hello World!
            Hello World!
            Hello World!
            Hello World!
            Hello World!
            Hello World!
            Hello World!
            Hello World!
            Hello World!
        </s:text>
    </s:RichEditableText>
</s:Application>
```

Adding scrollbars

The RichEditableText control does not add scroll bars for you, even when scrolling and clipping is enabled. To add scroll bars to a RichEditableText control, you can wrap the RichEditableText control in a Scroller class, as the following example shows:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/ScrollableRET.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <s:Scroller>
        <s:RichEditableText height="100" width="200"
            editable="true"
            selectable="true">
            <s:text>
                This text scrolls vertically!
                This text scrolls vertically!
                This text scrolls vertically!
                This text scrolls vertically!
                This text scrolls vertically!
                This text scrolls vertically!
                This text scrolls vertically!
                This text scrolls vertically!
                This text scrolls vertically!
                This text scrolls vertically!
                This text scrolls vertically!
                This text scrolls vertically!
                This text scrolls vertically!
                This text scrolls vertically!
            </s:text>
        </s:RichEditableText>
    </s:Scroller>
    <s:Label text="To enable horizontal scrolling, set lineBreak to explicit:"/>
    <s:Scroller>
        <s:RichEditableText height="100" width="200"
            editable="true"
            selectable="true"
            lineBreak="explicit">
            <s:text>
                This text scrolls horizontally! This text scrolls horizontally! This text 
scrolls horizontally!
                This text scrolls horizontally! This text scrolls horizontally! This text 
scrolls horizontally!
            </s:text>
        </s:RichEditableText>
    </s:Scroller>
</s:Application>
```

The RichEditableText control supports programmatic scrolling with its IViewport interface; it scrolls in response to the mousewheel; and it automatically scrolls as you drag-select or type more text than fits in the control's bounds. The Scroller class lets you put anything that implements the IViewport interface, such as the RichEditableText control, in it to be scrolled.

Selecting ranges

If you select a range of text that is not in the current viewport, you can programmatically scroll to that range by using the `scrollToRange()` method. The following example selects the 10th line and then scrolls to that line when you click the button:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/SelectScrollableRET.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            private function scrollToLine():void {
                myRET.selectRange(440, 471);
                myRET.scrollToRange(440, 471);
            }
        ]]>
    </fx:Script>

    <s:Scroller>
        <s:RichEditableText id="myRET"
            selectionHighlighting="always"
            selectable="true"
            height="100" width="200">
            <s:text>
                This text scrolls vertically1!
                This text scrolls vertically2!
                This text scrolls vertically3!
                This text scrolls vertically4!
                This text scrolls vertically5!
                This text scrolls vertically6!
                This text scrolls vertically7!
                This text scrolls vertically8!
                This text scrolls vertically9!
                This text scrolls vertically10!
                This text scrolls vertically11!
                This text scrolls vertically12!
                This text scrolls vertically13!
                This text scrolls vertically14!
            </s:text>
        </s:RichEditableText>
    </s:Scroller>
    <s:Button label="Select and Scroll to Line 10" click="scrollToLine()"/>
</s:Application>
```

For more information about using TLF with Spark text controls, see “Using Text Layout Framework” on page 758.

Adding content to text controls

The Spark text-based controls let you set and get text by using the following properties:

text Plain text without formatting information. All text based controls support this property. For information on using the `text` property, see “Using the text property” on page 751.

default Setting the default property is the same as using the `textFlow` property, and is less verbose. Tags set in the default property are parsed at compile time, just as any other MXML tag.

textFlow A rich set of tags and TLF formatting. Most Spark text-based controls support this property. You typically use this property if you do not know the contents of the rich text at compile time. For information on using the `textFlow` property, see "Creating TextFlow objects" on page 760.

Typically, if your text does not contain any formatting, use the `text` property. If your text contains formatting, use the `textFlow` or default properties.

You can set formatted text by using the `textFlow` or default properties, and get it back as a plain text string by using the `text` property.

If you set more than one content-related property on a Spark text control in ActionScript (such as `text`*and*`textFlow`), the last one set wins. If you set more than one of these properties as an attribute on an MXML tag, however, the winning setter cannot be predicted. The compiler does not guarantee the order in which MXML attributes get applied to a component.

Using the default property

You can use the default property (`content`) to add text to TLF-based text controls. These controls include the RichText, RichEditableText, and TextArea controls. Text that is added with the default property is parsed by the TLF and stored as a TextFlow object.

The following example sets the default property:

```
<s:RichText id="myRT" width="450">
    This is text.
</s:RichText>
```

If you are using TLF with your text controls, then you should generally use the `textFlow` property to set the contents. The default property is set only, and it is less efficient than the `textFlow` property. If you set the contents of a text control with the default property, you can then get it with either the `textFlow` property (gets a TextFlow object) or the `text` property (gets a plain text String object). For more information about using the `textFlow` property, see "Creating TextFlow objects" on page 760.

Typically, you start the value of the `content` property with a paragraph tag. That tag then contains `<span>` elements or breaks or anchor tags. TLF renders text set by the default property by putting it into a span, and that into a paragraph, and that into a TextFlow, and then rendering the TextFlow. The resulting tree uses the following structure:

```
<TextFlow>
    <p>
        <span>
            <contents ... >
```

When using the default property to add text to a control, you can use a subset of HTML in the content. This list matches the supported tags of the `<s:textFlow>` tag. For a list of supported tags, see "Markup tags supported in TextFlow objects" on page 766.

The content of the default property is typed as Object because you can set it to a String, a FlowElement, or an Array of Strings and FlowElement objects.

In the following example, the `<span>` tag is one FlowElement, and the character data "`World`" is treated as if it were wrapped in a `<String>` tag:

```
<s:RichText fontSize="12" xmlns="library://ns.adobe.com/flex/spark">
    <span fontWeight="bold">Hello</span>World
</s:RichText>
```

You can also set the content to a single FlowElement:

```
<s:RichText fontSize="12" xmlns="library://ns.adobe.com/flex/spark">
    <span fontWeight="bold">Hello World</span>
</s:RichText>
```

or to a single String:

```
<s:RichText fontSize="12" fontWeight="bold">Hello World</s:RichText>
```

Note that if you use a tag for the default property (such as `<span>`), you must specify the namespace in the opening tag of the text control. Otherwise, the compiler will not recognize the tag in the text.

Because there is only one format across all of the content, however, it is more efficient to set the formatting on the RichText tag and the content with the `text` property, as the following example shows:

```
<s:RichText fontSize="12" fontWeight="bold" text="Hello World"/>
```

There is no getter for the default property. Instead, you access the host component's `textFlow` property to get the parsed contents or the component's `text` property to get a simple string.

You can add special characters such as ampersands and angle brackets in the default property. To do this, use the same rules as described in "Specifying special characters in the text property" on page 752.

Using the text property

You can use the text property to specify the text string that appears in a text control or to get the text in the control as a plain text String. All text-based Flex controls support a `text` property. When you set this property, any tags (such as HTML) in the text string appear in the control as literal text.

The interpretation of \r, \n and \r\n as paragraph separators is the only interpretation that occurs when setting the value of the `text` property.

You cannot specify text formatting when you set the `text` property, but you can format the text in the control, as the following example shows:

```
<s:RichText fontSize="12" fontWeight="bold" text="Hello World"/>
```

For Spark controls that support TLF, you can set the text and then manipulate it with the TLF API. You can access nodes of the text object model and format parts of the content.

The following code line uses a `text` property to specify Label text:

```
<s:Label text="This is a simple text label"/>
```

You can also use a `<s:text>` child tag to specify text, as the following example shows:

```
<s:Label>
    <s:text>
    This is a simple text label.
    </s:text>
</s:Label>
```

The way you specify special characters, including quotation marks, greater than and less than signs, and apostrophes, depends on whether you use them in MXML tags or in ActionScript. It also depends on whether you specify the text directly or wrap the text in a CDATA section.

Note: *If you specify the value of the* `text` *property by using a string directly in MXML, Flex collapses white space characters. If you specify the value of the* `text` *property in ActionScript, Flex does not collapse white space characters.*

Specifying special characters in the text property

The following rules specify how to include special characters in the `text` property of a text control MXML tag, either in a property assignment, such as `text="the text"`, or in the body of a `<s:text>` subtag.

In standard text The following rules determine how you use special characters if you do not use a CDATA section:

- To use the special characters left angle bracket (<), right angle bracket (>), and ampersand (&), insert the XML character entity equivalents of `&lt;`, `&gt;`, and `&amp;`, respectively. You can also use `&quot;` and `&apos;` for double-quotation marks (") and single-quotation marks ('), and you can use numeric character references, such as &#165 for the Yen mark (¥). Do not use any other named character entities; Flex treats them as literal text.
- You cannot use the character that encloses the property text string inside the string. If you surround the string in double-quotation marks ("), use the escape sequence `\"` for any double-quotation marks in the string. If you surround the string in single-quotation marks (') use the escape sequence `\'` for any single-quotation marks in the string. You *can* use single-quotation marks inside a string that is surrounded in double-quotation marks, and double-quotation marks inside a string that is surrounded in single-quotation marks.
- Flex text controls ignore escape characters such as \t or \n in the `text` property. They ignore or convert to spaces, tabs and line breaks, depending on whether you are specifying a property assignment or a `<s:text>` subtag. To include line breaks, put the text in a CDATA section.

The following code example uses the `text` property with standard text:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/SparkStandardText.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    height="400">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Label width="400"
    text="This string contains a less than, &lt;,
    greater than, &gt;, ampersand, &amp;, apostrophe, ', and
    quotation mark &quot;."/>
  <s:Label width="400"
    text='This string contains a less than, &lt;,
    greater than, &gt;, ampersand, &amp;, apostrophe, &apos;, and
    quotation mark, ".'/>
  <s:Label width="400">
     <s:text>
        This string contains a less than, &lt;, greater than,
        &gt;, ampersand, &amp;, apostrophe, ', and quotation mark, ".
     </s:text>
  </s:Label>
</s:Application>
```

The resulting application contains three almost identical text controls, each with the following text. The first two controls, however, convert any tabs in the text to spaces. The third one has leading and trailing newlines and converts any tabs to newlines.

```
This string contains a less than, <, greater than, >, ampersand, &,apostrophe, ', and quotation
mark, ".
```

In a CDATA section If you wrap the text string in the CDATA tag, the following rules apply:

- You cannot use a CDATA section in a property assignment statement in the text control opening tag; you must define the property in a <s:text> child tag.
- Text inside the CDATA section appears as it is entered, including white space characters. Use literal characters, such as " or < for special characters, and use standard return and tab characters. Character entities, such as &gt;, and backslash-style escape characters, such as \n, appear as literal text.

The following code example follows these CDATA section rules:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/SparkTextCDATA.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    width="500">

  <s:Label width="100%">
     <s:text>
        <![CDATA[
            This string contains a less than, <, greater than, >,
            ampersand, &, apostrophe, ', return,
            tab. and quotation mark, ".
        ]]>
     </s:text>
  </s:Label>
</s:Application>
```

The displayed text appears on three lines, as follows:

```
    This string contains a less than, <, greater than, >,
    ampersand, &, apostrophe, ', return,
    tab. and quotation mark, ".
```

Specifying special characters in ActionScript

The following rules specify how to include special characters in a text control when you specify the control's text property value in ActionScript; for example, in an initialization function, or when assigning a string value to a variable that you use to populate the property:

- You cannot use the character that encloses the text string inside the string. If you surround the string in double-quotation marks ("), use the escape sequence \" for any double-quotation marks in the string. If you surround the string in single-quotation marks ('), use the escape sequence \' for any single-quotation marks in the string.
- Use backslash escape characters for special characters, including \t for the tab character, and \n or \r for a return/line feed character combination. You can use the escape character \" for the double-quotation mark and \' for the single-quotation mark.
- In standard text, but not in CDATA sections, you can use the special characters left angle bracket (<), right angle bracket (>), and ampersand (&), by inserting the XML character entity equivalents of &lt;, &gt;, and &amp;, respectively. You can also use &quot; and &apos; for double-quotation marks ("), and single-quotation marks ('), and you can use numeric character references, such as &#165; for the Yen mark (¥). Do not use any other named character entities; Flex treats them as literal text.
- In CDATA sections only, do not use character entities or references, such as &lt; or &#165; because Flex treats them as literal text. Instead, use the actual character, such as <.

The following example uses an initialization function to set the `text` property to a string that contains these characters:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/SparkInitText.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    initialize="initText()">

  <fx:Script>
     public function initText():void {
        //The following is on one line.
        myText.text="This string contains a return, \n, tab, \t, and quotation mark, \". " +
            "This string also contains less than, &lt;, greater than, &gt;, " +
            "ampersand, &amp;, and apostrophe, ', characters.";
     }
  </fx:Script>
  <s:RichText width="450" id="myText" tabStops="100 200 300 400"/>
</s:Application>
```

The following example uses an `<fx:Script>` tag with a variable in a CDATA section to set the `text` property:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/SparkVarText.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
            [Bindable]
            //The following is on one line.
          public var myText:String ="This string contains a return, \n, tab, \t, and quotation
mark, \". This string also contains less than, <, greater than, <, ampersand, <;, and
apostrophe, ', characters.";
        ]]>
    </fx:Script>
    <s:RichText width="450" text="{myText}" tabStops="100 200 300 400"/>

</s:Application>
```

The displayed text for each example appears on three lines. The first line ends at the return specified by the \n character. The remaining text wraps onto a third line because it is too long to fit on a single line. (Note: When you specify a tab character, you should be sure to create tab stops with the tabStops style property. Otherwise, the tab will instead be rendered as a carriage return. The RichText, RichEditableText, and Spark TextArea controls support the tabStops property, but the Label control does not.)

```
This string contains a return,
, tab,                   , and quotation mark, ". This string also contains less than, <,
greater than, >, ampersand, &, and apostrophe, ', characters.
```

Selecting text

The editable text controls provide properties and methods to select text regions and get the contents of the selections.

Creating a selection

The following controls let you select text:

- RichEditableText
- TextInput
- TextArea
- All controls that use these controls as a subcomponent

The selectable text controls provide the `selectRange()` method, which selects a range of text. You specify the zero-based indexes of the start character and the position immediately *after* the last character you want to select.

The following example shows how to select the first 10 characters of various text controls:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/SetSelectionTest.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            private function selectText():void {
                sparkTextArea.selectRange(0, 10);
                sparkTextInput.selectRange(0, 10);
                sparkRET.selectRange(0, 10);
            }
        ]]>
    </fx:Script>
    <s:TextArea id="sparkTextArea"
        selectionHighlighting="always"
        selectable="true"
        text="Spark TextArea control."/>
    <s:TextInput id="sparkTextInput"
        selectionHighlighting="always"
        selectable="true"
        text="Spark TextInput control."/>
    <s:RichEditableText id="sparkRET"
        selectionHighlighting="always"
        selectable="true"
        text="Spark RichEditableText control."/>

    <s:Button click="selectText()" label="Select Text"/>

</s:Application>
```

To determine when the selection is highlighted, you can use the `selectionHighlighting` property. Possible values are `always`, `whenFocused`, and `whenActive`.

To select all text in a text control, use the `selectAll()` method, as the following example shows:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/SelectAllExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            private function selectText(e:Event):void {
                e.currentTarget.selectAll();
            }
        ]]>
    </fx:Script>
    <s:TextArea id="sparkTextArea"
        text="Spark TextArea control." focusIn="selectText(event)"/>
    <s:TextInput id="sparkTextInput" text="Spark TextInput control."
focusIn="selectText(event)"/>

</s:Application>
```

TLF-based text controls have additional APIs that let you select text in different ways. For example, you can programmatically select a particular SpanElement object within a TextFlow, depending on where the cursor is. To do this, you walk the text object model's tree of elements (or leaves) and compare the cursor's position against each leaf element's character range.

The following example selects only the SpanElement that is under the mouse click:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/SparkSelectionExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import flashx.textLayout.elements.TextRange;
            import flashx.textLayout.elements.*;
            private function selectSomeText(e:Event):void {
                /* Get the location of the cursor. This is the character position of the
                   cursor in the RichEditableText control after the user clicks on it. */
                var activePos:int = richTxt1.selectionActivePosition;
                /* Get the first SpanElement in the TextFlow. */
                var leaf:SpanElement = new SpanElement();
                leaf = SpanElement(richTxt1.textFlow.getFirstLeaf());

                /* Get the start and end index values for the first SpanElement. */
                var spanStart:int = leaf.getParagraph().parentRelativeStart;
                var spanEnd:int = leaf.getParagraph().parentRelativeEnd;

                /* For the first SpanElement, if the cursor position falls within the
                   SpanElement's character range, then select the entire SpanElement. */
                if (activePos >= spanStart && activePos <= spanEnd) {
                    selectSpan(spanStart, spanEnd);
                    return;
                }
                /* Perform the same operations for each leaf in the TextFlow. */
                while(leaf = SpanElement(leaf.getNextLeaf())) {
                    spanStart = leaf.getParagraph().parentRelativeStart;
                    spanEnd = leaf.getParagraph().parentRelativeEnd;
                    if (activePos >= spanStart && activePos <= spanEnd) {
                        selectSpan(spanStart, spanEnd);
                        return;
                    }
                }
            }
            private function selectSpan(i1:int, i2:int):void {
                richTxt1.selectRange(i1, i2);
            }

        ]]>
    </fx:Script>

    <s:Panel>
        <s:RichEditableText id="richTxt1" click="selectSomeText(event)" selectable="true"
editable="true" textAlign="justify" percentWidth="100">
            <s:textFlow>
                <s:TextFlow>
                    <s:p><s:span>1) Lorem ipsum dolor sit amet, consectetur adipiscing
elit.</s:span></s:p>
                    <s:p><s:span>2) Cras posuere posuere sem, eu congue orci mattis
quis.</s:span></s:p>
                    <s:p><s:span>3) Curabitur pulvinar tellus venenatis ipsum tempus
lobortis.</s:span></s:p>
                </s:TextFlow>
            </s:textFlow>
        </s:RichEditableText>
    </s:Panel>
</s:Application>
```

Rather than iterating over all the leaf elements in the TextFlow object, you can also use the TextFlow class's `findLeaf()` method. This method lets you find an element based on a relative position. For an example of using the `findLeaf()` method, see "Navigating TextFlow objects" on page 767.

