          <Definition name="YellowRect">
               <Group>
                   <Rect height="10" width="10">
                         <stroke>
                              <SolidColorStroke color="#000000" weight=".5"/>
                         </stroke>
                         <fill>
                              <SolidColor color="#FFFF00"/>
                         </fill>
                   </Rect>
                </Group>
          </Definition>
     </Library>
     <YellowRect x="0" y="0"/>
     <YellowRect x="0" y="12"/>
     <YellowRect x="12" y="0"/>
     <YellowRect x="12" y="12"/>
</Graphic>
```

MXML graphics example

The following MXML graphics example uses the `<s:Group>` tag to define a group of yellow shapes:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/GroupCoordinateExampleMXML.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:comps="comps.*">
     <fx:Library>
          <fx:Definition name="YellowRect">
               <s:Group>
                   <s:Rect height="10" width="10">
                         <s:stroke>
                              <s:SolidColorStroke color="#000000" weight=".5"/>
                         </s:stroke>
                         <s:fill>
                              <s:SolidColor color="#FFFF00"/>
                         </s:fill>
                   </s:Rect>
                </s:Group>
          </fx:Definition>
     </fx:Library>
     <mx:Panel title="Group Coordinate MXML Graphics Example"
        height="75%" width="75%" layout="horizontal"
        paddingTop="10" paddingBottom="10" paddingLeft="10" paddingRight="10">
       <s:Group>
                 <fx:YellowRect x="0" y="0"/>
                 <fx:YellowRect x="0" y="12"/>
                 <fx:YellowRect x="12" y="0"/>
                 <fx:YellowRect x="12" y="12"/>
       </s:Group>
     </mx:Panel>
</s:Application>
```

Shapes in FXG and MXML graphics

FXG and MXML graphics define the following basic shapes:

- Rectangles
- Ellipses
- Lines

The MXML graphics classes for the basic shapes are defined in the spark.primitives package.

The default border for any shape is to have a stroke with a line width of 0. Therefore, you must define a stroke when you draw a shape, otherwise the shape will be invisible when rendered. You can optionally fill the shape with a fill.

Rectangles

In FXG, the `<Rect>` tag draws a rectangular shape; in MXML graphics, use the `<s:Rect>` tag or the spark.primitives.Rect class. You define the height and width of a rectangle. You can also define the stroke, or border, of the rectangle, and a fill.

When drawing rectangles, you have a great deal of control over the curvature of the corners of the rectangle. The FXG `<Rect>` tag and the `<s:Rect>` MXML tag class include properties such as `topLeftRadiusX`, `topLeftRadiusY`, `bottomRightRadiusX`, and `bottomRightRadiusY`. Convenience properties, `radiusX` and `radiusY`, let you set the radii of all corners.

FXG examples

The following FXG example draws a simple rectangle with a 1 point black stroke:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/SimpleRectExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:comps="comps.*">
     <mx:Panel title="Rectangle Graphic Example"
        height="75%" width="75%" layout="horizontal"
        paddingTop="10" paddingBottom="10" paddingLeft="10" paddingRight="10">
        <s:Group>
            <comps:SimpleRectComp />
        </s:Group>
     </mx:Panel>
</s:Application>
```

The following file defines the SimpleRectComp FXG component used in the previous example:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/comps/SimpleRectComp.fxg -->
<Graphic xmlns="http://ns.adobe.com/fxg/2008" version="2">
   <Rect height="100" width="200">
         <stroke>
              <SolidColorStroke color="#000000" weight="1"/>
         </stroke>
   </Rect>
</Graphic>
```

The following FXG-based example draws two rectangles with strokes and fills. One rectangle has rounded corners:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/RectExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:comps="comps.*">

     <mx:Panel title="Rectangle Graphic Example"
        height="75%" width="75%" layout="horizontal"
        paddingTop="10" paddingBottom="10" paddingLeft="10" paddingRight="10">
        <s:VGroup>
            <comps:FilledRectComp/>
            <comps:RoundRectComp/>
        </s:VGroup>
     </mx:Panel>
</s:Application>
```

The following file defines the FilledRectComp FXG component used in the previous example:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/comps/FilledRectComp.fxg -->
<Graphic xmlns="http://ns.adobe.com/fxg/2008" version="2">
    <!-- Draw rectangle with square corners. -->
   <Rect height="100" width="200">
         <stroke>
              <SolidColorStroke color="#000000" weight="2"/>
         </stroke>
         <fill>
              <RadialGradient>
                        <GradientEntry color="#0056FF" ratio="0" alpha=".5"/>
                        <GradientEntry color="#00CC99" ratio=".33" alpha=".5"/>
                        <GradientEntry color="#ECEC21" ratio=".66" alpha=".5"/>
              </RadialGradient>
         </fill>
   </Rect>
</Graphic>
```