Getting a selection

You get the anchor and active positions of the selected text to get a text control's current selection. You then get the value of the characters between those positions.

To get the selected text in a text control, you use the `selectionAnchorPosition` and `selectionActivePosition` properties of the text control. These properties define the position at the start of the selection and at the end of the selection, respectively. You use the `substring()` method on the contents of the control, and pass these positions to identify the range of characters to return.

The following example displays the selections of the RichEditableText control when you click the button:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/SparkTraceSelectionRanges.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp()">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import mx.core.IUITextField;
            import flashx.textLayout.elements.TextRange;
            private function initApp():void {
                sparkRET.selectRange(0, 10);
            }

            private function getTextSelection():void {
                var anchorPos:int = sparkRET.selectionAnchorPosition;
                var activePos:int = sparkRET.selectionActivePosition;
                myLabel.text = "Current Selection: \"" + sparkRET.text.substring(anchorPos, 
activePos) + "\"";
            }
        ]]>
    </fx:Script>
    <s:RichEditableText id="sparkRET"
        selectionHighlighting="always"
        selectable="true"
        text="Spark RichEditableText control."/>

    <s:Button click="getTextSelection()" label="Show Current Selection"/>

    <s:Label id="myLabel"/>

</s:Application>
```

Using Text Layout Framework

The Text Layout Framework (TLF) is a class library built on top of the Flash Text Engine (FTE). The FTE, available in Flash Player 10 and Adobe AIR 1.5, adds advanced text capabilities to Flash Player. FTE provides a set of low-level APIs for libraries that leverage these capabilities. The FTE classes are in the flash.text.engine package. In most cases, you will not use these classes directly.

The TLF classes are in the flashx.textLayout.* package. You are likely to use the TLF classes when you apply styles with HTML markup to text in text controls that support TLF. These controls include the RichText and RichEditableText controls, as well as the Spark TextArea control.

The primary difference between most Spark and MX text-based controls is the control over the formatting. For Spark controls, the formatting is provided by either FTE or TLF. This gives you a great deal of control over the text formatting, including support for HTML tags, columns, and bi-directional text.

TLF is not used by Flex text controls in mobile applications. When you create a mobile application, the mobile theme is automatically applied. As a result, text-based controls use the mobile skins, which do not support TLF. You can still use some of the same text controls, but be aware that TLF is not used when the mobile theme is applied. For more information on using TLF-based text controls with mobile applications, see Use text in a mobile application.

More Help topics

"Flow" TLF markup application

Features of TLF

Text Layout Framework (TLF) is a class library built on top of FTE. It provides high level text functionality, including:

- Bi-directional text, vertical text, and over 30 writing systems, including Arabic, Hebrew, Chinese, Japanese, Korean, Thai, Lao, and the major writing systems of India
- Selecting, editing, and flowing text across multiple columns and linked containers, as well as around inline images
- Vertical text, Tate-Chu-Yoko (horizontal within vertical text), and justifiers for East Asian typography
- Rich typographical controls, including kerning, ligatures, typographic case, digit case, digit width, and discretionary hyphens
- Cut, copy, paste, undo, and standard keyboard and mouse controls for editing
- Rich developer APIs to manipulate text content, layout, and markup and to create custom text components
- Robust list support including custom markers and numbering formats
- Inline images and positioning rules

When you add text to a control that uses TLF, the text is stored as a hierarchical tree of objects. The root element of this tree is the TextFlow class. Each node in the tree is an instance of a class defined in the flashx.textLayout.elements package. This tree is known as the text object model. The text object model is a subset of the FXG specification.

In the text object model, concepts such as paragraphs, spans, and hyperlinks are not represented as formats that affect the appearance of character runs in a single, central text string. Instead they are represented by runtime-accessible ActionScript objects, with their own properties, methods, and events (in some cases).

The following lists the objects you can have in a TextFlow object:

- Paragraphs (ParagraphElement)
- Images (InlineGraphicElement)
- Hyperlinks (LinkElement)
- Spans (SpanElement)
- TCY blocks (TCYElement)
- Tabs (TabElement) and line breaks (BreakElement)
- Lists (ListElement)

If a Spark text control supports the `textFlow` property, then you can use TLF to format and programmatically interact with the contents of that text control. If the control supports only the `text` property for its content, then you can only use a simple string for the text. The text does not get parsed into the text object model. If an MX control supports the `htmlText` property, then you can use a subset of HTML tags to format the text, but its content is still a simple string that does not support the formal text object model.

You use the `textFlow` property when you set the value of the text at run time. The content of the `textFlow` property is strongly typed as a TextFlow object rather than an Object.

You use the default property when you set the value of the property at compile time. This property takes a generic Object and converts it to a TextFlow. In general, you should avoid using the default property when the `textFlow` property is available.

The Spark versions of the TextArea and TextInput classes support TLF, as do the RichText and RichEditableText controls. The Spark Label control supports FTE. The default MX controls do not support TLF. However, it is possible to use TLF with some MX controls. For more informations, see “Using FTE in MX controls” on page 1594.

For detailed information about using TLF and advanced typography, see Basics of Working with text.

Creating TextFlow objects

The text object model is the tree that is created when you add content to a text-based control that supports TLF. This tree is defined by the TextFlow class.

When creating a TextFlow object, you can use the classes in the flashx.textLayout.elements.* package to provide formatting and additional functionality. These classes include DivElement, ParagraphElement, InlineGraphicElement, LinkElement, SpanElement, TabElement, BreakElement, and TCYElement.

You can create a TextFlow object in the following ways:

- Using the default property
- Using the `<s:textFlow>` child tag
- Importing content with the TextFlowUtil class
- Using ActionScript

Using the default property

You can create a TextFlow object by adding content to a text-based’s default property. When you do this, Flex creates a TextFlow object that defines the text object model for you. For more information, see “Using the default property” on page 750.

Creating a TextFlow object with child tags

You can also use the text control’s `<s:textFlow>` child tag to explicitly create a TextFlow object. This lets you structure the contents of the text control by using the supported TLF tags such as `<p>`, `<div>` and `<span>`.

When using the `<s:textFlow>` child tag, you must be sure to also include a `<s:TextFlow>` tag within that, so that the structure of the control’s uses the following structure:

```
<s:text_control>
    <s:textFlow>
        <s:TextFlow>
            <.../>
        </s:TextFlow>
    </s:textFlow>
</s:text_control>
```

You should keep in mind that the default property can also create a TextFlow object, so you could write the previous example as follows:

```
<s:text_control>
    <.../>
</s:text_control>
```

The following example creates two text controls; one text control defines a TextFlow object with the `<s:textFlow>` child tag, and the other with the default property.

```
<?xml version="1.0"?>
<!-- sparktextcontrols/CreateTextFlowChildTags.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:RichEditableText id="richTxt1" textAlign="justify" percentWidth="100">
        <s:textFlow>
            <s:TextFlow>
                <s:p fontSize="24">TextFlow Child Tag</s:p>
                <s:p>1) Lorem ipsum dolor sit amet, consectetur adipiscing elit.</s:p>
                <s:p>2) Cras posuere posuere sem, eu congue orci mattis quis.</s:p>
                <s:p>3) Curabitur pulvinar tellus venenatis ipsum tempus lobortis.</s:p>
            </s:TextFlow>
        </s:textFlow>
    </s:RichEditableText>
    <s:RichEditableText id="richTxt2" textAlign="justify" percentWidth="100">
        <s:p fontSize="24">Default Property</s:p>
        <s:p>1) Lorem ipsum dolor sit amet, consectetur adipiscing elit.</s:p>
        <s:p>2) Cras posuere posuere sem, eu congue orci mattis quis.</s:p>
        <s:p>3) Curabitur pulvinar tellus venenatis ipsum tempus lobortis.</s:p>
    </s:RichEditableText>
</s:Application>
```

It is also convenient to drop the prefix on the markup tags by making the Spark library namespace the default namespace on the text control's tag, as the following example shows:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/TextFlowNamespace.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:RichEditableText id="richTxt1" textAlign="justify" percentWidth="100"
xmlns="library://ns.adobe.com/flex/spark">
        <textFlow>
            <TextFlow>
                <p fontSize="24">TextFlow Child Tag</p>
                <p>1) Lorem ipsum dolor sit amet, consectetur adipiscing elit.</p>
                <p>2) Cras posuere posuere sem, eu congue orci mattis quis.</p>
                <p>3) Curabitur pulvinar tellus venenatis ipsum tempus lobortis.</p>
            </TextFlow>
        </textFlow>
    </s:RichEditableText>
</s:Application>
```

Creating a TextFlow object with the TextFlowUtil class

If you don’t know the rich text that you want to display until run-time, you can import HTML or XML to a TextFlow object. The TextFlowUtil class has the following methods that let you add XML and strings as the contents of a TextFlow object:

- `importFromString()`
- `importFromXML()`

The following example uses the `importFromString()` method to load a String object into the TextFlow:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/TextFlowMarkup.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="doSomething()">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script><![CDATA[
        import flashx.textLayout.elements.TextFlow;
        import spark.utils.TextFlowUtil;

        private function doSomething():void {
            var markup:String = "<p>This is paragraph 1.</p><p>This is paragraph 2.</p>";
            var flow:TextFlow = TextFlowUtil.importFromString(markup);
            myST.textFlow = flow;
        }
    ]]></fx:Script>
    <s:RichText id="myST" width="175"/>
</s:Application>
```

You can add also import XML by using the TextFlowUtil class’s `importFromXML()` method. Any XML that uses valid TLF markup can be passed into a TextFlow. This includes content returned by an HTTPService call, XML defined in the application file itself, or XML defined in an external file.

The following example uses an external file that defines a TextFlow object for a text control:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- sparktextcontrols/ExternalXMLFile.mxml -->
<s:Application name="Spark_RichText_text_test"
        xmlns:fx="http://ns.adobe.com/mxml/2009"
        xmlns:s="library://ns.adobe.com/flex/spark"
        xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Script>
        <![CDATA[
            import spark.utils.TextFlowUtil;

            XML.ignoreWhitespace = false;
        ]]>
    </fx:Script>

    <fx:Declarations>
        <fx:XML id="textFlowAsXML" source="externalTextFlow1.xml" />
    </fx:Declarations>

    <s:RichText id="richTxt"
            textFlow="{TextFlowUtil.importFromXML(textFlowAsXML)}"
            horizontalCenter="0" verticalCenter="0" />

</s:Application>
```

The previous example uses the following file:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- http://blog.flexexamples.com/2009/08/11/setting-text-in-a-spark-richtext-control-in-
flex-4/ -->
<TextFlow xmlns="http://ns.adobe.com/textLayout/2008" whiteSpaceCollapse="preserve">
    <p><span>The quick brown </span> <span fontWeight="bold">fox jumps over</span> <span> the
lazy dogg.</span></p>
</TextFlow>
```

If the first tag in an imported XML object is not a `<s:TextFlow>` tag, then the parser inserts one for you. If the first tag is a `<s:TextFlow>` tag, then you must also define the `"http://ns.adobe.com/textLayout/2008"` namespace in that tag.

The parser converts the TLF tags to TLF classes (such as SpanElement or DivElement) in the new TextFlow object.

This example used with permission from http://blog.flexexamples.com.

Creating a TextFlow object with the TextConverter class

You can use the TextConverter class to import content into a TextFlow. This is a little more advanced than using the TextFlowUtil methods to create a TextFlow object. Those methods act as wrappers around the TextConverter class. When you import text with the TextConverter class's `importToFlow()` method, however, you can specify the format of the text. This determines how the content is stored.

The following are the types of formats you can specify when using the `importToFlow()` method:

- HTML
- Plain text
- TLF

If you specify the TLF format, then the imported text is used to generate a text object model. If you specify plain text, then the text is not interpreted, but instead stored as a simple text string. If you specify HTML format, then the HTML tags in the text are mapped to TLF classes (for example, `<p>` is mapped to a ParagraphElement object in the text object model).

The following example imports an XML object into a TextFlow when you click the Button control:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/AddingContentAsXML.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
        import spark.utils.TextFlowUtil;
        import flashx.textLayout.elements.*;
        import flashx.textLayout.conversion.*;
        import mx.utils.*;
        private var xml:XML = <TextFlow
xmlns='http://ns.adobe.com/textLayout/2008'><p><span>This is a span</span></p></TextFlow>;

        private function addContent():void {
           myRET.textFlow= TextConverter.importToFlow(xml, TextConverter.TEXT_LAYOUT_FORMAT);
        }
        ]]>
    </fx:Script>

    <s:RichEditableText id="myRET" height="100" width="200"/>

    <s:Button click="addContent()" label="Add Content"/>
</s:Application>
```

The following example uses a variety of formats when importing a String into the TextFlow with the `importToFlow()` method:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- sparksparktextcontrols/ImportToFlowExample.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
        xmlns:s="library://ns.adobe.com/flex/spark"
        xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Script>
        <![CDATA[
            import flashx.textLayout.conversion.TextConverter;

            XML.ignoreWhitespace = false;
        ]]>
    </fx:Script>

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Declarations>
        <!-- Define a String to use with HTML and plain text format. -->
        <fx:String id="htmlTextAsHTML"><![CDATA[<p>Hello <b>world!</b></p>]]></fx:String>

        <!-- Define an XML object to use with TLF format. -->
        <fx:XML id="tfTextAsTextFlow">
            <TextFlow xmlns="http://ns.adobe.com/textLayout/2008">
                <p>Hello <span fontWeight="bold">world!</span></p>
            </TextFlow>
        </fx:XML>
    </fx:Declarations>

    <s:RichText id="richTxt"
            textFlow="{TextConverter.importToFlow(htmlTextAsHTML,
TextConverter.TEXT_FIELD_HTML_FORMAT)}"
            horizontalCenter="0" verticalCenter="0" />

     <s:RichText id="richTxt2"
             textFlow="{TextConverter.importToFlow(htmlTextAsHTML,
TextConverter.PLAIN_TEXT_FORMAT)}"
             horizontalCenter="0" verticalCenter="0" />

     <s:RichText id="richTxt3"
             textFlow="{TextConverter.importToFlow(tfTextAsTextFlow,
TextConverter.TEXT_LAYOUT_FORMAT)}"
             horizontalCenter="0" verticalCenter="0" />

</s:Application>
```

When you use the `TEXT_LAYOUT_FORMAT` type for the TextConverter, the imported text must observe the following rules:

1 The first tag must be a `<s:TextFlow>` tag. The parser will not insert one for you as it does with the `TextFlowUtil.importFromXML()` or `TextFlowUtil.importFromString()` methods.

2 The first tag must specify a namespace for the imported text. The namespace is `"http://ns.adobe.com/textLayout/2008"`.

3 Subsequent tags must be supported by the TextFlow class. For a list of supported tags, see "Markup tags supported in TextFlow objects" on page 766.

The TextConverter class also lets you export a TextFlow object's content in a variety of formats. For an example of a text exporter, see http://blog.flexexamples.com/2009/07/25/exporting-a-textflow-object-in-flex-4/.

Creating a TextFlow object in ActionScript

You can create TextFlow objects that are used by TLF-based text controls in ActionScript.

If you create a TextFlow object in ActionScript, the TextFlow object requires that either the ParagraphElement or DivElement be at the top level. The following example creates two ParagraphElement objects and wraps them in SpanElement objects. It then adds these objects as children of a TextFlow object, and adds them to a RichEditableText control's content:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/SimpleTextModelExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp()">

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        import flashx.textLayout.elements.*;
        private var textFlow:TextFlow = new TextFlow();
        private var paragraph1:ParagraphElement = new ParagraphElement();
        private var paragraph2:ParagraphElement = new ParagraphElement();
        private var span1:SpanElement = new SpanElement();
        private var span2:SpanElement = new SpanElement();

        private function initApp():void {
            span1.text = "This is paragraph one in myRET.";
            span2.text = "This is paragraph two in myRET.";
            paragraph1.addChild(span1);
            paragraph2.addChild(span2);
            textFlow.addChild(paragraph1);
            textFlow.addChild(paragraph2);

            myRET.textFlow = textFlow;
        }
    </fx:Script>

    <s:RichEditableText id="myRET" height="100" width="200"/>
</s:Application>
```

Markup tags supported in TextFlow objects

The TLF parser converts supported markup elements to TLF classes so that they can be used in the text object model. These markup elements are similar to the HTML tags of the same names. For example, if you specify a `<p>` tag in your text control's content, then the parser converts it to a ParagraphElement in the control's TextFlow.

The following table describes the supported elements of the text object model:

Element	Class	Description
div	DivElement	A division of text; can contain only div, list, or p elements.

Element	Class	Description
p	ParagraphElement	A paragraph; can contain any element except div, list, or li.
a	LinkElement	A hypertext link, also known as an anchor; can contain the tcy, span, img, tab, g, and br elements. This is the only class in the text object model that supports Flex events.
tcy	TCYElement	A run of horizontal text, used in vertical text such as Japanese; can contain the a, span, img, tab, g, or br elements.
span	SpanElement	A run of text in a paragraph; cannot contain other elements.
img	InlineGraphicElement	An image in a paragraph element.
tab	TabElement	A tab character.
br	BreakElement	A break character; text continues on the next line, but does not start a new paragraph.
list	ListElement	An ordered or unordered list. Can be simple list or nested. You can customize the bullets. Can contain li elements (ListItemElement) or other list elements.
li	ListItemElement	List items within a list element. Can be ordered or unordered, nested or flat lists. You can customize the markers as well as other settings of each list item.
g	SubParagraphGroupElement	A group element. Used for grouping elements in a paragraph. This lets you nest elements below the paragraph level.

Navigating TextFlow objects

The TLF API provides methods and properties that let you navigate the text object model after it is created. You can use this API to perform actions on a individual leaves or the entire tree.

The following example iterates over the RichEditableText control’s TextFlow and copies the contents of each SpanElement, one at a time, into another RichEditableText control:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/IterateOverLeaves.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import flashx.textLayout.elements.*;
            private function copyContents():void {
                /* Get the first leaf in the TextFlow. */
                var leaf:SpanElement = new SpanElement();
                leaf = SpanElement(richTxt1.textFlow.getFirstLeaf());

                /* Write the contents of the first leaf to the second RET control. */
                richTxt2.text = "LEAF:" + leaf.text + "\n";
                /* Iterate over the remaining leaves and write their contents
                   to the second RET control. */
                while(leaf = SpanElement(leaf.getNextLeaf())) {
                    richTxt2.text += "LEAF:" + leaf.text + "\n";
                }
            }
        ]]>
    </fx:Script>

    <s:Panel>
      <s:RichEditableText id="richTxt1" selectable="true" editable="true" textAlign="justify" 
percentWidth="100">
            <s:textFlow>
                <s:TextFlow>
                    <s:p><s:span>1) Lorem ipsum dolor sit amet, consectetur adipiscing 
elit.</s:span></s:p>
                    <s:p><s:span>2) Cras posuere posuere sem, eu congue orci mattis 
quis.</s:span></s:p>
                    <s:p><s:span>3) Curabitur pulvinar tellus venenatis ipsum tempus 
lobortis.</s:span></s:p>
                </s:TextFlow>
            </s:textFlow>
        </s:RichEditableText>
    </s:Panel>
    <s:HGroup>
        <s:Button label="Copy Contents" click="copyContents()"/>
        <s:Button label="Clear" click="richTxt2.text=''"/>
    </s:HGroup>
    <s:Panel>
        <s:RichEditableText id="richTxt2" textAlign="justify" percentWidth="100"/>
    </s:Panel>
</s:Application>
```

The `TextFlow.findLeaf()` method lets you specify a character position and returns the entire flow element where that character position occurs. The following example changes the color of the entire SpanElement whenever the user clicks on any location within that SpanElement's paragraph:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/FindLeafExample.mxml -->
<s:Application 
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import flashx.textLayout.elements.TextRange;
            import flashx.textLayout.elements.*;
            private function selectEntireLeaf(e:Event):void {
                /* Get the location of the cursor. This is the character position of the 
                   cursor in the RichEditableText control after the user clicks on it. */
                var activePos:int = richTxt1.selectionActivePosition;
                /* Change the color of the entire leaf under the cursor position. */
                var leaf:SpanElement = richTxt1.textFlow.findLeaf(activePos) as SpanElement;
                leaf.color = 0x00FF33;
            }
        ]]>
    </fx:Script>

    <s:Panel>
        <s:RichEditableText id="richTxt1" click="selectEntireLeaf(event)" selectable="true" 
editable="true" textAlign="justify" percentWidth="100">
            <s:textFlow>
                <s:TextFlow>
                    <s:p><s:span>1) Lorem ipsum dolor sit amet, consectetur adipiscing 
elit.</s:span></s:p>
                    <s:p><s:span>2) Cras posuere posuere sem, eu congue orci mattis 
quis.</s:span></s:p>
                    <s:p><s:span>3) Curabitur pulvinar tellus venenatis ipsum tempus 
lobortis.</s:span></s:p>
                </s:TextFlow>
            </s:textFlow>
        </s:RichEditableText>
    </s:Panel>
</s:Application>
```

You can access the objects in a TextFlow by their object names and set the values of properties such as `color` or `direction` on them in ActionScript. The text in the controls update accordingly, as the following example shows:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/ManipulateTextModelExample.mxml -->
<s:Application 
    xmlns:fx="http://ns.adobe.com/mxml/2009" 
    xmlns:mx="library://ns.adobe.com/flex/mx" 
    xmlns:s="library://ns.adobe.com/flex/spark" 
    creationComplete="initApp()">

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        import flashx.textLayout.elements.*;
        private var textFlow:TextFlow = new TextFlow();
        private var paragraph1:ParagraphElement = new ParagraphElement();
        private var paragraph2:ParagraphElement = new ParagraphElement();
        private var span1:SpanElement = new SpanElement();
        private var span2:SpanElement = new SpanElement();

        private function initApp():void {
            span1.text = "This is paragraph one.";
            span2.text = "This is paragraph two.";
            paragraph1.addChild(span1);
            paragraph2.addChild(span2);
            textFlow.addChild(paragraph1);
            textFlow.addChild(paragraph2);

            myRET.textFlow = textFlow;
        }

        private function changeColors():void {
            // Change color of first paragraph.
            paragraph1.color = 0xFF00FF;

            // Change color of second paragraph.
            paragraph2.setStyle("color", 0x00FF00);
        }
    </fx:Script>

    <s:RichEditableText id="myRET" height="100" width="200">
    </s:RichEditableText>

    <s:Button label="Change Colors" click="changeColors()"/>
</s:Application>
```

This example shows that you can set styles by using either the `setStyle()` method or the property accessors. For more information, see “Styling TLF-based text controls” on page 785.

You can also access the objects in the text object model by using their ids. You do this with the TextFlow class’s `getElementById()` method. This requires that you set the `id` property of the flow elements, as the following example shows:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/AccessTextFlowMethods.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp()">

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        import flashx.textLayout.elements.*;
        private var textFlow:TextFlow = new TextFlow();
        private var paragraph1:ParagraphElement = new ParagraphElement();
        private var paragraph2:ParagraphElement = new ParagraphElement();
        private var span1:SpanElement = new SpanElement();
        private var span2:SpanElement = new SpanElement();

        private function initApp():void {
            span1.id = "span1";
            span2.id = "span2";
            paragraph1.id = "paragraph1";
            paragraph2.id = "paragraph2";

            span1.text = "This is paragraph one.";
            span2.text = "This is paragraph two.";
            paragraph1.addChild(span1);
            paragraph2.addChild(span2);
            textFlow.addChild(paragraph1);
            textFlow.addChild(paragraph2);

            myRET.textFlow = textFlow;
        }

        private function changeColors():void {
            // Set color of paragraph one.
            textFlow.getElementByID("paragraph1").setStyle("color", 0xFF0000);
            // Set color of paragraph two.
        textFlow.getElementByID("paragraph2").setStyle("color", 0xFF0000);
        }
    </fx:Script>

    <s:RichEditableText id="myRET" height="100" width="200">
    </s:RichEditableText>

    <s:Button label="Change Colors" click="changeColors()"/>
</s:Application>
```

In the previous example, because the text flow elements are created programmatically, their `id` properties are also set explicitly on the objects that represent the span and paragraph elements. If you were creating the text flow with HTML markup, you would specify the value of the `id` property in the HTML tag (for example, `<span id="span1">`).

Another way to “walk the tree” of a TextFlow object is to use the methods of the ParagraphElement class. This class helps you access low-level items such as atoms and words. For example, you can use the `findNextWordBoundary()` and `findPreviousWordBoundary()` methods to navigate the word boundaries in the flow element’s text.

The following example uses methods of the ParagraphElement class to count the words and determine the average length of them in the TextFlow:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/FindWords.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import flashx.textLayout.elements.*;
            private function countWords():void {
                var leaf:SpanElement = new SpanElement();
                leaf = SpanElement(richTxt1.textFlow.getFirstLeaf());

                var p:ParagraphElement = new ParagraphElement();
                p = leaf.getParagraph();

                doSomething(p);
                while (leaf = SpanElement(leaf.getNextLeaf())) {
                    p = leaf.getParagraph();
                    doSomething(p);
                }
                wcLabel.text += "# Words: " + wordCount;
           lenLabel.text += "Avg length of each word: " + lenTotal/wordCount + " chars";
            }
            private var wordCount:int = 0;
            private var lenTotal:int = 0;
            private function doSomething(p:ParagraphElement):void {
                var wordBoundary:int = 0;
                var prevBoundary:int = 0;

                // If these are equal, then there are no more words.
                while (wordBoundary != p.findNextWordBoundary(wordBoundary)) {
                    if (p.findNextWordBoundary(wordBoundary) - wordBoundary > 1) {
                        wordCount += 1;
                    }
                    prevBoundary = wordBoundary;
                    wordBoundary = p.findNextWordBoundary(wordBoundary);
                  // If the value is greater than 1, then it's a word, otherwise it's a space.
                    if (wordBoundary - prevBoundary > 1) {
                        var s:String = p.getText().substring(prevBoundary, wordBoundary);
                        lenTotal += s.length;
                    }
                }
            }
        ]]>
    </fx:Script>

    <s:Panel>
      <s:RichEditableText id="richTxt1" selectable="true" editable="true" textAlign="justify"
percentWidth="100">
            <s:textFlow>
                <s:TextFlow>
                    <s:p><s:span>Lorem ipsum dolor sit amet, consectetur adipiscing
elit.</s:span></s:p>
                    <s:p><s:span>Cras posuere posuere sem, eu congue orci mattis
quis.</s:span></s:p>
                    <s:p><s:span>Curabitur pulvinar tellus venenatis ipsum tempus
lobortis.</s:span></s:p>
                </s:TextFlow>
            </s:textFlow>
        </s:RichEditableText>
    </s:Panel>
    <s:VGroup>
        <s:Button label="Count" click="countWords()"/>
        <s:Label id="wcLabel"/>
        <s:Label id="lenLabel"/>
    </s:VGroup>
</s:Application>
```

Adding images with TLF

TLF supports embedding images in text controls by using the InlineGraphicElement class. To add an image to the text object model, use the `<img>` tag in a `<s:textFlow>` tag or the default property, or create an instance of the InlineGraphicElement class.

The InlineGraphicElement class can point to an image file, such as a GIF, JPG, or PNG file.

You specify the location of the image by using the `source` property. The location can be relative to the deployed location of the application (for example, “images/butterfly.gif”) or it can be a full path to the image (for example, “http://yourserver.com/images/butterfly.gif”).

The following example loads a simple image from a local location:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/SimpleInlineGraphic.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="doSomething()">
    <fx:Script>
        <![CDATA[
            import flashx.textLayout.elements.*;
            import flashx.textLayout.*;

            [Bindable]
            private var textFlow:TextFlow;
            private var img:InlineGraphicElement;

            private function doSomething():void {
                textFlow = new TextFlow();
                var p:ParagraphElement = new ParagraphElement();
                img = new InlineGraphicElement();
                img.source = "assets/butterfly.gif";
                img.height = 100;
                img.width = 100;
                p.addChild(img);
                textFlow.addChild(p);
            }
            ]]>
    </fx:Script>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:Panel title="Simple Inline Graphic Image"
        width="90%" height="90%"
        horizontalCenter="0" verticalCenter="0">
        <s:RichEditableText id="richTxt" textAlign="justify" width="100%"
            textFlow="{textFlow}" />
    </s:Panel>
</s:Application>
```

As with text-based examples, you can use a variety of techniques to load the image with an InlineGraphicElement object. The following example uses child tags:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/SimpleInlineGraphicTags.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:Panel title="Simple Inline Graphic Image"
        width="90%" height="90%"
        horizontalCenter="0" verticalCenter="0">
        <s:RichEditableText id="richTxt" textAlign="justify" width="100%">
            <s:textFlow>
                <s:TextFlow>
                    <s:p>
                       <s:img source="@Embed(source='../assets/butterfly.gif')" height="100"
width="100"/>
                    </s:p>
                </s:TextFlow>
            </s:textFlow>
        </s:RichEditableText>
    </s:Panel>
</s:Application>
```

Rather than load the image at run time, you can also use an embedded image for the InlineGraphicImage object's source, as the following example shows:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/SimpleEmbed.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        [Embed(source="../assets/butterfly.gif")]
        [Bindable]
        public var imgCls:Class;
    </fx:Script>
        <s:RichEditableText id="richTxt" textAlign="justify" width="100%">
            <s:textFlow>
                <s:TextFlow>
                    <s:p>
                        <s:img id="myImage" source="{imgCls}" height="100" width="100"/>
                    </s:p>
                </s:TextFlow>
            </s:textFlow>
        </s:RichEditableText>

</s:Application>
```

The InlineGraphicElement class can also display a drawn element, such as a Sprite or an FXG component. The following example loads an FXG component into the InlineGraphicElement:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/FXGInlineGraphic.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:comps="comps.*"
    creationComplete="doSomething()">
    <fx:Script>
        <![CDATA[
            import flashx.textLayout.elements.*;
            import flashx.textLayout.*;
            import comps.*;

            [Bindable]
            private var textFlow:TextFlow;
            private var img:InlineGraphicElement;

            private function doSomething():void {
                textFlow = new TextFlow();
                var p:ParagraphElement = new ParagraphElement();
                img = new InlineGraphicElement();
                img.source = new ArrowAbsolute();
                img.height = 100;
                img.width = 100;
                p.addChild(img);
                textFlow.addChild(p);
            }
            ]]>
    </fx:Script>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:Panel title="FXG Inline Graphic Image"
        width="90%" height="90%"
        horizontalCenter="0" verticalCenter="0">
        <s:RichEditableText id="richTxt" textAlign="justify" width="100%"
            textFlow="{textFlow}" />
    </s:Panel>
</s:Application>
```

The FXG component used in this example is as follows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- textcontrols/comps/ArrowAbsolute.fxg -->
<fxg:Graphic xmlns:fxg="http://ns.adobe.com/fxg/2008" version="1">
    <!-- Use Use compact syntax with absolute coordinates. -->
    <fxg:Path data="
         M 20 0
         C 50 0 50 35 20 35
         L 15 35
         L 15 45
         L 0 32
         L 15 19
         L 15 29
         L 20 29
         C 44 29 44 6 20 6
    ">
         <!-- Define the border color of the arrow. -->
         <fxg:stroke>
              <fxg:SolidColorStroke color="#888888"/>
         </fxg:stroke>
         <!-- Define the fill for the arrow. -->
         <fxg:fill>
              <fxg:LinearGradient rotation="90">
                   <fxg:GradientEntry color="#000000" alpha="0.8"/>
                   <fxg:GradientEntry color="#FFFFFF" alpha="0.8"/>
              </fxg:LinearGradient>
         </fxg:fill>
    </fxg:Path>
</fxg:Graphic>
```

For more information about using FXG, see “FXG and MXML graphics” on page 1714.

If you do not know the image’s dimensions, you can use the InlineGraphicElement class’s `measuredHeight` and `measuredWidth` properties to define the size of the image. You can only use these properties after the image loads. To do this, you can trigger a function that sizes the image off of the TextFlow object’s `StatusChangeEvent` event, as the following example shows:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/LoadImageEvent.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark" creationComplete="initApp()">
    <fx:Script>
        <![CDATA[
            import flashx.textLayout.events.StatusChangeEvent;
            import flashx.textLayout.elements.*;
            import flashx.textLayout.*;

            [Bindable]
            private var textFlow:TextFlow;
            private var img:InlineGraphicElement;

            private function initApp():void {
                textFlow = new TextFlow();
                textFlow.addEventListener(StatusChangeEvent.INLINE_GRAPHIC_STATUS_CHANGE,
sizeGraphic);
                var p:ParagraphElement = new ParagraphElement();
                img = new InlineGraphicElement();
                img.source = "assets/butterfly.gif";
                p.addChild(img);
                textFlow.addChild(p);
            }
            private function sizeGraphic(e:StatusChangeEvent):void {
                if (e.status == "ready" || e.status == "sizePending") {
                    img.height = img.measuredHeight;
                    img.width = img.measuredWidth;
                }
            }
            ]]>
    </fx:Script>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:Panel title="Sizing Inline Graphic Image"
        width="90%" height="90%"
        horizontalCenter="0" verticalCenter="0">
        <s:RichEditableText id="richTxt" textAlign="justify" width="100%"
            textFlow="{textFlow}" />
    </s:Panel>
</s:Application>
```

You can get a reference to the InlineGraphicElement's graphic by using the `graphic` property. This property points to the embedded DisplayObject. This lets you interact with the InlineGraphicElement in the same ways that you can interact with any DisplayObject. For example, you can apply blend modes, change the alpha, rotate, and scale the image.

The following example changes the `alpha` of the DisplayObject when you move the slider:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/DisplayObjectImageElement.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        private function changeAlpha():void {
            myImage.graphic.alpha = .5;
        }
    </fx:Script>
        <s:RichEditableText id="richTxt" textAlign="justify" width="100%">
            <s:textFlow>
                <s:TextFlow>
                    <s:p>
                        <s:img id="myImage"
                            source="@Embed(source='../assets/butterfly.gif')"
                            height="100" width="100"/>
                    </s:p>
                </s:TextFlow>
            </s:textFlow>
        </s:RichEditableText>

        <s:HSlider id="hSlider"
            minimum="0" maximum="1"
            value="1"
            stepSize="0.1"
            snapInterval="0.1"
            liveDragging="true"
            valueCommit="myImage.graphic.alpha=hSlider.value;"/>

</s:Application>
```

Note that the previous example uses a RichEditableText control and not a RichText control. The RichEditableText control supports user interaction, while the RichText control does not.