The following file defines the RoundRectComp FXG component used in the previous example:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/comps/RoundRectComp.fxg -->
<Graphic xmlns="http://ns.adobe.com/fxg/2008" version="2">
    <!-- Draw rectangle with rounded corners. -->
    <Rect height="100" width="200" radiusX="25" radiusY="25">
         <stroke>
              <SolidColorStroke color="#000000" weight="2"/>
         </stroke>
         <fill>
              <RadialGradient>
                        <GradientEntry color="#0056FF" ratio="0" alpha=".5"/>
                        <GradientEntry color="#00CC99" ratio=".33" alpha=".5"/>
                        <GradientEntry color="#ECEC21" ratio=".66" alpha=".5"/>
              </RadialGradient>
         </fill>
    </Rect>
</Graphic>
```

MXML graphics examples

The following MXML graphics example draws a simple rectangle with a 1 point black stroke:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/SimpleRectExampleMXML.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
     <mx:Panel title="Rectangle MXML Graphics Example"
        height="75%" width="75%" layout="horizontal"
        paddingTop="10" paddingBottom="10" paddingLeft="10" paddingRight="10">
        <s:Group>
           <s:Rect height="100" width="200">
                 <s:stroke>
                      <s:SolidColorStroke color="0x000000" weight="1"/>
                 </s:stroke>
           </s:Rect>
        </s:Group>
     </mx:Panel>
</s:Application>
```

The following MXML graphics example draws two rectangles with strokes and fills. One rectangle has rounded corners:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/RectExampleMXML.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

     <mx:Panel title="Rectangle MXML Graphics Example"
        height="75%" width="75%" layout="horizontal"
        paddingTop="10" paddingBottom="10" paddingLeft="10" paddingRight="10">
        <s:VGroup>
           <s:Rect height="100" width="200">
                 <s:stroke>
                      <s:SolidColorStroke color="0x000000" weight="2"/>
                 </s:stroke>
                 <s:fill>
                      <s:RadialGradient>
                                <s:GradientEntry color="0x0056FF" ratio="0" alpha=".5"/>
                                <s:GradientEntry color="0x00CC99" ratio=".33" alpha=".5"/>
                                <s:GradientEntry color="0xECEC21" ratio=".66" alpha=".5"/>
                      </s:RadialGradient>
                 </s:fill>
           </s:Rect>
          <s:Rect height="100" width="200" radiusX="25" radiusY="25">
                 <s:stroke>
                      <s:SolidColorStroke color="0x000000" weight="2"/>
                 </s:stroke>
                 <s:fill>
                      <s:RadialGradient>
                                <s:GradientEntry color="0x0056FF" ratio="0" alpha=".5"/>
                                <s:GradientEntry color="0x00CC99" ratio=".33" alpha=".5"/>
                                <s:GradientEntry color="0xECEC21" ratio=".66" alpha=".5"/>
                      </s:RadialGradient>
                 </s:fill>
            </s:Rect>
        </s:VGroup>
     </mx:Panel>
</s:Application>
```

For more information, see the Rect class in the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Ellipses

In FXG, use the `<Ellipse>` tag to draw circles and ellipses; in MXML graphics, use the `<s:Ellipse>` tag or the spark.primitives.Ellipse class.

To define the dimensions of the ellipse, use the `height` and `width` attributes. These attributes are relative to the graphic's upper left corner. If you set the `height` and `width` attributes to the same value, the ellipse is a circle.

FXG examples

The following FXG-based example draws a simple circle:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/SimpleEllipseExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:comps="comps.*">
     <mx:Panel title="Ellipse Graphic Example"
        height="75%" width="75%" layout="horizontal"
        paddingTop="10" paddingBottom="10" paddingLeft="10" paddingRight="10">
        <s:Group>
            <comps:CircleComp />
        </s:Group>
     </mx:Panel>
</s:Application>
```

The following file defines the CircleComp FXG component used in the previous example:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/comps/CircleComp.fxg -->
<Graphic xmlns="http://ns.adobe.com/fxg/2008" version="2">
    <Ellipse height="200" width="200">
          <stroke>
               <SolidColorStroke color="#000000" weight="1"/>
          </stroke>
    </Ellipse>
</Graphic>
```

The following FXG-based example draws an ellipse with a fill:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/EllipseExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:comps="comps.*">

     <mx:Panel title="Ellipse Graphic Example"
        height="75%" width="75%" layout="horizontal"
        paddingTop="10" paddingBottom="10" paddingLeft="10" paddingRight="10">
        <s:Group>
            <comps:FilledCircleComp/>
        </s:Group>
     </mx:Panel>
</s:Application>
```

The following file defines the FilledCircleComp FXG component used in the previous example:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/comps/FilledCircleComp.fxg -->
<Graphic xmlns="http://ns.adobe.com/fxg/2008" version="2">
    <Ellipse height="100" width="250">
          <stroke>
               <SolidColorStroke color="#000000" weight="2"/>
          </stroke>
        <fill>
           <RadialGradient>
             <GradientEntry color="#0056FF" ratio="0" alpha=".5"/>
             <GradientEntry color="#00CC99" ratio=".33" alpha=".5"/>
             <GradientEntry color="#ECEC21" ratio=".66" alpha=".5"/>
         </RadialGradient>
        </fill>
    </Ellipse>
</Graphic>
```

MXML graphics examples

The following MXML graphics example draws a simple circle:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/SimpleEllipseExampleMXML.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
     <mx:Panel title="Ellipse MXML Graphics Example"
        height="75%" width="75%" layout="horizontal"
        paddingTop="10" paddingBottom="10" paddingLeft="10" paddingRight="10">
        <s:Group>
            <s:Ellipse height="200" width="200">
                  <s:stroke>
                       <s:SolidColorStroke color="0x000000" weight="1"/>
                  </s:stroke>
            </s:Ellipse>
        </s:Group>
     </mx:Panel>
</s:Application>
```

The following MXML graphics example draws an ellipse with a fill:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/EllipseExampleMXML.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:comps="comps.*">