Positioning images inline

To position the InlineGraphicElement within a text element, you use the following properties:

- `float` property of the InlineGraphicElement class
- `clearFloats` property of the FlowElement (or the `clearFloats` style property of the text container)
- `paddingTop/paddingBottom/paddingLeft/paddingRight` properties on the FlowElement class

The `float` property controls the placement of the inline graphic within the text. The following example shows a simple image surrounded by text. By changing the value of the `float` property, you can change the way text flows around the image, as the following example shows:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/TLFFloat.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            private function changeSelection(event:Event):void {
                image1.float = event.currentTarget.selectedItem;
            }
        ]]>
    </fx:Script>
    <s:HGroup>
        <s:Label text="float for the image (default:none):"/>
        <s:ComboBox id="cb1"
            change="changeSelection(event)"
            creationComplete="cb1.selectedIndex=0">
            <s:ArrayCollection>
                <fx:String>none</fx:String>
                <fx:String>left</fx:String>
                <fx:String>right</fx:String>
                <fx:String>start</fx:String>
                <fx:String>end</fx:String>
            </s:ArrayCollection>
        </s:ComboBox>
    </s:HGroup>

    <s:RichEditableText id="myRET1" width="300">
        <s:textFlow>
            <s:TextFlow columnWidth="290">
               <s:p id="p1">Images in a flow are a good thing. For example, here is a float.
<s:img id="image1" float="none" source="@Embed(source='../assets/bulldog.jpg')"
paddingRight="10" paddingTop="10" paddingBottom="10" paddingLeft="10"></s:img>Don't you
agree?
                It should show on the left. If it doesn't show up on the left, then it is a
bug. You can submit bugs at http://bugs.adobe.com/jira/. You can set how the float is positioned
within
               the paragraph by using the ComboBox below. You can select left, right, start,
end, or none. This example does not use the clearFloats property. That is in a different
example.</s:p>
            </s:TextFlow>
        </s:textFlow>
    </s:RichEditableText>

</s:Application>
```

You use the constants defined by the flashx.textLayout.formats.Float class to set the value of the `float` property. The values “left” and “right” indicate that the image should be left-aligned or right-aligned within the text. The values of “start” and “end” are similar, in that they left- and right-align the image, but the meanings of them depend on the direction of the text (RTL or LTR). For RTL text, for example, “end” means the end of the line, which is typically the left side and “start” means the start of the line, which is typically the right side. The value of “none” means that no text should flow around the image. The default value is “none”.

The `clearFloats` property controls the placement of the paragraph elements relative to the `float`. For example, if you want to ensure that a second paragraph after a floating image starts below the image, you might set `clearFloats` on the second paragraph to “both” or “left”, as the following example shows:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/TLFClearFloats.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:HGroup>
        <s:Label text="clearFloats for second paragraph (default:none):"/>
        <s:ComboBox id="cb1"
            change="p2.clearFloats = cb1.selectedItem"
            creationComplete="cb1.selectedIndex=0">
            <s:ArrayCollection>
                <fx:String>none</fx:String>
                <fx:String>left</fx:String>
                <fx:String>right</fx:String>
                <fx:String>start</fx:String>
                <fx:String>end</fx:String>
                <fx:String>both</fx:String>
            </s:ArrayCollection>
        </s:ComboBox>
    </s:HGroup>
    <s:RichEditableText id="myRET1" width="300" height="400">
        <s:textFlow>
            <s:TextFlow columnWidth="275">
                <s:p id="p0" fontWeight="bold">Heading 1</s:p>
              <s:p id="p1">Images in a flow are a good thing. <s:img id="image1" float="left"
source="@Embed(source='../assets/bulldog.jpg')" paddingRight="10" paddingTop="10"
paddingBottom="10" paddingLeft="10"></s:img> You can use the ComboBox to change the clearFloats
value on the second paragraph ("Heading 2"). This should ensure that Heading 2 starts on a new
line after the image.</s:p>
                <s:p id="p2" fontWeight="bold">Heading 2</s:p>
            </s:TextFlow>
        </s:textFlow>
    </s:RichEditableText>

</s:Application>
```

You use the constants defined by the flashx.textLayout.formats.ClearFloats class to set the value of the `clearFloats` property. The values "left" and "right" indicate that the new paragraph should be placed after any float that appears on the left or right. As with the `float` property, the "start" and "end" values are dependent on the direction of the text in the paragraph. A value of "both" causes text to appear after all floats. A value of "none" lets the text appear next to the float. The default value is "none".

Note that you can also set the `clearFloats` property as a style on the TLF-based text controls such as RichEditableText and Spark TextArea. This style property is inheritable, which means that all child flow elements will inherit the value you set on the control.

To further customize the location of images within text blocks, you can apply the padding properties (`paddingTop`, `paddingBottom`, `paddingRight`, and `paddingLeft`) to any FlowElement object, including an InlineGraphicElement object such as an image. This lets you control the offset of the image from the margin as well as the offset between the image and the text that wraps around it. For more information, see Using padding in TLF.

TLF Floats

Adding hyperlinks with TLF

TLF-based text controls support hyperlinks with the LinkElement class. To insert a hyperlink into the TextFlow, you use the `<a>` tag in a `<s:textFlow>` tag or the default property, or create an instance of the LinkElement class.

You can only use hyperlinks in a TextFlow object in the TextArea and RichEditableText controls. The Spark Label, TextInput, and RichText controls do not support hyperlinks.

The default behavior of a LinkElement object in the text object model is to launch a new browser window and navigate to the location specified in the `href` property of the LinkElement object. The following example shows a basic navigation link:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/SimpleLinkElement.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
        <s:RichEditableText id="richTxt"
            editable="false"
            focusEnabled="false">
            <s:textFlow>
                <s:TextFlow>
                    <s:p>
                        The following link takes you to: <s:a
href="http://www.adobe.com">Adobe.com</s:a>
                    </s:p>
                </s:TextFlow>
            </s:textFlow>
        </s:RichEditableText>
        <s:RichEditableText id="richTxt2"
            editable="true"
            focusEnabled="false">
            <s:textFlow>
                <s:TextFlow>
                    <s:p>
                        Hold CTRL key down when using the following link: <s:a
href="http://www.adobe.com">Adobe.com</s:a>
                    </s:p>
                </s:TextFlow>
            </s:textFlow>
        </s:RichEditableText>

</s:Application>
```

To ensure that your links use the hand cursor when the user mouses over them, set the `editable` property to `false` on the RichEditableText object. If you do not, then your user must hold the Control key down while moving the cursor over the link to be able to click on that link.

The LinkElement is the only flow element that supports Flex events. Supported events include `click`, `mouseDown`, and `rollOut`.

While the default behavior of the LinkElement object is to launch a new browser window and open the specified link as a new page, you can also define a custom event handler for the `click` event. The easiest way to do this is to exclude the `href` attribute from the anchor tag.

The following example defines custom behavior for the `click` event of the LinkElement object. It does not specify a destination link in the LinkElement, but instead builds one in the `click` event handler:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/CustomLinkElement.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import flashx.textLayout.events.FlowElementMouseEvent;
            import mx.collections.ArrayCollection;

            [Bindable]
            public var myArray:ArrayCollection = new ArrayCollection(["Flex", "Flash",
"ActionScript"]);
            private function handleClickEvent(e:FlowElementMouseEvent):void {
               var url:String = "http://www.google.com/search?q=" + productList.selectedItem;
                navigateToURL(new URLRequest(url), '_blank');
            }
        ]]>
    </fx:Script>
    <s:RichEditableText id="richTxt"
        editable="false"
        focusEnabled="false">
        <s:textFlow>
            <s:TextFlow>
                <s:p>
                 Search for product info on <s:a click="handleClickEvent(event)">Google</s:a>
                </s:p>
            </s:TextFlow>
        </s:textFlow>
    </s:RichEditableText>
    <s:ComboBox id="productList" dataProvider="{myArray}" prompt="Select one"/>

</s:Application>
```

You can also suppress the click event in the event handler by calling the `stopPropagation()` and `preventDefault()` methods in the `click` event's handler.

The `stopPropagation()` method prevents processing of any event listeners in nodes subsequent to the current node in the event flow. The `preventDefault()` method cancels the event's default behavior.

You can then access properties of the LinkElement object to carry out additional actions. The following example presents the user with an option of navigating to the target location or cancelling the action:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/CustomLinkElementHandling.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        import flashx.textLayout.events.FlowElementMouseEvent;
        import flashx.textLayout.elements.LinkElement;
        import mx.controls.Alert;
        import mx.events.CloseEvent;

        private var linkTarget:String;

        private function doSomething(e:FlowElementMouseEvent):void {
            e.stopImmediatePropagation();
            e.preventDefault();
            var le:LinkElement = e.flowElement as LinkElement;
            linkTarget = le.href;
            Alert.show("You are about to navigate away from this page.","Alert",Alert.OK |
Alert.CANCEL, this, alertListener, null, Alert.OK);
        }
        private function alertListener(e:CloseEvent):void {
            if (e.detail == Alert.OK) {
                navigateToURL(new URLRequest(linkTarget), '_self')
            }
        }
    </fx:Script>
        <s:RichEditableText id="richTxt"
            editable="false"
            focusEnabled="false">
            <s:textFlow>
                <s:TextFlow>
                    <s:p>
                        The following link takes you to: <s:a href="http://www.adobe.com"
target="_blank" click="doSomething(event)">Adobe.com</s:a>
                    </s:p>
                </s:TextFlow>
            </s:textFlow>
        </s:RichEditableText>

</s:Application>
```

The default styling for a LinkElement is underlined, blue text. To style the links in TLF, you can use a SpanElement object and set style properties on that. The following example removes the underline, and makes the link color red rather than blue:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/StyledLinkElement.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
        <s:RichEditableText id="richTxt"
            editable="false"
            focusEnabled="false">
            <s:textFlow>
                <s:TextFlow>
                    <s:p>
                    The following link takes you to: <s:a href="http://www.adobe.com"><s:span
color="0xFF0066" textDecoration="none">Adobe.com</s:span></s:a>
                    </s:p>
                </s:TextFlow>
            </s:textFlow>
        </s:RichEditableText>
</s:Application>
```

You can also use the TextLayoutFormat class to style hyperlinks. For more information, see "Applying styles with the TextLayoutFormat class" on page 789.

TLF FlowElement and LinkElement Events and EventMirrors

Styling TLF-based text controls

The Spark text controls TextInput, TextArea, Label, RichText, and RichEditableText support specifying default text formatting with CSS styles. The complete set of styles supports all of TLF's formatting capabilities, including kerning and bidirectionality.

The names and descriptions of the styles supported by the TLF text controls are the described in the TextLayoutFormat and SelectionFormat classes.

The default values for these styles is defined by the `global` selector in the defaults.css file. This file is compiled into the framework.swc file. To change the values of the defaults, you can create your own global selector; for example:

```
<fx:Styles>
    global {
        fontFamily: "Verdana"
    }
</fx:Style>
```

TLF's FlowElement tags such as `<p>` and `<span>`, which are supported in the content of the RichText or RichEditableText controls, support formatting only with properties, not using CSS. As a result, to set styles on individual flow elements, you must set them as you would set a style property, but not in CSS.

The following example shows setting style properties on the paragraphs. It shows you that you can set the style properties either with the `setStyle()` method or as a property assignment.

```
<?xml version="1.0"?>
<!-- sparktextcontrols/TLFStylesProperties.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        import flashx.textLayout.elements.*;

        private function initApp():void {
            // You cannot set these properties in CSS.

            // Set color of first paragraph to red with the setStyle() method.
            myRET.textFlow.getChildAt(0).setStyle("color", 0xFF0000);
            // Set color of second paragraph to green with a property assignment.
            myRET.textFlow.getChildAt(1).color = 0x00FF00;
        }
    </fx:Script>

    <s:RichEditableText id="myRET" height="100" width="200">
        <s:p id="p1">This is paragraph 1.</s:p>
        <s:p id="p2">This is paragraph 2.</s:p>
    </s:RichEditableText>

    <s:Button click="initApp()" label="Apply Styles"/>
</s:Application>
```

The RichText and RichEditableText controls support additional style properties that Label does not. These properties include properties related to columns and paragraphs, including `columnCount`, `columnGap`, `paragraphSpaceAfter`, `paragraphStartIndent`, and `whiteSpaceCollapse`.

The RichEditableText control supports style properties that are not supported by the Label and RichText controls. These properties include `selectionColor`, `inactiveSelectionColor`, and `unfocusedSelectionColor`.

Style inheritance

Some styles are inheriting, meaning that if you set them on a container they affect the children of that container. Generally, the choice of whether a CSS style is inheriting or non-inheriting is made based on whether the corresponding TLF format inherits from the parent FlowElement to the child FlowElement.

The following example shows an inheriting style and a non-inheriting style set on the Button control. The inheriting style, `color`, is applied to the text, but the non-inheriting style, `backgroundColor`, is not.

```
<?xml version="1.0"?>
<!-- sparktextcontrols/TLFStyles.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Style>
        @namespace s "library://ns.adobe.com/flex/spark";

        s|Button {
            color: red;
            backgroundColor: #33CC99;
        }
    </fx:Style>
    <s:Button label="Click Me"/>
</s:Application>
```

Because a skinnable component is a type of Spark container, inheriting styles are inherited by children of the container. If you set an inheriting style such as `fontSize` on a Spark Button, for example, the style is applied to the Label class that renders the Button's label. The Label control is defined in the ButtonSkin class. The parts that make up a larger component are known as subcomponents. If you set a non-inheriting style such as `backgroundColor` it will not affect the Label subcomponent of a Button; instead you can create a custom type selector for Label, or you can reskin the Button and set the value of the `backgroundColor` property directly on the Label.

To set the value of a non-inheriting style property on the Button's label, you can set the value of the `backgroundColor` property in a Label type selector. The following example sets the `backgroundColor` style to #33CC99 for the Label type, which affects the way the Button control's label is rendered because the Label class is a subcomponent of Button:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/TLFStylesSubComps.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Style>
        @namespace s "library://ns.adobe.com/flex/spark";

        s|Button {
            color: red;
        }

        s|Label {
            backgroundColor: #33CC99;
        }
    </fx:Style>
    <s:Button label="Click Me"/>
</s:Application>
```

For the TextArea and TextInput controls, the text is rendered by a RichEditableText subcomponent. You can access the RichEditableText subcomponent by casting the result of the `textDisplay` property to a type that supports the `setStyle()` method. You can then call the `setStyle()` method on this object, which applies non-inheritable style properties to the subcomponent.

Note that this technique does not work for mobile versions of the TextArea and TextInput controls because the mobile skins do not include support for the RichEditableText subcomponent. For more information on using TLF-based text controls with mobile applications, see Text controls.

The following example illustrates the difference between correctly and incorrectly applying a non-inheriting style property to a pair of TextArea controls:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/TextAreaStyling.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark" creationComplete="doSomething()">
    <fx:Script>
        import spark.components.RichEditableText;

        private function doSomething():void {
            /* To set a non-inheritable style on a TextArea, you must actually
               apply it to the underlying RichEditableText subcomponent, which is
               accessed through the textDisplay property: */
            RichEditableText(text1.textDisplay).setStyle("columnCount", 2);
            /* Setting a non-inheritable style directly on the TextArea does
               not apply the style properly. */
            text2.setStyle("columnCount", 2);
        }

    </fx:Script>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <s:TextArea id="text1" width="200" height="100">
        <s:textFlow>
            <s:TextFlow>
              <s:p>This is TextArea #1. This is enough text to ensure that there will be more
than one column if the columnCount property is properly applied.</s:p>
            </s:TextFlow>
        </s:textFlow>
    </s:TextArea>
    <s:TextArea id="text2" width="200" height="100">
        <s:textFlow>
            <s:TextFlow>
              <s:p>This is TextArea #2. This is enough text to ensure that there will be more
than one column if the columnCount property is properly applied.</s:p>
            </s:TextFlow>
        </s:textFlow>
    </s:TextArea>
</s:Application>
```

You can also change the number of columns in a TextFlow object by setting the `columnCount` property on the `<s:TextFlow>` tag, as the following example shows:

```
<s:TextFlow columnCount="2">
```

Applying styles with the TextLayoutFormat class

To style TLF-based text controls, you can also use the TextLayoutFormat class. You begin by creating an instance of the TextLayoutFormat class. You can then set any formatting properties on that object, including paragraph indentation, leading, justification, and typographic case. Finally, you specify the custom TextLayoutFormat with the TextFlow object's `hostFormat` property.

The following example sets various styles on the text:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/TextLayoutFormatExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp()">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        import flashx.textLayout.formats.*;

        private function initApp():void {
            var textLayoutFormat:TextLayoutFormat = new TextLayoutFormat();
            textLayoutFormat.color = 0x336633;
            textLayoutFormat.fontFamily = "Arial, Helvetica, _sans";
            textLayoutFormat.fontSize = 14;
            textLayoutFormat.paragraphSpaceBefore = 15;
            textLayoutFormat.paragraphSpaceAfter = 15;
            textLayoutFormat.typographicCase = TLFTypographicCase.LOWERCASE_TO_SMALL_CAPS;
            textFlow.hostFormat = textLayoutFormat;

        }
    </fx:Script>
        <s:RichEditableText id="richTxt"
            editable="false"
            focusEnabled="false">
            <s:textFlow>
                <s:TextFlow id="textFlow">
                    <s:p>
                        The following link takes you to <s:a
href="http://www.adobe.com">Adobe.com</s:a>
                    </s:p>
                    <s:p>
                        The following link takes you to <s:a
href="http://www.omniture.com">Omniture.com</s:a>
                    </s:p>
                </s:TextFlow>
            </s:textFlow>
        </s:RichEditableText>
</s:Application>
```

You can define a TextLayoutFormat object inline, rather than in ActionScript. The following example defines TextLayoutFormat objects that style the hyperlink, based on its state:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/StyledLinkElement2.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:RichEditableText id="richTxt"
        editable="false"
        focusEnabled="false">
        <s:textFlow>
            <s:TextFlow>
                <s:p>
                    <s:linkHoverFormat>
                        <s:TextLayoutFormat color="#33CC00" textDecoration="underline"/>
                    </s:linkHoverFormat>
                    <s:linkNormalFormat>
                        <s:TextLayoutFormat color="#009900"/>
                    </s:linkNormalFormat>
                    <s:a href="http://www.adobe.com">Adobe.com</s:a>
                </s:p>
            </s:TextFlow>
        </s:textFlow>
    </s:RichEditableText>
</s:Application>
```

Applying styles with the Configuration class

Another approach to styling TLF is to use the Configuration class. This class provides access to some properties of text, such as its state. For example, you can use this class to define the appearance of a hyperlink when it is active or when it is hovered over. You can also use this class to define the appearance of text when it is selected.

To use a Configuration object with TLF, you define the styles on the TextLayoutFormat or SelectionFormat objects and assign them to the Configuration object's format properties.

The format properties include the following:

- `defaultLinkActiveFormat`
- `defaultLinkHoverFormat`
- `defaultLinkNormalFormat`
- `focusedSelectionFormat`
- `inactiveSelectionFormat`
- `textFlowInitialFormat`
- `unfocusedSelectionFormat`

The following example defines the appearance of the hyperlink by using custom TextLayoutFormat objects attached to a Configuration object:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- sparktextcontrols/StylingWithConfig.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
               xmlns:s="library://ns.adobe.com/flex/spark"
               creationComplete="initApp()">
    <fx:Script>
        <![CDATA[
            import flashx.textLayout.conversion.TextConverter;
            import flashx.textLayout.elements.Configuration;
            import flashx.textLayout.elements.IConfiguration;
            import flashx.textLayout.formats.ITextLayoutFormat;
            import flashx.textLayout.formats.TextDecoration;
            import flashx.textLayout.formats.TextLayoutFormat;
            private function initApp():void {
                var txt:String = "Check out our website at <a
href='http://www.adobe.com/'>adobe.com</a>.";
                var cfg:Configuration = new Configuration(true);
                var normalFmt:TextLayoutFormat = new
TextLayoutFormat(cfg.defaultLinkNormalFormat);
                normalFmt.color = 0xFF0000; // red
                normalFmt.textDecoration = TextDecoration.NONE;
            var hoverFmt:TextLayoutFormat = new TextLayoutFormat(cfg.defaultLinkHoverFormat);
                hoverFmt.color = 0xFF00FF; // purple
                hoverFmt.textDecoration = TextDecoration.UNDERLINE;
                cfg.defaultLinkNormalFormat = normalFmt;
                cfg.defaultLinkHoverFormat = hoverFmt;
                rt.textFlow = TextConverter.importToFlow(txt,
TextConverter.TEXT_FIELD_HTML_FORMAT, cfg);
            }
        ]]>
    </fx:Script>

    <s:RichEditableText id="rt" x="20" y="20" editable="false"/>

</s:Application>
```

Skinning TLF-based text controls

You do not typically add skins or chrome to the Spark text controls.

The Label, RichText, and RichEditableText Spark text controls are used in the skins of skinnable components. Because each has a different set of features, you can use the lightest weight text control that meets your needs.

For example, the default skin of a Spark Button uses the Label class to render the label of the Button. If you have a Button that requires rich text, you can sometimes replace the Label control in its skin with a RichText control.

The default skins of the Spark TextInput and TextArea controls use a RichEditableText control to provide an area in which text can be edited. The border and background are provided by a Rect class, and the scrollbars by a Scroller class.

For more information on skinning Spark controls, see “Spark Skinning” on page 1602.

Mirroring and bidirectional text

Some languages, such as Hebrew and Arabic, read from right to left. However, those languages often include text from other languages that read from left to right. Most of a sentence in Hebrew, for example, might read from right to left, but it might include English words that are read from left to right. This makes it necessary for Flex controls to support bidirectional text.

To use bidirectional text in a TLF text-based control, use the `direction` style.

Bidirectional text lets you render text from left-to-right (LTR) or right-to-left (RTL). You can embed RTL text inside an LTR block so that portions of a paragraph render LTR and portions render RTL. There is a dominant direction for the entire paragraph, but parts of the paragraph can be read in the opposite direction, and this can be nested.

The following simple example embeds a small amount of Hebrew text in a text control, and sets the `direction` style to `rtl`. The text is written and stored using the UTF-8 encoding.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- sparktextcontrols/RTLHebrewExample.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
        xmlns:s="library://ns.adobe.com/flex/spark"
        xmlns:mx="library://ns.adobe.com/flex/mx">
        <s:layout><s:VerticalLayout/></s:layout>
    <s:Graphic>
       <s:Label direction="rtl" text="???? ??????? ????? ????? ??????  This is a Hebrew test"
width="100" height="100"/>
    </s:Graphic>
</s:Application>
```

The following example includes English and two examples of RTL text (Hebrew and Arabic). The text is defined as Unicode characters, which makes it easier to follow. You can click the button to toggle the RichEditableText control from RTL to LTR.

```
<?xml version="1.0"?>
<!-- sparktextcontrols/RTLTest.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"

           U+05B6,
           U+05E8,
           U+0645,      /* The necessary Arabic letters */
           U+062F,
           U+0631,
           U+0633,
           U+0629;
     }
     s|RichText {
        fontFamily: myFontFamily;
        fontSize: 32;
        paddingTop: 10;
     }
  </fx:Style>

  <fx:Script>
  import flashx.textLayout.formats.*;
  import spark.utils.TextFlowUtil;
    private function addText():void {
        myRT.textFlow = TextFlowUtil.importFromString("school is written " +
            String.fromCharCode(0x0645, 0x062f, 0x0631, 0x0633, 0x0629) +
           " in Arabic and " + String.fromCharCode(0x05E1, 0x05B5, 0x05E4, 0x05B6, 0x05E8) +
            " in Hebrew.");
    }
    private function mirrorText():void {
        if (myRT.getStyle("direction")=="ltr") {
            myRT.setStyle("direction", flashx.textLayout.formats.Direction.RTL);
        } else {
            myRT.setStyle("direction", flashx.textLayout.formats.Direction.LTR);
        }
    }
  </fx:Script>
  <s:Panel title="RTL and LTR with embedded font">
        <s:RichText id="myRT" width="400" height="150"/>
  </s:Panel>
  <s:Button click="mirrorText()" label="Toggle Direction"/>
</s:Application>
```

Mirroring refers to laying the chrome of a component, or an entire application, out in one direction and then display in the opposite direction. For example, a mirrored TextArea would have its vertical scrollbar on the left. A mirrored Tree would have its disclosure triangles on the right. A mirrored HGroup would have its first child on the right, and a mirrored TabBar would have its first tab on the right. Mirroring can apply to subcomponents as well as chrome. For example, a mirrored RadioButton would have its label on the left side instead of the right side (the default).

Mirroring of components complement bidirectional text by having the application and components reflect the text direction.

Using numbered and bulleted lists with TLF-based text controls

You can use the ListElement and ListItemElement classes to add bulleted lists to your text controls. The bulleted lists can be nested and can be customized to use different bullets (or markers) and auto-numbering.

To create lists in your applications, use the `<s:list>` tag inside a text control that uses TLF. You then use `<s:li>` tags within the `<s:list>` tag for each list item in the list. You can customize the appearance of the bullets by using the ListMarkerFormat class.

The following example creates simple lists:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/TLFLists.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <!-- Simple bulleted list. -->
    <s:RichEditableText id="myRET1" width="200">
        <s:p>Simple bulleted list:</s:p>
        <s:list id="list1" listStylePosition="outside">
            <s:li>Item 1</s:li>
            <s:li>Item 2</s:li>
            <s:li>Item 3</s:li>
        </s:list>
    </s:RichEditableText>
    <!-- Nested bulleted list. -->
    <s:RichEditableText id="myRET2" width="200">
        <s:p>Nested bulleted list:</s:p>
        <s:list id="list2">
            <s:li>Dry cleaning</s:li>
            <s:li>Groceries
                <s:list id="list1a">
                    <s:li>Quart of milk</s:li>
                    <s:li>Loaf of bread</s:li>
                    <s:li>Stick of butter</s:li>
                </s:list>
            </s:li>
            <s:li>Oil change
                <s:list id="list1b">
                    <s:li>Item 1b</s:li>
                </s:list>
            </s:li>
        </s:list>
    </s:RichEditableText>
    <!-- Custom spacing list. -->
    <s:RichEditableText id="myRET3" width="200">
        <s:p>List with custom indents:</s:p>
        <s:list id="list3" paddingLeft="20">
            <s:li>Dry cleaning</s:li>
            <s:li>Groceries
                <s:list id="list31" paddingLeft="20">
                    <s:li>Quart of milk</s:li>
                    <s:li>Loaf of bread</s:li>
                    <s:li>Stick of butter</s:li>
                </s:list>
            </s:li>
            <s:li>Item 3</s:li>
        </s:list>
    </s:RichEditableText>
    <!-- Custom styled list. -->
    <s:RichEditableText id="myRET4" width="200">
        <s:p>Styled bulleted list:</s:p>
        <s:list id="list4" listStylePosition="inside">
            <s:listMarkerFormat>
                <s:ListMarkerFormat fontSize="14" fontWeight="bold" color="0xFF0066" 
afterContent=" "/>
            </s:listMarkerFormat>
            <s:li>Quart of milk</s:li>
            <s:li>Loaf of bread</s:li>
            <s:li>Stick of butter</s:li>
        </s:list>
    </s:RichEditableText>
</s:Application>
```

To change the type of marker or use numbering in the list, use the `listStyleType` property of the ListElement. This property can be any value defined by the ListStyleType class (such as `check`, `circle`, `decimal`, and `box`). The following example creates lists with various marker types and a custom increment:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/TLFListsCustomBullets.mxml -->
<s:Application 
    xmlns:fx="http://ns.adobe.com/mxml/2009" 
    xmlns:mx="library://ns.adobe.com/flex/mx" 
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <!-- Custom bullets lists. -->
    <s:RichEditableText id="myRET1" width="200">
        <s:p>Lists with custom bullets:</s:p>
        <s:p>Box:</s:p>
        <s:list id="list1" listStyleType="box">
            <s:li>Quart of milk</s:li>
            <s:li>Loaf of bread</s:li>
        </s:list>
        <s:p>Decimal:</s:p>
        <s:list id="list2" listStyleType="decimal">
            <s:li>Quart of milk</s:li>
            <s:li>Loaf of bread</s:li>
        </s:list>
        <s:p>Check:</s:p>
        <s:list id="list3" listStyleType="check">
            <s:li>Quart of milk</s:li>
            <s:li>Loaf of bread</s:li>
        </s:list>
        <s:p>Nested Roman:</s:p>
        <s:list id="list4" listStyleType="upperRoman">
            <s:li>Item 1
```

```
                <s:list id="list41" listStyleType="lowerRoman">
                    <s:li>Quart of milk</s:li>
                    <s:li>Loaf of bread</s:li>
                </s:list>
            </s:li>
            <s:li>Item 2</s:li>
        </s:list>
    </s:RichEditableText>

    <!-- List with custom increment. -->
    <s:RichEditableText id="myRET2" width="200">
        <s:p>List with countdown:</s:p>
        <s:list id="list5" listStyleType="decimal">
            <s:listMarkerFormat>
                <!-- Increments the list by 2s rather than 1s. -->
                <s:ListMarkerFormat counterIncrement="ordered 2"/>
            </s:listMarkerFormat>
            <s:li>Quart of milk
                <s:listMarkerFormat>
                    <!-- Causes counter to start at 10. -->
                    <s:ListMarkerFormat counterReset="ordered 9"/>
                </s:listMarkerFormat>
            </s:li>
            <s:li>Loaf of bread</s:li>
            <s:li>Stick of butter</s:li>
        </s:list>
    </s:RichEditableText>
</s:Application>
```

You can further customize the appearance of the markers in your lists by using the ListMarkerFormat class to define "before" and "after" content. This is content that appears before and after the content of the marker.

The following example adds the word "Chapter" before the marker, and a colon after the marker. The marker, or content, is ordered upper-case Roman numerals.

```
<?xml version="1.0"?>
<!-- sparktextcontrols/TLFListsBeforeAfter.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <!-- Before/After content. -->
    <s:RichEditableText id="myRET" width="500">
        <s:p>List with Before/After content:</s:p>
        <s:list id="myList" paddingLeft="10" listStylePosition="inside">
            <s:listMarkerFormat>
            <!-- Note that this example inserts an empty string with &quote; HTML entities. -->
                <s:ListMarkerFormat
                    beforeContent="Chapter "
                    content="counters(ordered,&quot;&quot;,upperRoman)"
                    afterContent=": "/>
            </s:listMarkerFormat>
            <s:li>Beginning</s:li>
            <s:li>Middle</s:li>
            <s:li>End</s:li>
        </s:list>
        <s:list id="myList2" paddingLeft="10" listStylePosition="inside">
            <s:listMarkerFormat>
                <s:ListMarkerFormat
                    beforeContent="*BEFORE*"
                    content="counters(ordered,&quot;*SUFFIX*&quot;,upperRoman)"
                    afterContent="*AFTER*"/>
            </s:listMarkerFormat>
            <s:li>Beginning</s:li>
            <s:li>Middle</s:li>
            <s:li>End</s:li>
        </s:list>
    </s:RichEditableText>
</s:Application>
```

As the previous example shows, you can use the `content` property to insert a suffix: a string that appears after the marker, but before the `afterContent`. To insert this string when providing XML content to the flow, wrap the string in `&quote;` HTML entities rather than quotation marks (`"<`*`string`*`>"`). The previous example inserted an empty string.

TLF 2.0 Lists Markup

Using prompts with text controls

The Spark TextInput and TextArea controls support a `prompt` property that lets you specify text that helps users know what to enter. For example, an input field might include prompt text that says "Search".

Prompt text appears when the text control is first created. Prompt text disappears when the control gets focus or when the control's `text` property is non-null. Prompt text reappears when the control loses focus, but only if no text was entered (if the value of the text field is the empty string).

For text controls, if the user enters text, but later deletes it, the prompt text reappears when the control loses focus. You can also cause the prompt text to reappear programmatically by setting the text control's text property to `null` or the empty string.

The following example creates a TextInput and TextArea control with prompt text. You can focus on the text controls and enter text, which causes the prompt text to disappear. If you click the Reset button, the prompt text reappears.

```
<?xml version="1.0"?>
<!-- sparktextcontrols/BasicPromptExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

  <fx:Script>
    <![CDATA[
        /* If you reset the text properties of the TextInput and TextArea controls to null
            or the empty string, the prompt text reappears. */
        private function resetPrompts():void {
            myTextInput.text = "";
            myTextArea.text = "";
        }
      ]]>
  </fx:Script>

    <s:TextInput id="myTextInput" prompt="Enter name..."/>
    <s:TextArea id="myTextArea" prompt="Enter details..."/>
    <s:Button label="Reset" click="resetPrompts()"/>

</s:Application>
```

The Spark ComboBox control also supports the `prompt` property because it uses the Spark TextInput control as a subcontrol. For more information, see "Use prompt text with the Spark ComboBox control" on page 542.

Text prompt styles

The default prompt styles are defined in the current theme's default style sheet. By default, the prompt text is gray and italicised. The style of the prompt text is defined by the text control's pseudo selectors.

Pseudo selectors let you apply styles to a component based on its current state. For example, if your TextInput control has prompt text and is not disabled, the style is defined by the `normalWithPrompt` pseudo selector because it is in the `normalWithPrompt` state. If the control is disabled, then the styles defined by the `disabledWithPrompt` pseudo selector are used.

You can change the prompt text styles by overriding the default CSS. The following example changes the prompt text styles by defining different behavior for the `normalWithPrompt` and `disabledWithPrompt` pseudo selectors for the TextInput and TextArea controls:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/StylingPrompts.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Style>
        @namespace s "library://ns.adobe.com/flex/spark";
        s|TextInput:normalWithPrompt {
            color: #CCCCFF;
            fontStyle: italic;
        }
        s|TextArea:normalWithPrompt {
            color: #CCCCFF;
            fontStyle: italic;
        }
        s|TextInput:disabledWithPrompt {
            color: #CCFFFF;
            fontStyle: italic;
        }
        s|TextArea:disabledWithPrompt {
            color: #CCFFFF;
            fontStyle: italic;
        }
    </fx:Style>

  <fx:Script>
    <![CDATA[
        private function resetPrompts():void {
            myTextInput.text = "";
            myTextArea.text = "";
        }

        /* Disabling the controls causes the disabledWithPrompt pseudo selector to be used
            instead of the normalWithPrompt pseudo selector. */
        private function disableControls():void {
            if (myTextInput.enabled) {
                myTextInput.enabled = false;
                myTextArea.enabled = false;
            } else {
                myTextInput.enabled = true;
                myTextArea.enabled = true;
            }
        }
      ]]>
  </fx:Script>

    <s:TextInput id="myTextInput" prompt="Enter name..."/>
    <s:TextArea id="myTextArea" prompt="Enter details..."/>

    <s:HGroup>
        <s:Button label="Reset" click="resetPrompts()"/>
        <s:Button label="Toggle Enabled/Disabled" click="disableControls()"/>
    </s:HGroup>
</s:Application>
```

In general, you should avoid setting the prompt text to be larger or smaller than the regular text in the text control. Unless you explicitly define the height and width of the control, the text control's size will grow or shrink as the size of the text or prompt text grows and shrinks.

To simplify your CSS you can also define text prompt styles on the SkinnableTextBase type selector. Styles set on this selector will apply to the TextArea and TextInput controls, as the following example shows:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/SimplerStylingPrompts.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Style>
        @namespace s "library://ns.adobe.com/flex/spark";
        s|SkinnableTextBase:normalWithPrompt {
            color: #CCCCFF;
            fontStyle: italic;
        }
        s|SkinnableTextBase:disabledWithPrompt {
            color: #CCFFFF;
            fontStyle: italic;
        }
    </fx:Style>

  <fx:Script>
    <![CDATA[
        private function resetPrompts():void {
            myTextInput.text = "";
            myTextArea.text = "";
        }
        /* Disabling the controls causes the disabledWithPrompt pseudo selector to be used
            instead of the normalWithPrompt pseudo selector. */
        private function disableControls():void {
            if (myTextInput.enabled) {
                myTextInput.enabled = false;
                myTextArea.enabled = false;
            } else {
                myTextInput.enabled = true;
                myTextArea.enabled = true;
            }
        }
      ]]>
  </fx:Script>

    <s:TextInput id="myTextInput" prompt="Enter name..."/>
    <s:TextArea id="myTextArea" prompt="Enter details..."/>

    <s:HGroup>
        <s:Button label="Reset" click="resetPrompts()"/>
        <s:Button label="Toggle Enabled/Disabled" click="disableControls()"/>
    </s:HGroup>
</s:Application>
```

Text prompt skins and transitions

The prompt text of the TextArea and TextInput controls is implemented as a Label control on the skins. The prompt text is defined in the skin as a skin part named `promptDisplay`. You can change the behavior and appearance of the prompt text by creating custom skins for those controls.