     <mx:Panel title="Ellipse MXML Graphic Example"
        height="75%" width="75%" layout="horizontal"
        paddingTop="10" paddingBottom="10" paddingLeft="10" paddingRight="10">
        <s:Group>
            <s:Ellipse height="100" width="250">
                  <s:stroke>
                       <s:SolidColorStroke color="0x000000" weight="2"/>
                  </s:stroke>
                <s:fill>
                   <s:RadialGradient>
                     <s:GradientEntry color="0x0056FF" ratio="0" alpha=".5"/>
                     <s:GradientEntry color="0x00CC99" ratio=".33" alpha=".5"/>
                     <s:GradientEntry color="0xECEC21" ratio=".66" alpha=".5"/>
                 </s:RadialGradient>
                </s:fill>
            </s:Ellipse>
        </s:Group>
     </mx:Panel>
</s:Application>
```

For more information, see the Ellipse class in the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Lines

To draw a line from one point to another in FXG, use the `<Line>` tag; in MXML graphics, use the `<s:Line>` tag or the spark.primitives.Line class.

The default width of a line is 0; you must define a stroke so that the line is visible. Strokes can be one of the following:

- SolidColorStroke
- LinearGradientStroke
- RadialGradientStroke

You can optionally define the color, joint types, and other properties of the line.

FXG examples

The following FXG-based example draws a simple 1 point black line with the SolidColorStroke child:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/SimpleLineExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:comps="comps.*">
     <mx:Panel title="Line Graphic Example"
        height="75%" width="75%" layout="horizontal"
        paddingTop="10" paddingBottom="10" paddingLeft="10" paddingRight="10">
        <s:Group>
            <comps:LineComp/>
        </s:Group>
     </mx:Panel>
</s:Application>
```

The following file defines the LineComp FXG component used in the previous example:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/comps/LineComp.fxg -->
<Graphic xmlns="http://ns.adobe.com/fxg/2008" version="2">
   <Line xFrom="0" xTo="100" yFrom="0" yTo="100">
         <stroke>
              <SolidColorStroke color="#000000" weight="1"/>
         </stroke>
   </Line>
</Graphic>
```

The following FXG-based example draws a series of lines with varying widths:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/LineExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:comps="comps.*">
     <mx:Panel title="Line Graphic Example"
        height="75%" width="75%" layout="horizontal"
        paddingTop="10" paddingBottom="10" paddingLeft="10" paddingRight="10">
        <s:Group>
            <comps:MultipleLineComp x="20" y="20"/>
        </s:Group>
     </mx:Panel>
</s:Application>
```

The following file defines the MultipleLineComp FXG component used in the previous example:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/comps/MultipleLineComp.fxg -->
<Graphic xmlns="http://ns.adobe.com/fxg/2008" version="2">
    <Line xFrom="0" xTo="0" yFrom="0" yTo="100">
         <!-- Define the border color of the line. -->
         <stroke>
              <SolidColorStroke color="#000000" weight="1" caps="square"/>
         </stroke>
    </Line>
    <Line xFrom="6" xTo="6" yFrom="0" yTo="100">
         <stroke>
              <SolidColorStroke color="#000000" weight="1" caps="square"/>
         </stroke>
    </Line>
    <Line xFrom="12" xTo="12" yFrom="0" yTo="100">
         <stroke>
              <SolidColorStroke color="#000000" weight="2" caps="square"/>
         </stroke>
    </Line>
    <Line xFrom="20" xTo="20" yFrom="0" yTo="100">
         <stroke>
              <SolidColorStroke color="#000000" weight="3" caps="square"/>
         </stroke>
    </Line>
    <Line xFrom="30" xTo="30" yFrom="0" yTo="100">
         <stroke>
              <SolidColorStroke color="#000000" weight="5" caps="square"/>
         </stroke>
    </Line>
    <Line xFrom="43" xTo="43" yFrom="0" yTo="100">
         <stroke>
              <SolidColorStroke color="#000000" weight="8" caps="square"/>
         </stroke>
    </Line>
    <Line xFrom="58" xTo="58" yFrom="0" yTo="100">
         <stroke>
              <SolidColorStroke color="#000000" weight="13" caps="square"/>
         </stroke>
    </Line>
    <Line xFrom="84" xTo="84" yFrom="0" yTo="100">
         <stroke>
              <SolidColorStroke color="#000000" weight="21" caps="square"/>
         </stroke>
    </Line>
    <Line xFrom="123" xTo="123" yFrom="0" yTo="100">
         <stroke>
              <SolidColorStroke color="#000000" weight="34" caps="square"/>
         </stroke>
    </Line>
</Graphic>
```

To use a LinearGradientStroke or RadialGradientStroke in FXG, you add one or more `<GradientEntry>` elements as children. These gradients are used to define the fill of the stroke. The following example defines a line whose color shifts from blue to yellow:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/LinearGradientLineExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:comps="comps.*">
     <mx:Panel title="Linear Gradient Line Example"
        height="75%" width="75%" layout="horizontal"
        paddingTop="10" paddingBottom="10" paddingLeft="10" paddingRight="10">
        <s:Group>
            <comps:LinearGradientLineComp x="20" y="20"/>
        </s:Group>
     </mx:Panel>
</s:Application>
```