Typically, you copy the text control's skin class (for example, the TextInputSkin class) and customize it. You then apply the new skin class by pointing the `skinClass` property on the text control to your new skin.

The following example uses a custom skin called CustomTextInputSkin:

```
<?xml version="1.0"?>
<!-- sparktextcontrols/CustomPromptExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <fx:Script>
    <![CDATA[
        private function resetPrompts():void {
            myTextInput.text = "";
        }
      ]]>
  </fx:Script>

    <s:TextInput id="myTextInput" prompt="Enter name..."
        skinClass="mySkins.CustomTextInputSkin"/>
    <s:Button label="Reset" click="resetPrompts()"/>
</s:Application>
```

The following custom skin adds a transition to the prompt text when the state changes to `normalWithPrompt`. Most of the skin is directly copied from the original TextInputSkin class. The only new code is the `<s:transitions>` block near the bottom of the example. When you enter some text, and then click the Reset button, you should notice that the prompt text fades in.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- sparktextcontrols\mySkins\CustomTextInputSkin.mxml -->
<s:SparkSkin xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:fb="http://ns.adobe.com/flashbuilder/2009"
    alpha.disabledStates="0.5" blendMode="normal">
    <fx:Metadata>

MX text controls

MX text controls in an Adobe® Flex® application can display text, let the user enter text, or do both.

Flex defines two sets of components: Spark and MX. The Spark components are new for Flex 4 and are defined in the spark.* packages. The MX components shipped in previous releases of Flex and are defined in the mx.* packages.

Even though you can use both component sets in a single application, Adobe recommends using the Spark component set where possible. For information about the Spark text controls, see “Spark text controls” on page 734.

About MX text controls

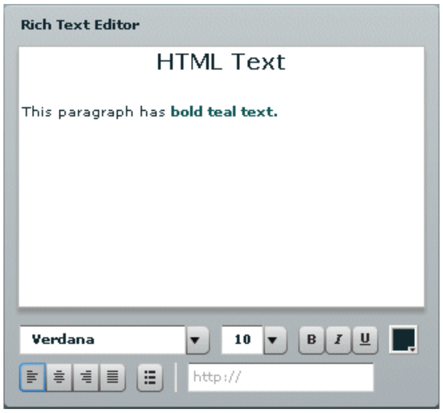
You use Flex text-based controls to display text and to let users enter text into your application. The following table lists the controls, and indicates whether the control can have multiple lines of input instead of a single line of text, and whether the control can accept user input:

MX Control	Multiline	Allows user Input
Label	No	No
TextInput	No	Yes
Text	Yes	No
TextArea	Yes	Yes
RichTextEditor	Yes	Yes

All controls except the RichTextEditor control are single components with a simple text region. For example, the following code creates an MX TextInput control in a simple form:

```
<?xml version="1.0"?>
<!-- textcontrols/FormItemLabel.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
  <s:Form id="myForm" width="500" backgroundColor="#909090">
     <!-- Use a FormItem to label the field. -->
     <s:FormItem label="First Name">
        <s:TextInput id="ti1" width="150"/>
     </s:FormItem>
  </s:Form>
</s:Application>
```

The RichTextEditor control is a compound control; it consists of a Panel control that contains an MX TextArea control and a ControlBar with several controls for specifying the text format and HTTP links. The following image shows a RichTextEditor control:



Rich Text Editor

HTML Text

This paragraph has **bold teal text.**

The following code produces the preceding image:

```
<?xml version="1.0"?>
<!-- textcontrols/RTECDATA.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
  <mx:RichTextEditor id="rte1" title="Rich Text Editor">
     <mx:htmlText>
        <![CDATA[
           <p align='center'><b><font size='16'>HTML Text</font></b>
           This paragraph has <font color='#006666'><b>bold teal text.
           </b></font></p>
        ]]>
     </mx:htmlText>
  </mx:RichTextEditor>
</s:Application>
```

Flex text-based controls let you set and get text by using the following properties:

text Plain text without formatting information. For information on using the `text` property, see "Using the text property" on page 807.

htmlText Rich text that represents formatting by using a subset of HTML tags, and can include bulleted text and URL links. For information on using the `htmlText` property, see "Using the htmlText property" on page 810.

Both properties set the same underlying text, but you can use different formats. For example, you can do the following to set, modify, and get text:

- You can set formatted text by using the `htmlText` property, and get it back as a plain text string by using the `text` property.
- You can set formatted text in user-editable text controls (MX TextInput, TextArea, RichTextEditor) by setting the text string with the `text` property and formatting a section of this text by using the TextRange class. If you get the text back by using the `htmlText` property, the property string includes HTML tags for the formatting. For more information on using the TextRange class, see "Selecting and modifying text" on page 820.

Using the text property

You can use the text property to specify the text string that appears in a text control or to get the text in the control as a plain text String. When you set this property, any HTML tags in the text string appear in the control as literal text.

You cannot specify text formatting when you set the `text` property, but you can format the text in the control. You can use the text control styles to format all of the text in the control, and you can use the TextRange class to format ranges of text**.** **(**For more information on using the TextRange class, see "Selecting and modifying text" on page 820.)

The following code line uses a `text` property to specify label text:

```
<mx:Label text="This is a simple text label"/>
```

The way you specify special characters, including quotation marks, greater than and less than signs, and apostrophes, depends on whether you use them in MXML tags or in ActionScript. It also depends on whether you specify the text directly or wrap the text in a CDATA section.

***Note:** If you specify the value of the `text` property by using a string directly in MXML, Flex collapses white space characters. If you specify the value of the `text` property in ActionScript, Flex does not collapse white space characters.*

Specifying special characters in the text property

The following rules specify how to include special characters in the `text` property of a text control MXML tag, either in a property assignment, such as `text="the text"`, or in the body of an `<mx:text>` subtag.

In standard text The following rules determine how you use special characters if you do not use a CDATA section:

- To use the special characters left angle bracket (<), right angle bracket (>), and ampersand (&), insert the XML character entity equivalents of `&lt;`, `&gt;`, and `&amp;`, respectively. You can also use `&quot;` and `&apos;` for double-quotation marks (") and single-quotation marks ('), and you can use numeric character references, such as &#165 for the Yen mark (¥). Do not use any other named character entities; Flex treats them as literal text.
- You cannot use the character that encloses the property text string inside the string. If you surround the string in double-quotation marks ("), use the escape sequence `\"` for any double-quotation marks in the string. If you surround the string in single-quotation marks (') use the escape sequence `\'` for any single-quotation marks in the string. You *can* use single-quotation marks inside a string that is surrounded in double-quotation marks, and double-quotation marks inside a string that is surrounded in single-quotation marks.
- Flex text controls ignore escape characters such as \t or \n in the `text` property. They ignore or convert to spaces, tabs and line breaks, depending on whether you are specifying a property assignment or an `<mx:text>` subtag. To include line breaks, put the text in a CDATA section. In the Text control `text="`*string*`"` attribute specifications, you can also specify them as numeric character entities, such as &#013; for a Return character or &#009; for a Tab character, but you cannot do this in an `<mx:text>` subtag.

The following code example uses the `text` property with standard text:

```
<?xml version="1.0"?>
<!-- textcontrols/StandardText.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    height="400">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <mx:Text width="400"
    text="This string contains a less than, &lt;,
    greater than, &gt;, ampersand, &amp;, apostrophe, ', and
    quotation mark &quot;."/>
  <mx:Text width="400"
    text='This string contains a less than, &lt;,
    greater than, &gt;, ampersand, &amp;, apostrophe, &apos;, and
    quotation mark, ".'/>
  <mx:Text width="400">
     <mx:text>
        This string contains a less than, &lt;, greater than,
        &gt;, ampersand, &amp;, apostrophe, ', and quotation mark, ".
     </mx:text>
  </mx:Text>
</s:Application>
```

The resulting application contains three almost identical text controls, each with the following text. The first two controls, however, convert any tabs in the text to spaces.

```
This string contains a less than, <, greater than, >, ampersand, &,apostrophe, ', and quotation
mark, ".
```

In a CDATA section If you wrap the text string in the `CDATA` tag, the following rules apply:

- You cannot use a CDATA section in a property assignment statement in the text control opening tag; you must define the property in an `<mx:text>` child tag.
- Text inside the CDATA section appears as it is entered, including white space characters. Use literal characters, such as " or < for special characters, and use standard return and tab characters. Character entities, such as &gt;, and backslash-style escape characters, such as \n, appear as literal text.

The following code example follows these CDATA section rules. The second and third lines of text in the `<mx:text>` tag are not indented because any leading tab or space characters would appear in the displayed text.

```
<?xml version="1.0"?>
<!-- textcontrols/TextCDATA.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    width="500">

  <mx:Text width="100%">
     <mx:text>
        <![CDATA[This string contains a less than, <, greater than, >,
            ampersand, &, apostrophe, ', return,
            tab. and quotation mark, ".]]>
     </mx:text>
  </mx:Text>
</s:Application>
```

The displayed text appears on three lines, as follows:

```
This string contains a less than, <, greater than, >,
ampersand, &, apostrophe, ', return,
tab. and quotation mark, ".
```

Specifying special characters in ActionScript

The following rules specify how to include special characters in a text control when you specify the control's `text` property value in ActionScript; for example, in an initialization function, or when assigning a string value to a variable that you use to populate the property:

- You cannot use the character that encloses the text string inside the string. If you surround the string in double-quotation marks ("), use the escape sequence \" for any double-quotation marks in the string. If you surround the string in single-quotation marks ('), use the escape sequence \' for any single-quotation marks in the string.
- Use backslash escape characters for special characters, including \t for the tab character, and \n or \r for a return/line feed character combination. You can use the escape character \" for the double-quotation mark and \' for the single-quotation mark.
- In standard text, but not in CDATA sections, you can use the special characters left angle bracket (<), right angle bracket (>), and ampersand (&), by inserting the XML character entity equivalents of `&lt;`, `&gt;`, and `&amp;`, respectively. You can also use `&quot;` and `&apos;` for double-quotation marks ("), and single-quotation marks ('), and you can use numeric character references, such as `&#165;` for the Yen mark (¥). Do not use any other named character entities; Flex treats them as literal text.
- In CDATA sections only, do not use character entities or references, such as `&lt;` or &#165; because Flex treats them as literal text. Instead, use the actual character, such as <.

The following example uses an initialization function to set the `text` property to a string that contains these characters:

```
<?xml version="1.0"?>
<!-- textcontrols/InitText.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    initialize="initText()">

  <fx:Script>
     public function initText():void {
        //The following is on one line.
        myText.text="This string contains a return, \n, tab, \t, and quotation mark, \". " +
            "This string also contains less than, &lt;, greater than, &gt;, " +
            "ampersand, &amp;, and apostrophe, ', characters.";
     }
  </fx:Script>
  <mx:Text width="450" id="myText"/>
</s:Application>
```

The following example uses an `<fx:Script>` tag with a variable in a CDATA section to set the `text` property:

```
<?xml version="1.0"?>
<!-- textcontrols/VarText.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
            [Bindable]
            // The following is on one line.
          public var myText:String ="This string contains a return, \n, tab, \t, and quotation
mark, \". This string also contains less than, <, greater than, <, ampersand, <;, and
apostrophe, ', characters.";
        ]]>
    </fx:Script>
    <mx:Text width="450" text="{myText}"/>

</s:Application>
```

The displayed text for each example appears on three lines. The first line ends at the return specified by the \n character. The remaining text wraps onto a third line because it is too long to fit on a single line. (Note: Although the tab character may be noticeable in the following output, it is included in the right location.)

```
This string contains a return,
, tab, , and quotation mark, ". This string also contains less than, <,
greater than, >, ampersand, &, and apostrophe, ', characters.
```

Using the htmlText property

You use the `htmlText` property to set or get an HTML-formatted text string. You can also use one tag that is not part of standard HTML, the `textFormat` tag. For details of supported tags and attributes, see “Using tags in HTML text” on page 813.

You can also specify text formatting by using Flex styles. You can set a base style, such as the font characteristics or the text weight, by using a style, and override the base style in sections of your text by using tags, such as the `<font>` tag. In the following example, the `<mx:Text>` tag styles specify blue, italic, 14 point text, and the `<mx:htmlText>` tag includes HTML tags that override the color and point size.

```
<?xml version="1.0"?>
<!-- textcontrols/HTMLTags.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <mx:Text width="100%" color="blue" fontStyle="italic" fontSize="14">
        <mx:htmlText>
            <![CDATA[
                This is 14 point blue italic text.<br>
                <b><font color="#000000" size="10">This text is 10 point black, italic, and 
bold.</font></b>
            ]]>
        </mx:htmlText>
    </mx:Text>
</s:Application>
```

Specifying HTML tags and text

To prevent the Flex compiler from generating errors when it encounters HTML tags in the text, use one of the following techniques:

- Wrap your text in a `CDATA` tag.
- Specify HTML markup by using the `&lt;`, `&gt;`, and `&amp;` character entities in place of the left angle bracket (<), right angle bracket (>), and ampersand (&) HTML delimiters.

Adobe recommends using CDATA sections for all but simple HTML markup, because the character entity technique has significant limitations:

- Extensive HTML markup can be cumbersome to write and difficult to read.
- You must use a complex escape sequence to include the less than and ampersand characters in your text.

For example, to display the following string:

A less than character < and **bold text**.

without using a CDATA section, you must use the following text:

```
A less than character &amp;c#060; and &lt;b&gtbold text&lt;/b&gt.
```

In a CDATA section, you use the following text:

```
A less than character &lt; and <b>bold text</b>.
```

Specifying HTML text

When you specify HTML text for a text control, the following rules apply:

- You cannot use a CDATA section directly in an inline `htmlText` property in an `<mx:Text>` tag. You must put the text in an `<mx:htmlText>` subtag, or in ActionScript code.
- Flex collapses consecutive white space characters, including return, space, and tab characters, in text that you specify in MXML property assignments or ActionScript outside of a CDATA section.

- If you specify the text in a CDATA section, you can use the text control's `condenseWhite` property to control whether Flex collapses white space. By default, the `condenseWhite` property is `false`, and Flex does not collapse white space.
- Use HTML <p> and <br> tags for breaks and paragraphs. In ActionScript CDATA sections you can also use \n escape characters.
- If your HTML text string is surrounded by single- or double-quotation marks because it is in an assignment statement (in other words, if it is not in an `<mx:htmlText>` tag), you must escape any uses of that quotation character in the string:
    - If you use double-quotation marks for the assignment delimiters, use &quot; for the double-quotation mark (") character in your HTML. In ActionScript, you can also use the escape sequence \".

      ***Note:** You do not need to escape double-quotation marks if you're loading text from an external file; it is only necessary if you're assigning a string of text in ActionScript.*
    - If you use single-quotation marks for the assignment delimiters, use &apos; for the single-quotation mark character (') in your HTML. In ActionScript, you can also use the escape sequence \'.
- When you enter HTML-formatted text, you must include attributes of HTML tags in double- or single-quotation marks. Attribute values without quotation marks can produce unexpected results, such as improper rendering of text. You must follow the escaping rules for quotation marks within quotation marks, as described in "Escaping special characters in HTML text" on page 813.

The following example shows some simple HTML formatted text, using MXML and ActionScript to specify the text:

```
<?xml version="1.0"?>
<!-- textcontrols/HTMLFormattedText.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    width="500">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

  <fx:Script><![CDATA[
     //The following is on one line.
     [Bindable]
     public var myHtmlText:String="This string contains <b>less than </b>, &lt;, <b>greater
than</b>, &gt;, <b>ampersand</b>, &amp;, and <b>double quotation mark</b>, &quot;,
characters.";
  ]]></fx:Script>
  <mx:Text id="htmltext2" width="450" htmlText="{myHtmlText}" />
  <mx:Text width="450">
     <mx:htmlText>
        <!-- The following is on one line. Line breaks would appear in the output. -->
        <![CDATA[
           This string contains <b>less than</b>, &lt;, <b>greater than </b>, &gt;,
<b>ampersand</b>, &amp;, and <b>double quotation mark</b>,&quot;, characters.
        ]]>
     </mx:htmlText>
  </mx:Text>
</s:Application>
```

Escaping special characters in HTML text

The rules for escaping special characters in HTML text differ between CDATA sections and standard text.

In CDATA sections When you specify the `htmlText` string, the following rules apply:

- In ActionScript, but not in an `<mx:htmlText>` tag, you can use standard backslash escape sequences for special characters, such as \t for tab and \n for a newline character. You can also use the backslash character to escape many special characters, such as \\xd5 and \" for single- and double-quotation marks. You cannot use the combination \<, and a backslash before a return character has no effect on displayed text; it allows you to break the assignment statement across multiple text lines.
- In both ActionScript and the `<mx:htmlText>` tag, you can use HTML tags and numeric character entities; for example in place of \n, you can use a `<br>` tag.
- To include a left angle bracket (<), right angle bracket (>), or ampersand (&) character in displayed text, use the corresponding character entities: `&lt;`, `&gt;`, and `&amp;, respectively`. You can also use the `&quot;` and `&apos;` entities for single- and double-quotation marks. These are the only named character entities that Adobe® Flash® Player and Adobe® AIR™ recognize. They recognize numeric entities, such as `&#165;` for the Yen mark (¥),;however, they do not recognize the corresponding character entity, `&yen;`.

  The following code example uses the `htmlText` property to display formatted text:

```
<?xml version="1.0"?>
<!-- textcontrols/HTMLTags2.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    width="500">
  <mx:Text width="100%">
     <mx:htmlText><![CDATA[<p>This string contains a <b>less than</b>, &lt;.
        </p><p>This text is in a new paragraph.<br>This is a new line.</p>]]>
     </mx:htmlText>
  </mx:Text>
</s:Application>
```

In standard text The following rules apply:

- You must use character entities, as described in "Using the htmlText property" on page 810, to use the left angle bracket (<), right angle bracket (>), or ampersand (&) character in HTML; for example, when you open a tag or start a character entity.
- You must use the `&amp;` named entity combined with an HTML numeric character entity to display the less than character (use `&amp;#060;`) and ampersand character (use `&amp;#038;`). You can use the standard character entities, `&gt;`, `&quot;`, and `&apos;`, for the greater than, double-quotation mark and single-quotation mark characters, respectively. For all other character entities, use numeric entity combinations, such as `&amp;#165;`, for the Yen mark (¥).
- In ActionScript, but not in an `<mx:htmlText>` tag or inline `htmlText` property, you can use a backslash character to escape special characters, including the tab, newline, and quotation mark characters (but not the ampersand). In all cases, you can use (properly escaped) HTML tags and numeric character entities; for example in place of \n, you can use a `&lt;br&gt;` tag or `&amp;#013;` entity.