The following file defines the LinearGradientLineComp FXG component used in the previous example:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/comps/LinearGradientLineComp.fxg -->
<Graphic xmlns="http://ns.adobe.com/fxg/2008" version="2">
    <Line xFrom="0" xTo="200" yFrom="0" yTo="0">
         <stroke>
              <LinearGradientStroke weight="20" caps="square">
                    <GradientEntry color="#0056FF" ratio="0" alpha=".5"/>
                    <GradientEntry color="#ECEC21" ratio=".66" alpha=".5"/>
              </LinearGradientStroke>
         </stroke>
    </Line>
</Graphic>
```

MXML graphics examples

The following MXML graphics example draws a simple 1 point black line with the SolidColorStroke child:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/SimpleLineExampleMXML.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
     <mx:Panel title="Line MXML Graphics Example"
        height="75%" width="75%" layout="horizontal"
        paddingTop="10" paddingBottom="10" paddingLeft="10" paddingRight="10">
        <s:Group>
           <s:Line xFrom="0" xTo="100" yFrom="0" yTo="100">
                 <s:stroke>
                      <s:SolidColorStroke color="0x000000" weight="1"/>
                 </s:stroke>
           </s:Line>
        </s:Group>
     </mx:Panel>
</s:Application>
```

The following MXML graphics example draws a series of lines with varying widths:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/LineExampleMXML.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:comps="comps.*">
     <mx:Panel title="Line MXML Graphic Example"
        height="75%" width="75%" layout="horizontal"
        paddingTop="30" paddingBottom="10" paddingLeft="10" paddingRight="10">
        <s:Group x="20" y="20">
            <s:Line xFrom="0" xTo="0" yFrom="0" yTo="100">
                 <!-- Define the border color of the line. -->
                 <s:stroke>
                      <s:SolidColorStroke color="0x000000" weight="1" caps="square"/>
                 </s:stroke>
            </s:Line>
            <s:Line xFrom="6" xTo="6" yFrom="0" yTo="100">
                 <s:stroke>
                      <s:SolidColorStroke color="0x000000" weight="1" caps="square"/>
                 </s:stroke>
            </s:Line>
            <s:Line xFrom="12" xTo="12" yFrom="0" yTo="100">
                 <s:stroke>
                      <s:SolidColorStroke color="0x000000" weight="2" caps="square"/>
                 </s:stroke>
            </s:Line>
            <s:Line xFrom="20" xTo="20" yFrom="0" yTo="100">
                 <s:stroke>
                      <s:SolidColorStroke color="0x000000" weight="3" caps="square"/>
                 </s:stroke>
            </s:Line>
            <s:Line xFrom="30" xTo="30" yFrom="0" yTo="100">
                 <s:stroke>
                      <s:SolidColorStroke color="0x000000" weight="5" caps="square"/>
                 </s:stroke>
            </s:Line>
            <s:Line xFrom="43" xTo="43" yFrom="0" yTo="100">
                 <s:stroke>
                      <s:SolidColorStroke color="0x000000" weight="8" caps="square"/>
```

```
                </s:stroke>
            </s:Line>
            <s:Line xFrom="58" xTo="58" yFrom="0" yTo="100">
                <s:stroke>
                    <s:SolidColorStroke color="0x000000" weight="13" caps="square"/>
                </s:stroke>
            </s:Line>
            <s:Line xFrom="84" xTo="84" yFrom="0" yTo="100">
                <s:stroke>
                    <s:SolidColorStroke color="0x000000" weight="21" caps="square"/>
                </s:stroke>
            </s:Line>
            <s:Line xFrom="123" xTo="123" yFrom="0" yTo="100">
                <s:stroke>
                    <s:SolidColorStroke color="0x000000" weight="34" caps="square"/>
                </s:stroke>
            </s:Line>
        </s:Group>
     </mx:Panel>
</s:Application>
```

To use a LinearGradientStroke or RadialGradientStroke in MXML graphics, you add one or more `<s:GradientEntry>` tags as children. These gradients are used to define the fill of the stroke. The following MXML graphics example defines a line whose color shifts from blue to yellow:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/LinearGradientLineExampleMXML.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:comps="comps.*">
     <mx:Panel title="Linear Gradient Line MXML Graphic Example"
        height="75%" width="75%" layout="horizontal"
        paddingTop="10" paddingBottom="10" paddingLeft="10" paddingRight="10">
            <s:Group x="20" y="20">
                <s:Line xFrom="0" xTo="200" yFrom="0" yTo="0">
                    <s:stroke>
                        <s:LinearGradientStroke weight="20" caps="square">
                              <s:GradientEntry color="0x0056FF" ratio="0" alpha=".5"/>
                              <s:GradientEntry color="0xECEC21" ratio=".66" alpha=".5"/>
                        </s:LinearGradientStroke>
                    </s:stroke>
                </s:Line>
            </s:Group>
     </mx:Panel>
</s:Application>
```

For more information, see the Line class in the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Text in FXG and MXML graphics

Text is rendered as a graphic element similar to paths and shapes, but with a restricted subset of rendering options. Text elements are always rendered using a solid fill color, modified by any opacity, blend mode, and color transformation defined by parent elements, and clipped to any clipping content defined on its parent elements. Text content is only filled, not stroked.

To use text in an FXG 2.0 document, use the `<RichText>` tag. In FXG 1.0, use the `<TextGraphic>` tag.

In MXML, you can use the RichText, RichEditableText, or Label classes to render text. For more information on using text controls in MXML, see "MX text controls" on page 805.