Using tags in HTML text

When you use the `htmlText` property, you use a subset of HTML that is supported by Flash Player and AIR, which support the following tags:

Anchor tag (<a>)

The anchor `<a>` tag creates a hyperlink and supports the following attributes:

href Specifies the URL of the page to load in the browser. The URL can be absolute or relative to the location of the SWF file that is loading the page.

target Specifies the name of the target window to load the page into.

For example, the following HTML snippet creates the link “Go Home” to the Adobe Web site.

```
<a href='http://www.adobe.com' target='_blank'>Go Home</a>
```

The `<a>` tag does *not* make the link text blue or underline the text. You must apply formatting tags to change the text format. You can do this with the `<font color="`*`color`*`">` tag and the `<u>` tag.

You can also define `a:link`, `a:hover`, and `a:active` styles for anchor tags by using the StyleSheet class, if the component supports the `styleSheet` property. This property is defined on MX TextArea and TextField controls. The following example shows how to use it on text inside an MX TextArea control:

```
<?xml version="1.0"?>
<!-- textcontrols/StyleSheetExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp()">

    <fx:Script>
        <![CDATA[
            import flash.text.StyleSheet;
            private function initApp():void {
                    var ss:StyleSheet = new StyleSheet;
                    // Define an object for the "hover" state of the "a" tag.
                    var hoverStyles:Object = new Object;
                    hoverStyles.textDecoration = "underline";
                    hoverStyles.color = "#FF00CC";
                    // Define an object for the non-hover state of the "a" tag.
                    var linkStyles:Object = new Object;
                    linkStyles.color = "#FF00CC";
                    // Apply the newly defined styles.
                    ss.setStyle("a:hover", hoverStyles);
                    ss.setStyle("a", linkStyles);
                    // Apply the StyleSheet to the TextArea control.
                    myTA.styleSheet = ss;
                }
            ]]>
    </fx:Script>

    <fx:Style>
        @namespace mx "library://ns.adobe.com/flex/mx";
        mx|TextArea {
            fontFamily:Courier;
            linkcolor:#CC3300;
        }
    </fx:Style>

    <mx:TextArea id="myTA" height="100" width="200">
        <mx:htmlText>
            <![CDATA[<a href="http://www.adobe.com">This</a> is a link.]]>
        </mx:htmlText>
    </mx:TextArea>
</s:Application>
```

The MX Label, Text, and TextArea controls can dispatch a `link` event when the user selects a hyperlink in the `htmlText` property. To generate the `link` event, prefix the hyperlink destination with `event:`, as the following example shows:

```
<?xml version="1.0"?>
<!-- textcontrols/LabelControlLinkEvent.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            import flash.events.TextEvent;
            public function linkHandler(event:TextEvent):void {
                myTA.text="The link was clicked.";

                // Open the link in a new browser window.
                navigateToURL(new URLRequest(event.text), '_blank')
            }
        ]]>
    </fx:Script>

    <mx:Label selectable="true" link="linkHandler(event);">
        <mx:htmlText>
            <![CDATA[This link lets you <a href='event:http://www.adobe.com'>Navigate to 
Adobe.com.</a>]]>
        </mx:htmlText>
    </mx:Label>
    <mx:TextArea id="myTA"/>

</s:Application>
```

The MX Label control must have the `selectable` property set to `true` to generate the `link` event.

When you use the `link` event, the event is generated and the text following `event:` in the hyperlink destination is included in the `text` property of the event object. However, the hyperlink is not automatically executed; you must execute the hyperlink from within your event handler. This allows you to modify the hyperlink, or even prohibit it from occurring, in your application.

Bold tag (<b>)

The bold `<b>` tag renders text as bold. If you use embedded fonts, a boldface font must be available for the font or no text appears. If you use fonts that you expect to reside on the local system of your users, their system may approximate a boldface font if none exists, or it may substitute the normal font face instead of boldface. In either case, the text inside the bold tags will appear.

The following snippet applies boldface to the word *bold*:

```
This word is <b>bold</b>.
```

You cannot use the `</b>` end tag to override bold formatting that you set for all text in a control by using the `fontWeight` style.

Break tag (<br>)

The break `<br>` tag creates a line break in the text. This tag has no effect in MX Label or MX TextInput controls.

The following snippet starts a new line after the word *line*:

```
The next sentence is on a new line.<br>Hello there.
```

Font tag (<font>)

The `<font>` tag specifies the following font characteristics: color, face, and size.

The font tag supports the following attributes:

color Specifies the text color. You must use hexadecimal (`#FFFFFF`) color values. Other formats are not supported.

face Specifies the name of the font to use. You can also specify a list of comma-separated font names, in which case Flash Player and AIR choose the first available font. If the specified font is not installed on the playback system, or isn't embedded in the SWF file, Flash Player and AIR choose a substitute font. The following example shows how to set the font face.

size Specifies the size of the font in points. You can also use relative sizes (for example, +2 or -4).

The following example shows the use of the `<font>tag:`

```
<?xml version="1.0"?>
<!-- textcontrols/FontTag.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

  <mx:TextArea height="100" width="250">
     <mx:htmlText>
        <![CDATA[
           You can vary the <font size='20'>font size</font>,<br><font
color="#0000FF">color</font>,<br><font face="CourierNew, Courier, Typewriter">face</font>,
or<br><font size="18" color="#FF00FF"face="Times, Times New Roman, _serif">any combination of
the three.</font>
        ]]>
     </mx:htmlText>
  </mx:TextArea>
</s:Application>
```

Image tag (<img>)

***Note:** The `<img>` tag is not fully supported, and might not work in some cases.*

The image `<img>` tag lets you embed external JPEG, GIF, PNG, and SWF files inside text fields. Text automatically flows around images you embed in text fields. This tag is supported only in dynamic and input text fields that are multiline and wrap their text.

By default, Flash displays media embedded in a text field at full size. To specify dimensions for embedded media, use the `<img>` tag's `height` and `width` attributes.

In general, an image embedded in a text field appears on the line following the `<img>` tag. However, when the `<img>` tag is the first character in the text field, the image appears on the first line of the text field.

The `<img>` tag has one required attribute, `src`, which specifies the path to an image file. All other attributes are optional.

The `<img>` tag supports the following attributes:

src Specifies the URL to a GIF, JPEG, PNG, or SWF file. This attribute is required; all other attributes are optional. External files are not displayed until they have downloaded completely.

align Specifies the horizontal alignment of the embedded image within the text field. Valid values are `left` and `right`. The default value is `left`.

height Specifies the height of the image, in pixels.

hspace Specifies the amount of horizontal space that surrounds the image where no text appears. The default value is 8.

id Specifies the identifier for the imported image. This is useful if you want to control the embedded content with ActionScript.

vspace Specifies the amount of vertical space that surrounds the image where no text.

width Specifies the width of the image, in pixels. The default value is 8.

The following example shows the use of the `<img>` tag and how text can flow around the image:

```
<?xml version="1.0"?>
<!-- textcontrols/ImgTag.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    width="300" height="300">
  <mx:Text height="100%" width="100%">
     <mx:htmlText>
        <![CDATA[
           <p>You can include an image in your HTML text with the &lt;img&gt; tag.</p>
          <p><img src='assets/butterfly.gif' width='30' height='30' align='left' hspace='10'
vspace='10'>
           Here is text that follows the image. I'm extending the text by lengthening this
sentence until it's long enough to show wrapping around the bottom of the image.</p>
        ]]>
     </mx:htmlText>
  </mx:Text>
</s:Application>
```

Making hyperlinks out of embedded images

To make a hyperlink out of an embedded image, enclose the `<img>` tag in an `<a>` tag, as the following example shows:

```
<?xml version="1.0"?>
<!-- textcontrols/ImgTagWithHyperlink.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
  <mx:TextArea width="100%" height="100%">
     <mx:htmlText>
        <![CDATA[
           <a href='http://www.adobe.com'><img src='assets/butterfly.gif'/></a>
           Click the image to go to the Adobe home page.
        ]]>
     </mx:htmlText>
  </mx:TextArea>
</s:Application>
```

When the user moves the mouse pointer over an image that is enclosed by `<a>` tags, the mouse pointer does not change automatically to a hand icon, as with standard hyperlinks. To display a hand icon, specify `buttonMode="true"` for the MX TextArea (or Text) control. Interactivity, such as mouse clicks and key presses, do not register in SWF files that are enclosed by `<a>` tags.

Italic tag (<i>)

The italic `<i>` tag displays the tagged text in italic font. If you're using embedded fonts, an italic font must be available or no text appears. If you use fonts that you expect to reside on the local system of your users, their system may approximate an italic font if none exists, or it may substitute the normal font face instead of italic. In either case, the text inside the italic tags appears.

The following snippet applies italic font to the word *italic*:

```
The next word is in <i>italic</i>.
```

You cannot use the `</i>` end tag to override italic formatting that you set for all text in a control by using the `fontStyle` style.

List item tag (<li>)

The list item `<li>` tag ensures that the text that it encloses starts on a new line with a bullet in front of it. You cannot use it for any other type of HTML list item. The ending `</li>` tag ensures a line break (but `</li><li>` generates a single line break). Unlike in HTML, you do not surround `<li>` tags in `<ul>` tags. For example, the following Flex code generates a bulleted list with two items:

```
<?xml version="1.0"?>
<!-- textcontrols/BulletedListExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
  <mx:Text>
     <mx:htmlText >
        <![CDATA[
           <p>This is a bulleted list:<li>First Item</li><li>Second Item</li></p>
        ]]>
     </mx:htmlText>
  </mx:Text>
</s:Application>
```

***Note:** The `<li>` tag does not work properly with MX Label controls. With MX TextInput controls, it must be put before the first character in the text.*

Paragraph tag (<p>)

The paragraph `<p>` tag creates a new paragraph. The opening `<p>` tag does *not* force a line break, but the closing `</p>` tag does. Unlike in HTML, the `<p>` tag does not force a double space between paragraphs; the spacing is the same as that generated by the `<br>` tag.

The `<p>` tag supports the following attribute:

align Specifies alignment of text in the paragraph; valid values are `left`, `right`, `center`, and `justify`.

The following snippet generates two centered paragraphs:

```
<p align="center">This is a first centered paragraph</p>
<p align="center">This is a second centered paragraph</p>
```

Text format tag (<textformat>)

The text format `<textformat>` tag lets you use a subset of paragraph formatting properties of the TextFormat class in HTML text fields, including line leading, indentation, margins, and tab stops. You can combine text format tags with the built-in HTML tags. The text format tag supports the following attributes:

blockindent Specifies the indentation, in points, from the left margin to the text in the `<textformat>` tag body.

indent Specifies the indentation, in points, from the left margin or the block indent, if any, to the first character in the `<textformat>` tag body.

leading Specifies the amount of leading (vertical space) between lines.

leftmargin Specifies the left margin of the paragraph, in points.

rightmargin Specifies the right margin of the paragraph, in points.

tabstops Specifies custom tab stops as an array of nonnegative integers.

Underline tag (<u>)

The underline `<u>` tag underlines the tagged text.

The following snippet underlines the word *underlined*:

```
The next word is <u>underlined</u>.
```

You cannot use the `</u>` end tag to override underlining that you set for all text in a control by using the `textDecoration` style.

Selecting and modifying text

You can select and modify text in the MX TextArea, MX TextInput, and RichTextEditor controls. To change a MX Label or Text control's text, assign a new value to the control's `text` or `HTMLtext` property. For more information on the `HTMLText` property, see "Using the htmlText property" on page 810.

Selecting text

The Flex editable controls provide properties and methods to select text regions and get selections. You can modify the contents of the selection as described in "Modifying text" on page 821.

Creating a selection

The MX TextInput and TextArea controls, including the RichTextEditor control's TextArea subcontrol, provide the following text selection properties and method:

- `setSelection()` method selects a range of text. You specify the zero-based indexes of the start character and the position immediately *after* the last character in the text.
- `selectionBeginIndex` and `selectionEndIndex` set or return the zero-based location in the text of the start and position immediately *after* the end of a selection.

To select the first 10 characters of the myTextArea TextArea control, for example, use the following method:

```
myTextArea.setSelection(0, 10);
```

To change the last character of this selection to be the twenty-fifth character in the MX TextArea control, use the following statement:

```
myTextArea.endIndex=25;
```

To select text in a RichTextEditor control, use the control's TextArea subcontrol, which you access by using the `textArea` id. To select the first 10 characters in the myRTE RichTextEditor control, for example, use the following code:

```
myRTE.textArea.setSelection(0, 10);
```

Getting a selection

You get a text control's selection by getting a TextRange object with the selected text. You can then use the TextRange object to modify the selected text, as described in "Modifying text" on page 821. The technique you use to get the selection depends on the control type.

Get the selection in an MX TextArea or MX TextInput control

Use the TextRange class constructor to get a TextRange object with the currently selected text in an MX TextArea or MX TextInput control. For example, to get the current selection of the myTextArea control, use the following line:

```
var mySelectedTextRange:TextRange = new TextRange(myTextArea, true);
```

The second parameter, `true`, tells the constructor to return a TextRange object with the selected text.

Get the selection in a RichTextEditor control

Use the `selection` read-only property of the RichTextEditor to get a TextRange object with the currently selected text in its MX TextArea subcontrol. You can use the TextRange object to modify the selected text, as described in Modifying text. For example, to get the current selection of the MyRTE RichTextEditor control, us the following line:

```
public var mySelectedTextRange:TextRange = myRTE.selection;
```

Modifying text

You use the TextRange class to modify the text in an MX TextArea, MX TextInput, or RichTextEditor control. This class lets you affect the following text characteristics:

- `text` or `htmltext` property contents
- text color, decoration (underlining), and alignment
- font family, size, style (italics), and weight (bold)
- URL of an HTML <a> link

Getting a TextRange object

To get a TextRange object you use the following techniques:

- Get a TextRange object that contains the current text selection.
- Create a TextRange object that contains a specific range of text.

To create a TextRange object with a specific range of text, use a TextRange constructor with the following format:

```
new TextRange(control, modifiesSelection, beginIndex, endIndex)
```

Specify the control that contains the text, whether the TextRange object corresponds to a selection (that is, represents and modifies selected text), and the zero-based indexes in the text of the first and last character of the range. As a general rule, do not use the TextRange constructor to set a selection; use the `setSelection()` method, as described in “Selecting text” on page 820. For this reason, the second parameter should always be `false` when you specify the begin and end indexes.

To get a TextRange object with the fifth through twenty-fifth characters of an MX TextArea control named myTextArea, for example, use the following line:

```
var myTARange:TextRange = new TextRange(myTextArea, false, 4, 25);
```

Changing text

After you get a TextRange object, use its properties to modify the text in the range. The changes you make to the TextRange appear in the text control.

You can get or set the text in a TextRange object as HTML text or as a plain text, independent of any property that you might have used to initially set the text. If you created an MX TextArea control, for example, and set its `text` property, you can use the TextRange `htmlText` property to get and change the text. The following example shows this usage, and shows using the TextRange class to access a range of text and change its properties. It also shows using String properties and methods to get text indexes.

```
<?xml version="1.0"?>
<!-- textcontrols/TextRangeExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <fx:Script><![CDATA[
     import mx.controls.textClasses.TextRange
    private function resetText():void {
        ta1.text = "This is a test of the emergency broadcast system. It is only a test.";
    }
     public function alterText():void {
        // Create a TextRange object starting with "the" and ending at the
        // first period. Replace it with new formatted HTML text.
        var tr1:TextRange = new TextRange(
            ta1, false, ta1.text.indexOf("the", 0), ta1.text.indexOf(".", 0)
        );
        tr1.htmlText="<i>italic HTML text</i>"
        // Create a TextRange object with the remaining text.
        // Select the text and change its formatting.
        var tr2:TextRange = new TextRange(
            ta1, true, ta1.text.indexOf("It", 0), ta1.text.length-1
        );
        tr2.color=0xFF00FF;
        tr2.fontSize=18;
        tr2.fontStyle = "italic"; // any other value turns italic off
        tr2.fontWeight = "bold"; // any other value turns bold off
        ta1.setSelection(0, 0);
     }
  ]]></fx:Script>
  <mx:TextArea id="ta1" fontSize="12" fontWeight="bold" width="100%" height="100">
     <mx:text>
        This is a test of the emergency broadcast system. It is only a test.
     </mx:text>
  </mx:TextArea>
  <s:HGroup>
    <mx:Button label="Alter Text" click="alterText();"/>
    <mx:Button label="Reset" click="resetText();"/>
  </s:HGroup>
</s:Application>
```

Example: Changing selected text in a RichTextEditor control

The following example shows how you can use the `selectedText` property of theRichTextEditor control to get a TextRange when a user selects some text, and use TextRange properties to get and change the characteristics of the selected text. To use the example, select a range of text with your mouse. When you release the mouse button, the string "This is replacement text. ", formatted in fuchsia Courier 20-point font replaces the selection and the text area reports on the original and replacement text.

```
<?xml version="1.0"?>
<!-- textcontrols/TextRangeSelectedText.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    width="600" height="500">

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

set to right.</b></font></p>";
     public function changeSelectionText():void {
        //Get a TextRange with the selected text and find its length.
        var sel:TextRange = rte1.selection;
        var selLength:int = sel.endIndex - sel.beginIndex;
        //Do the following only if the user made a selection.
        if (selLength) {
           //Display the selection size and font color, size, and family.
           t1.text="Number of characters selected: " + String(selLength);
           t1.text+="\n\nOriginal Font Family: " + sel.fontFamily;
           t1.text+="\nOriginal Font Size: " + sel.fontSize;
           t1.text+="\nOriginal Font Color: " + sel.color;
           //Change font color, size, and family and replace selected text.
           sel.text="This is replacement text. "
           sel.color="fuchsia";
           sel.fontSize=20;
           sel.fontFamily="courier"
           //Show the new font color, size, and family.
```

```
            t1.text+="\n\nNew text length: " + String(sel.endIndex - sel.beginIndex);
            t1.text+="\nNew Font Family: " + sel.fontFamily;
            t1.text+="\nNew Font Size: " + sel.fontSize;
            t1.text+="\nNew Font Color: " + sel.color;
         }
      }
   ]]></fx:Script>
   <!-- The text area. When you release the mouse after selecting text,
      it calls the func1 function. -->
   <mx:RichTextEditor id="rte1"
     htmlText="{htmlData}"
     width="100%" height="100%"
     mouseUp="changeSelectionText()"/>

   <mx:TextArea id="t1"
     editable="false"
     fontSize="12"
     fontWeight="bold"
     width="300" height="180"/>
</s:Application>
```

MX Label control

The Label control is part of both the MX and Spark component sets. While you can use the MX controls in your application, Adobe recommends that you use the Spark controls instead. For more information about using Spark text controls, see “Spark text controls” on page 734.