In FXG, the `<RichText>` tag supports the following child elements:

- `<content>`
- `<transform>`

To specify text in a `<RichText>` tag, you use a single `<content>` child tag. The following FXG-based example shows several methods of using text in a `<RichText>` tag:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/FXGRichTextExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:comps="comps.*" height="100%" width="100%">

     <mx:Panel title="RichText Example"
        height="75%" width="75%" layout="horizontal"
        paddingTop="10" paddingBottom="10" paddingLeft="10" paddingRight="10">
        <s:HGroup>
            <s:Group>
                <comps:TextComp/>
            </s:Group>
            <s:Group>
                <comps:JustifiedTextComp/>
            </s:Group>
            <s:Group>
                <comps:FormattedTextComp/>
            </s:Group>
        </s:HGroup>
     </mx:Panel>
</s:Application>
```

The following file defines the TextComp FXG component used in the previous example:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/comps/TextComp.fxg -->
<Graphic xmlns="http://ns.adobe.com/fxg/2008" version="2">
    <RichText>
       <content>Hello World!</content>
    </RichText>
</Graphic>
```

The following file defines the JustifiedTextComp FXG component used in the previous example:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/comps/JustifiedTextComp.fxg -->
<Graphic xmlns="http://ns.adobe.com/fxg/2008" version="2">
    <RichText textAlign="justify" width="100">
       <content>This is a block of text that is justified, so you can see formatting
applied.</content>
    </RichText>
</Graphic>
```

The following file defines the FormattedTextComp FXG component used in the previous example:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/comps/FormattedTextComp.fxg -->
<Graphic xmlns="http://ns.adobe.com/fxg/2008" version="2">
    <RichText>
       <content>This text is <span fontWeight="bold">BOLD</span>,<br/>
       this text is <span textDecoration="underline">UNDERLINED</span>,<br/>
       and this text is <span fontStyle="italic">ITALIC</span>.
       <p>This is a new paragraph.</p></content>
    </RichText>
</Graphic>
```

The `<content>` child tag supports the following child elements:

- `<p>`
- `<span>`
- `<br>`
- `<tcy>`
- `<a>`
- `<img>`
- `<tab>`
- `<linkNormalFormat>`
- `<linkHoverFormat>`
- `<linkActiveFormat>`

The `<content>` child tag can also take raw text.

If you do not explicitly use a `<p>` tag as the first tag in a `<content>` tag, then it is implied.

If you apply style attributes to the `<RichText>` tag (such as `fontFamily="arial"`), then the `<span>` tag is implied on the content of the `<RichText>` tag. The following example has multiple text formats, with one implied span and one explicit span:

```
<RichText fontFamily="Verdana" fontWeight="bold">
    <content>Hello, <span fontWeight="normal">World</span></content>
</RichText>
```

The contents of the `<RichText>` tag support a set of style attributes that define formatting. These styles are a subset of the MXML RichText class. Some styles are applied at the character and paragraph level, and some are applied at the container level. Container-level attributes (whose level is listed as including `<RichText>`), affect the entire text flow when applied to the container. Paragraph-level attributes (whose level is listed as including `<p>`), affect the paragraph when applied to a `<p>` tag. And character-level attributes (whose level is listed as including `<span>`) affect only the current span when applied to a `<span>` tag.

The following table describes the formatting attributes supported by FXG:

Attribute	**Description**	**Level**
alignmentBaseline	Specifies which of the baselines of the line containing the element the dominantBaseline snaps to, thus determining the vertical position of the element in the line. The default value is useDominantBaseline. Valid values are roman, ascent, descent, ideographicTop, ideographicCenter, ideographicBottom, and useDominantBaseline.	<RichText>, <p>, or <span>
backgroundAlpha	Alpha (transparency) value for the background. A value of 0 is fully transparent, and a value of 1 is fully opaque. The default value is 1.	<RichText>, <p>, or <span>
backgroundColor	Background color of the text. Can be either transparent, or an integer containing three 8-bit RGB components. The default value is transparent.	<RichText>, <p>, or <span>
baselineShift	Indicates the baseline shift for the element in pixels. The element is shifted perpendicular to the baseline by this amount. In horizontal text, a positive baseline shift moves the element up and a negative baseline shift moves the element down. The default value is 0.0, indicating no shift. A value of superscript shifts the text up by an amount specified in the font, and applies a transform to the fontSize also based on preferences in the font. A value of subscript shifts the text down by an amount specified in the font, and also transforms the fontSize. A percent value shifts the text by a percentage of the fontSize attribute. The minimum/maximum percent are -1000%/1000%. A Number shifts the text by that number of pixels. The minimum/maximum Number values are -1000/1000.	<RichText>, <p>, or <span>
blockProgression	Controls the direction in which lines are stacked. In Latin text, this is tb, because lines start at the top and proceed downward. In vertical Chinese or Japanese, this is rl, because lines should start at the right side of the container and proceed leftward. Valid values are tb and rl.	<RichText> or <p>
breakOpportunity	Controls where a line can legally break. Valid values are auto, any, none, or all. A value of auto means line breaking opportunities are based on standard Unicode character properties, such as breaking between words and on hyphens. A value of any indicates that the line may end at any character. This value is typically used when Roman text is embedded in Asian text and it is desirable for breaks to happen in the middle of words. A value of none means that no characters in the range are treated as line break opportunities. A value of all means that all characters in the range are treated as mandatory line break opportunities; this results in one character per line. The default value is auto.	<RichText>, <p>, or <span>
color	Sets the color of the text. The default value is 0x000000.	<RichText>, <p>, or <span>