The MX Label control is a noneditable single-line text label. It has the following characteristics:

- The user cannot change the text, but the application can modify it.
- You can specify text formatting by using styles or HTML text.
- You can control the alignment and sizing.
- The control is transparent and does not have a `backgroundColor` property, so the background of the component’s container shows through.
- The control has no borders, so the label appears as text written directly on its background.
- The control cannot take the focus.

To create a multiline, noneditable text field, use a Text control. For more information, see “MX Text control” on page 826. To create user-editable text fields, use MX TextInput or MX TextArea controls. For more information, see “MX TextInput control” on page 825 and “MX TextArea control” on page 827.

The following image shows an MX Label control:

For the code used to create this sample, see Creating an MX Label control.

Creating an MX Label control

You define an MX Label control in MXML by using the `<mx:Label>` tag, as the following example shows. Specify an `id` value if you intend to refer to a component elsewhere in your MXML, either in another tag or an ActionScript block.

```
<?xml version="1.0"?>
<!-- textcontrols/LabelControl.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    width="150" height="80">
  <mx:Label text="Label1"/>
</s:Application>
```

You use the `text` property to specify a string of raw text, and the `htmlText` property to specify an HTML-formatted string. For more information on using these properties, see "Using the text property" on page 807 and "Using the htmlText property" on page 810.

Sizing an MX Label control

If you do not specify a width, the MX Label control automatically resizes when you change the value of the `text` or `htmlText` property.

If you explicitly size an MX Label control so that it is not large enough to accommodate its text, the text is truncated and terminated by an ellipsis (...). The full text displays as a tooltip when you move the mouse over the MX Label control. If you also set a tooltip by using the `tooltip` property, the tooltip is displayed rather than the text.

MX TextInput control

The TextInput control is part of both the MX and Spark component sets. While you can use the MX controls in your application, Adobe recommends that you use the Spark controls instead. For more information about using Spark text controls, see "Spark text controls" on page 734.

The MX TextInput control is a single-line text field that is optionally editable. The MX TextInput control supports the HTML rendering capabilities of Adobe Flash Player.

The following image shows an MX TextInput control:

123456789

To create a multiline, editable text field, use an MX TextArea control. For more information, see "MX TextArea control" on page 827. To create noneditable text fields, use MX Label and Text controls. For more information, see "MX Label control" on page 824 and "MX Text control" on page 826.

The MX TextInput control does not include a label, but you can add one by using an MX Label control or by nesting the MX TextInput control in a FormItem container in a Form layout container, as shown in the example in "About MX text controls" on page 805. MX TextInput controls dispatch `change`, `textInput`, and `enter` events.

If you disable an MX TextInput control, it displays its contents in a different color, represented by the `disabledColor` style. You can set an MX TextInput control's `editable` property to `false` to prevent editing of the text. You can set an MX TextInput control's `displayAsPassword` property to conceal the input text by displaying characters as asterisks.

Creating an MX TextInput control

You define an MX TextInput control in MXML by using the `<mx:TextInput>` tag, as the following example shows. Specify an `id` value if you intend to refer to a control elsewhere in your MXML, either in another tag or in an ActionScript block.

```
<?xml version="1.0"?>
<!-- textcontrols/TextInputControl.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
  <mx:TextInput id="text1" width="100"/>
</s:Application>
```

Just as you can for the MX Label control, you use the `text` property to specify a string of raw text, and the `htmlText` property to specify an HTML-formatted string. For more information, see "Using the text property" on page 807 and "Using the htmlText property" on page 810.

Sizing an MX TextInput control

If you do not specify a width, the MX TextInput control automatically resizes when you change the value of the `text` or `htmlText` property. It does not resize in response to typed user input.

Binding to an MX TextInput control

In some cases, you might want to bind a variable to the text property of an MX TextInput control so that the control represents a variable value, as the following example shows:

```
<?xml version="1.0"?>
<!-- textcontrols/BoundTextInputControl.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
  <fx:Script><![CDATA[
     [Bindable]
     public var myProp:String="This is the initial String myProp.";
  ]]></fx:Script>
  <mx:TextInput text="{myProp}" width="250"/>
</s:Application>
```

In this example, the MX TextInput control displays the value of the myProp variable. Remember that you must use the `[Bindable]` metadata tag if the variable changes value and the control must track the changed values; also, the compiler generates warnings if you do not use this metadata tag.

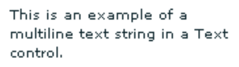
MX Text control

The MX Text control displays multiline, noneditable text. The control has the following characteristics:

- The user cannot change the text, but the application can modify it.
- The control does not support scroll bars. If the text exceeds the control size, users can use keys to scroll the text.
- The control is transparent so that the background of the component's container shows through.
- The control has no borders, so the label appears as text written directly on its background.
- The control supports HTML text and a variety of text and font styles.
- The text always word-wraps at the control boundaries, and is always aligned to the top of the control.

To create a single-line, noneditable text field, use the MX Label control. For more information, see "MX Label control" on page 824. To create user-editable text fields, use the MX TextInput or TextArea controls. For more information, see "MX TextInput control" on page 825 and "MX TextArea control" on page 827.

The following image shows an example of a Text control with a width of 175 pixels:



This is an example of a
multiline text string in a Text
control.

Creating a Text control

You define a Text control in MXML by using the `<mx:Text>` tag, as the following example shows. Specify an `id` value if you intend to refer to a component elsewhere in your MXML, either in another tag or in an ActionScript block.

```
<?xml version="1.0"?>
<!-- textcontrols/TextControl.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <mx:Text width="175"
        text="This is an example of a multiline text string in a Text control."/>
</s:Application>
```

You use the `text` property to specify a string of raw text, and the `htmlText` property to specify an HTML-formatted string. For more information, see "Using the text property" on page 807 and "Using the htmlText property" on page 810.

This control does not support a `backgroundColor` property; its background is always the background of the control's container.

Sizing a Text control

Flex sizes the Text control as follows:

- If you specify a pixel value for both the `height` and `width` properties, any text that exceeds the size of the control is clipped at the border.
- If you specify an explicit pixel width, but no height, Flex wraps the text to fit the width and calculates the height to fit the required number of lines.
- If you specify a percentage-based width and no height, Flex does *not* wrap the text, and the height equals the number of lines as determined by the number of Return characters.
- If you specify only a height and no width, the height value does not affect the width calculation, and Flex sizes the control to fit the width of the maximum line.

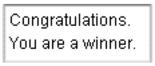
As a general rule, if you have long text, you should specify a pixel-based `width` property. If the text might change and you want to ensure that the Text control always takes up the same space in your application, set explicit `height` and `width` properties that fit the largest expected text.

MX TextArea control

The TextArea control is part of both the MX and Spark component sets. While you can use the MX controls in your application, Adobe recommends that you use the Spark controls instead. For more information about using Spark text controls, see "Spark text controls" on page 734.

The MX TextArea control is a multiline, editable text field with a border and optional scroll bars. The MX TextArea control supports the HTML and rich text rendering capabilities of Flash Player and AIR. The MX TextArea control dispatches `change` and `textInput` events.

The following image shows an MX TextArea control:



Congratulations.
You are a winner.

To create a single-line, editable text field, use the MX TextInput control. For more information, see "MX TextInput control" on page 825. To create noneditable text fields, use the MX Label and Text controls. For more information, see "MX Label control" on page 824 and "MX Text control" on page 826.

If you disable an MX TextArea control, it displays its contents in a different color, represented by the `disabledColor` style. You can set an MX TextArea control's `editable` property to `false` to prevent editing of the text. You can set an MX TextArea control's `displayAsPassword` property to conceal input text by displaying characters as asterisks.

Creating an MX TextArea control

You define an MX TextArea control in MXML by using the `<mx:TextArea>` tag, as the following example shows. Specify an `id` value if you intend to refer to a control elsewhere in your MXML, either in another tag or in an ActionScript block.

```
<?xml version="1.0"?>
<!-- textcontrols/TextAreaControl.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <mx:TextArea id="textConfirm"
        width="300" height="100"
        text="Please enter your thoughts here."/>
</s:Application>
```

Just as you can for the Text control, you use the `text` property to specify a string of raw text, and the `htmlText` property to specify an HTML-formatted string. For more information, see "Using the text property" on page 807 and "Using the htmlText property" on page 810.

Sizing the MX TextArea control

The MX TextArea control does not resize to fit the text that it contains. If the new text exceeds the capacity of the MX TextArea control and the `horizontalScrollPolicy` is `true` (the default value), the control adds a scrollbar.

MX RichTextEditor control

The MX RichTextEditor control lets users enter, edit, and format text. Users apply text formatting and URL links by using subcontrols that are located at the bottom of the RichTextEditor control.

There is no Spark equivalent of the RichTextEditor control.

For complete reference information, see the *Adobe Flex Language Reference*.

About the RichTextEditor control

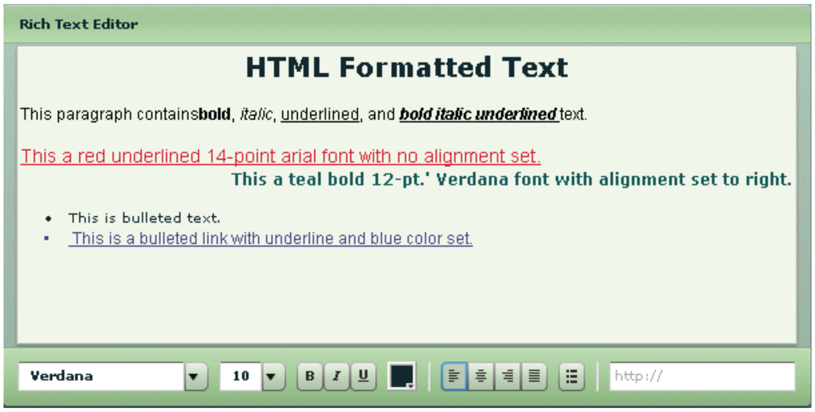
The RichTextEditor control consists of a Panel control with two direct children:

- An MX TextArea control in which users can enter text

- A tool bar container with format controls that let a user specify the text characteristics. Users can use the tool bar subcontrols to apply the following text characteristics:
  - Font family
  - Font size

    ***Note:** When using the RichTextEditor control, you specify the actual pixel value for the font size. This size is not equivalent to the relative font sizes specified in HTML by using the* `size` *attribute of the HTML* `<font>` *tag.*
  - Any combination of bold, italic and underline font styles
  - Text color
  - Text alignment: left, center, right, or justified
  - Bullets
- URL links

The following image shows a RichTextEditor control with some formatted text:



Rich Text Editor

HTML Formatted Text

This paragraph contains**bold**, *italic*, underlined, and ***bold italic underlined*** text.

This a red underlined 14-point arial font with no alignment set.

This a teal bold 12-pt.' Verdana font with alignment set to right.

- This is bulleted text.
- This is a bulleted link with underline and blue color set.

For the source for this example, see “Creating a RichTextEditor control” on page 829.

You use the RichTextEditor interactively as follows:

- Text that you type is formatted as specified by the control settings.
- To apply new formatting to existing text, select the text and set the controls to the required format.
- To create a link, select a range of text, enter the link target in the text box on the right, and press Enter. You can only specify the URL; the link always opens in a _blank target. Also, creating the link does not change the appearance of the link text; you must separately apply any color and underlining.
- You can cut, copy, and paste rich text within and between Flash HTML text fields, including the RichTextEditor control’s TextArea subcontrol, by using the normal keyboard commands. You can copy and paste plain text between the TextArea and any other text application, such as your browser or a text editor.

Creating a RichTextEditor control

You define a RichTextEditor control in MXML by using the `<mx:RichTextEditor>` tag, as the following example shows. Specify an `id` value if you intend to refer to a control elsewhere in your MXML, either in another tag or in an ActionScript block.

```
<?xml version="1.0"?>
<!-- textcontrols/RichTextEditorControl.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
  <mx:RichTextEditor id="myRTE" text="Congratulations, winner!" />
</s:Application>
```

You can use the `text` property to specify an unformatted text string, or the `htmlText` property to specify an HTML-formatted string. For more information on using these properties, see "Using the text property" on page 807, and "Using the htmlText property" on page 810. For information on selecting, replacing, and formatting text that is in the control, see "Selecting and modifying text" on page 820.

The following example shows the code used to create the image in "About the RichTextEditor control" on page 828:

```
<?xml version="1.0"?>
<!-- textcontrols/RichTextEditorControlWithFormattedText.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
  <!-- The HTML text string used to populate the RichTextEditor control's
     TextArea subcomponent. The text is on a single line. -->
  <fx:Script><![CDATA[
     [Bindable]
     public var htmlData:String="<textformat leading='2'><p align='center'><b><font
size='20'>HTML Formatted Text</font></b></p></textformat><br><textformat leading='2'><p
align='left'><font face='_sans' size='12' color='#000000'>This paragraph contains<b>bold</b>,
<i>italic</i>, <u>underlined</u>, and <b><i><u>bold italic underlined
</u></i></b>text.</font></p></textformat><br><p><u><font face='arial' size='14'
color='#ff0000'>This a red underlined 14-point arial font with no alignment
set.</font></u></p><p align='right'><font face='verdana' size='12' color='#006666'><b>This a
teal bold 12-pt.' Verdana font with alignment set to right.</b></font></p><br><li>This is
bulleted text.</li><li><font face='arial' size='12' color='#0000ff'><u> <a
href='http://www.adobe.com'>This is a bulleted link with underline and blue color
set.</a></u></font></li>";
  ]]></fx:Script>
  <!-- The RichTextEditor control. To reference a subcomponent prefix its ID with the
RichTextEditor control ID. -->
  <mx:RichTextEditor id="rte1"
     backgroundColor="#ccffcc"
     width="500"
     headerColors="[#88bb88, #bbeebb]"
     footerColors="[#bbeebb, #88bb88]"
     title="Rich Text Editor"
     htmlText="{htmlData}"
     initialize="rte1.textArea.setStyle('backgroundColor', '0xeeffee')"
  />
</s:Application>
```

Sizing the RichTextEditor control

The control does not resize in response to the size of the text in the MX TextArea control. If the text exceeds the viewable space, by default, the MX TextArea control adds scroll bars. If you specify a value for either the `height` or `width` property but not both, the control uses the default value for the property that you do not set.

If you set a `width` value that results in a width less than 605 pixels wide, the RichTextEditor control stacks the subcontrols in rows.

Programming RichTextEditor subcontrols

Your application can control the settings of any of the RichTextEditor subcontrols, such as the MX TextArea, the ColorPicker, or any of the MX ComboBox or MX Button controls that control text formatting. To refer to a RichTextEditor subcontrol, prefix the requested control's ID with the RichTextEditor control ID. For example, to refer to the ColorPicker control in a RichTextEditor control that has the ID rte1, use rte1.colorPicker.

Inheritable styles that you apply directly to a RichTextEditor control affect the underlying Panel control and the subcontrols. Properties that you apply directly to a RichTextEditor control affect the underlying Panel control only.

For more information, see the RichTextEditor in the *Adobe Flex Language Reference*.

Setting RichTextEditor subcontrol properties and styles

The following simple code example shows how you can set and change the properties and styles of the RichTextEditor control and its subcontrols. This example uses styles that the RichTextEditor control inherits from the Panel class to set the colors of the Panel control header and the tool bar container, and sets the MX TextArea control's background color in the RichTextEditor control's creationComplete event member. When users click the buttons, their click event listeners change the TextArea control's background color and the selected color of the ColorPicker control.

```
<?xml version="1.0"?>
<!-- textcontrols/RTESubcontrol.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    height="420">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

  <!-- The RichTextEditor control. To set the a subcomponent's style or property,
  fully qualify the control ID. The footerColors style sets the ControlBar colors. -->
  <mx:RichTextEditor id="rte1"
     backgroundColor="#ccffcc"
     headerColors="[#88bb88, #bbeebb]"
     footerColors="[#bbeebb, #88bb88]"
     title="Rich Text Editor"
     creationComplete="rte1.textArea.setStyle('backgroundColor','0xeeffee')"
     text="Simple sample text"/>
  <!-- Button to set a white TextArea background. -->
  <s:Button
     label="Change appearance"
     click="rte1.textArea.setStyle('backgroundColor',
'0xffffff');rte1.colorPicker.selectedIndex=27;"/>
  <!-- Button to reset the display to its original appearance. -->
  <s:Button
     label="Reset Appearance"
     click="rte1.textArea.setStyle('backgroundColor',
'0xeeffee');rte1.colorPicker.selectedIndex=0;"/>
</s:Application>
```

Removing and adding RichTextEditor subcontrols

You can remove any of the standard RichTextEditor subcontrols, such as the alignment buttons. You can also add your own subcontrols, such as a button that pops up a find-and-replace dialog box.

Remove an existing subcontrol