Attribute	Description	Level
columnCount	Defines the number of columns in the RichText element. The column number overrides the other column settings. The value can be an Integer, or auto if unspecified. If it's an integer, the range of legal values is 0 to 50. If columnCount is not specified, but columnWidth is, then columnWidth is used to create as many columns as can fit in the container. The default value is auto.	<RichText>
columnGap	Defines th space between columns in pixels. Does not include space before the first column or after the last column. Use the padding properties to define that. Legal values range from 0 to 1000. The default value is 0.	<RichText>
columnWidth	Defines the width of columns in pixels. If you specify the width of the columns, but not the count, Flex creates as many columns of that width as possible given the the container width and columnGap settings. Any remainder space is left after the last column. Legal values are 0 to 8000. The default value is auto.	<RichText>
digitCase	Defines the case for digits. Valid values are default, lining, and oldStyle. A value of default uses the normal digit case from the font. A value of lining uses the lining digit case from the font. A value of oldStyle uses the old style digit case from the font. The default value is default.	<RichText>, <p>, or <span>
digitWidth	Specifies how wide digits will be when the text is set. Valid values are proportional, tabular, and default. A value of proportional means that the proportional widths from the font are used, and different digits will have different widths. A value of tabular means that every digits has the same width. A value of default means that the normal width from the font is used. The default value is default.	<RichText>, <p>, or <span>
direction	Controls the dominant writing direction for the paragraphs (left-to-right or right-to-left), and how characters with no implicit writing direction, such as punctuation, are treated. Valid values are ltr and rtl. The default value is ltr.	<RichText> or <p>

Attribute	Description	Level
`dominantBaseline`	Specifies which of the baselines of the element snaps to the alignmentBaseline to determine the vertical position of the element on the line. Valid values are `auto`, `roman`, `ascent`, `descent`, `ideographicTop`, `ideographicCenter`, and `ideographicBottom`. A value of `auto` gets resolved based on the `textRotation` of the span and the locale of the parent paragraph. A `textRotation` of `rotate270` resolves to `ideographicCenter`. A locale of Japanese ("ja") or Chinese ("zh-XX", "zh_XX", etc), resolves to `ideographicCenter`, whereas all others are resolved to `roman`. The default value is `auto`.	`<RichText>`, `<p>`, or `<span>`
`firstBaselineOffset`	Specifies the position of the first line of text in the container (first in each column) relative to the top of the container. The first line may appear at the position of the line's ascent, or below by the `lineHeight` of the first line. Or it may be offset by a pixel amount. Valid values are `auto`, `ascent`, `lineHeight`, and a Number. The default value (auto) specifies that the line top be aligned to the container top inset. The baseline that this property refers to is deduced from the container's locale as follows: `ideographicBottom` for Chinese and Japanese locales, `roman` otherwise. Minumum/maximum values are 0/1000. The default value is `auto`.	`<RichText>`
`fontFamily`	Defines the font family name used to render the text. The font depends on the glyphs that are being rendered and the fonts that are available on the client system. For most platforms, the default value is Arial.	`<RichText>`, `<p>`, or `<span>`
`fontSize`	Sets the size of the glyphs that are used to render the text, specified in point sizes. The default value is 12. The minimum value is 1. The maximum value is 500.	`<RichText>`, `<p>`, or `<span>`
`fontStyle`	Italicizes text. Valid values are `normal` and `italic`. The default value is `normal`.	`<RichText>`, `<p>`, or `<span>`
`fontWeight`	Bolds text. Valid values are `normal` and `bold`. The default value is `normal`.	`<RichText>`, `<p>`, or `<span>`
`justificationRule`	Defines the justifier. A value of `eastAsian` enables justification for Japanese. The default value is `auto`. A value of `auto` is resolved based on the locale of the paragraph. Values for Japanese ("ja") and Chinese ("zh-XX", "zh_XX", etc) resolve to `eastAsian`, while all other locales resolve to space.	`<RichText>` or `<p>`

Attribute	Description	Level
justificationStyle	Defines the justification style. A value of auto is resolved based on the locale of the paragraph. Currently, all locales resolve to pushInKinsoku, however, this value is only used in conjunction with a justificationRule value of eastAsian, so is only applicable to "ja" and all "zh" locales. A value of prioritizeLeastAdjustment bases justification on either expanding or compressing the line, whichever gives a result closest to the desired width. A value of pushInKinsoku bases justification on compressing kinsoku at the end of the line, or expanding it if there is no kinsoku or if that space is insufficient. A value of pushOutOnly bases justification on expanding the line. Valid values are auto, prioritizeLeastAdjustment, pushInKinsoku, and pushOutOnly. The default value is auto.	<RichText> or <p>
kerning	Applies pair kerning to text. Valid values are on, off, and auto. If on, pair kerns are honored. If off, there is no font-based kerning applied. If auto, kerning is applied to all characters except Kanji, Hiragana or Katakana. The default value is auto.	<RichText>, <p>, or <span>
leadingModel	Specifies the leading basis (baseline to which the lineHeight property refers) and the leading direction (which determines whether the lineHeight property refers to the distance of a line's baseline from that of the line before it or the line after it). The default value is auto which is resolved based on locale. Locale values of Japanese ("ja") and Chinese ("zh-XX", "zh_XX", etc) resolve auto to ideographicTopDown and other locales resolve to romanUp. Valid values are auto, romanUp, ideographicTopUp, ideographicCenterUp, ascentDescentUp, ideographicTopDown, and ideographicCenterDown.	<RichText> or <p>
ligatureLevel	Controls which ligatures in the font will be used. Valid values are minimum, common, uncommon, and exotic. A value of minimum turns on rlig, common is rlig + clig + liga; uncommon is rlig + clig + liga + dlig; exotic is rlig + clig + liga + dlig + hlig. You cannot turn the various ligature features on independently. The default value is common.	<RichText>, <p>, or <span>
lineBreak	Determines whether the text wraps the lines at the edge of the enclosing <RichText> element. Set to toFit to wrap the lines. Set to explicit to break the lines only at a Unicode line end character (such as a newline or line separator). Valid values are toFit and explicit. The default value is toFit.	<RichText>

Attribute	Description	Level
`lineHeight`	Defines the leading, or the distance from the previous line's baseline to the current line, in points. This can be specified in absolute pixels, or as a percentage of the point size. The default value is 120%. The minimum value for percent or number is 0.	`<RichText>`, `<p>`, or `<span>`
`lineThrough`	Whether to apply a strike through to the text. Set to `true` to apply a line through the text; otherwise set to `false`. The default value is `false`.	`<RichText>`, `<p>`, or `<span>`
`locale`	Defines the locale of the text. This controls case transformations and shaping. Standard locale identifiers as described in Unicode Technical Standard #35 are used. For example en, en_US and en-US are all English, ja is Japanese. Locale applied at the paragraph and higher level impacts resolution of "auto" values for `dominantBaseline`, `justificationRule`, `justificationStyle` and `leadingModel`. See individual attributes for resolution values.	`<RichText>`, `<p>`, or `<span>`
`marginBottom`	Defines the space after the paragraph. As in CSS, adjacent vertical space collapses. No margin is necessary if the paragraph falls at the bottom of the `<RichText>` tag. The default value is 0. The minimum value is 0.	`<RichText>` or `<p>`
`marginLeft`	Defines the indentation applied to the left edge of the `<RichText>` tag, measured in pixels. The default value is 0.	`<RichText>` or `<p>`
`marginRight`	Defines the indentation applied to the right edge of the `<RichText>` tag, measured in pixels. The default value is 0.	`<RichText>` or `<p>`
`marginTop`	Defines the space before the paragraph. As in CSS, adjacent vertical space collapses. Given two adjoining paragraphs (A, B), where A has `marginBottom` 12 and B has `marginBottom` 24, the total space between the paragraphs is 24, the maximum of the two, and not 36, the sum. If the paragraph is at the top of the column, no extra space is left for the margin. The default value is 0. The minimum value is 0.	`<RichText>` or `<p>`
`paddingBottom`	Defines the inset from bottom edge to content area, in pixels. The default value is 0. The minumum/maximum values are 0/1000.	`<RichText>`
`paddingLeft`	Defines the inset from left edge to content area, in pixels. The default value is 0. The minumum/maximum values are 0/1000.	`<RichText>`
`paddingRight`	Defines the inset from right edge to content area, in pixels. The default value is 0. The minumum/maximum values are 0/1000.	`<RichText>`
`paddingTop`	Defines the inset from top edge to content area, in pixels. The default value is 0. The minumum/maximum values are 0/1000.	`<RichText>`

Attribute	**Description**	**Level**
`paragraphEndIndent`	Defines the indentation applied to the end edge of a paragraph (right edge if direction is ltr, left edge otherwise). Measured in pixels. Legal values range from 0 to 1000. Default is 0.	`<RichText>` or `<p>`
`paragraphSpaceAfter`	Defines the amount of whitespace that appears the paragraph. As in CSS, adjacent vertical space collapses (see note for paragraphSpaceBefore). No "space after" is necessary if the paragraph falls at the bottom of the RichText. Legal values range from 0 to 1000. The default value is 0. The minimum value is 0.	`<RichText>` or `<p>`
`paragraphSpaceBefore`	Specifies the amount of whitespace that appears above a paragraph. As in CSS, adjacent vertical space collapses. For two adjoining paragraphs (A, B), where A has paragraphSpaceAfter 12 and B has paragraphSpaceBefore 24, the total space between the paragraphs will be 24, the maximum of the two, and not 36, the sum. If the paragraph comes at the top of the column, no extra space is left before it. Legal values range from 0 to 1000. The default value is 0. The minimum value is 0.	`<RichText>` or `<p>`
`paragraphStartIndent`	Defines the indentation applied to the start edge of the paragraph (left edge if direction is ltr, right edge otherwise). Measured in pixels. Legal values range from 0 to 1000. The default value is 0.	`<RichText>` or `<p>`
`tabStops`	Defines an array of tab stops. For more information, see the FXG 2.0 Specification.	`<RichText>` or `<p>`
`textAlpha`	Sets the opacity level of the text, ranging from 0 (completely transparent) to 1 (completely opaque). The default value is 1.	`<RichText>`, `<p>`, or `<span>`
`textAlign`	Aligns text relative to the text box edges. Valid values are `left`, `right`, `center`, and `justify`. The default value is `left`.	`<RichText>` or `<p>`
`textAlignLast`	Aligns the last line of the paragraph. To make a paragraph set all lines justified, set the `textAlign` and `textAlignLast` attributes to `justify`. Valid values are `left`, `center`, `right`, and `justify`. The default value is `left`.	`<RichText>` or `<p>`
`textDecoration`	Underlines text. Valid values are `none` and `underline`. The default value is `none`.	`<RichText>`, `<p>`, or `<span>`
`textIndent`	Indent the first line of text in a paragraph. The indent is relative to the left margin. Measured in pixels. The default value is 0. This attribute can be negative.	`<RichText>` or `<p>`

Attribute	Description	Level
`textJustify`	Applies when `justificationRule` is space. A value of `interWord` spreads justification space out to spaces in the line. A value of `distribute` spreads it out to letters as well as spaces. The default value is `interWord`. Valid values are `interWord` and `distribute`.	`<RichText>` or `<p>`
`textRotation`	Controls the rotation of the text, in ninety degree increments. Valid values are `auto`, `rotate0`, `rotate90`, `rotate180`, and `rotate270`. The default value is `auto`.	`<RichText>`, `<p>`, or `<span>`
`trackingLeft`	Adds space to the left of each character. Can be a percent value or a Number. A Number tracks by a pixel amount, with the minimum/maximum values -100/1000. A percent value is the percentage of the `fontSize` attribute. Legal values for percentages are -100% to 1000%. Negative values bring characters closer together. The default value is 0.	`<RichText>`, `<p>`, or `<span>`
`trackingRight`	Adds space to the right of each character. Can be a percent value or a Number. A Number tracks by a pixel amount, with the minimum/maximum values -100/1000. A percent value is the percentage of the `fontSize` attribute. Legal values for percentages are -100% to 1000%. Negative values bring characters closer together. The default value is 0.	`<RichText>`, `<p>`, or `<span>`

Attribute	Description	Level
typographicCase	Controls the case in which the text appears. Valid values are default, capsToSmallCaps, uppercase, lowercase, and lowercaseToSmallCaps. A value of default does not apply any case changes.A value of smallCaps converts all characters to uppercase and applies c2sc. A value of uppercase and lowercase are case conversions.A value of caps turns on case.A value of lowercaseToSmallCaps converts all characters to uppercase, and for those characters which have been converted, applies c2sc. The default value is default.	<RichText>, <p>, or <span>
verticalAlign	Sets the vertical alignment of the lines within the container. Valid values are top, middle, bottom, justify, and inherit. The lines might appear at the top of the container, centered within the container, at the bottom, or evenly spread out across the depth of the container. The default value is top.	<RichText>
whiteSpaceCollapse	Determines how whitespace such as line feeds, newlines, and tabs are treated. Valid values are collapse and preserve. Set to collapse to convert line feeds, newlines, and tabs to spaces, collapse adjacent spaces to one, and trim leading and trailing whitespace. Set to preserve to maintain whitespace without changes.	<RichText>, <p>, or <span>

Not all of the properties in MXML text-based controls are supported by the <RichText> tag in FXG, and not all properties of FXG are supported by the MXML text-based controls. For example, the RichText class in MXML does not have the margin-related properties that the <RichText> tag in FXG has.

The <RichText> tag is not optimized when an FXG document is compiled. It is the only FXG element that is not optimized because there are no low-level Flash Player instructions for RichText.

If you do not specify a the width or height properties of the <RichText> tag, or if the specified width or height is 0, the width and height are calculated based on the text content. This is done using the following logic for horizontal text:

- If the width is specified, but the height is not, the container height is set to the height required to fit the text. Text wraps to the width of the container, and the total height of the text becomes the container height.
- If the width is not specified, then the text breaks only at line breaks and at the paragraph end. The width of the container is then set to the width of the longest line.
- If neither width nor height are specified, the width is set as described above, and then the height is set based on the width.
- If the height is specified, and the text exceeds what will fit, then the remaining text is preserved but does not appear in the container; it is clipped. You can choose to add scroll bars to view the additional text, but scroll bars are not part of FXG.

Fills in FXG and MXML graphics

Fills and strokes generally define a default bounding area that they fill, clipped by the path they are filling. Fills and strokes can define their own user coordinate space, which defaults to the coordinate space of the object they are filling. A fill or stroke can modify its coordinate space with transform attributes and child elements, similar to a Group, that is concatenated with its parent's transforms to define a fill region in document coordinates.

To define a fill in FXG, you use the `<fill>` tag as the child of a graphic element, such as a Rect. In MXML graphics, you use the `<s:fill>` tag, or a class that implements the mx.graphics.IFill interface. Fill elements and tags can contain a single tag that defines the type of fill.

The following types of fills are supported by FXG and MXML graphics:

- SolidColor
- RadialGradient
- LinearGradient
- BitmapFill

SolidColor fills

A solid color fill fills a path or shape with a single solid color or solid color with opacity. The value of the `color` property is a hexadecimal number, such as #FF00FF. In FXG, you cannot use the 0x notation that is supported in MXML graphics.

In FXG, you use the `<SolidColor>` tag to create a solid color fill. In MXML graphics, you use the `<s:SolidColor>` tag.

FXG example

The following FXG-based example creates a rectangle with a SolidColor fill at 50% opacity:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/SolidColorExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:comps="comps.*">
     <mx:Panel title="Solid Color Example"
        height="75%" width="75%" layout="horizontal"
        paddingTop="10" paddingBottom="10" paddingLeft="10" paddingRight="10">
           <s:Group>
                <comps:SolidColorComp/>
           </s:Group>
     </mx:Panel>
</s:Application>
```

The following FXG file defines the SolidColorComp FXG component used in the previous example:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/comps/SolidColorComp.fxg -->
<Graphic xmlns="http://ns.adobe.com/fxg/2008" version="2">
    <!-- Draw rectangle that is filled with a SolidColor. -->
   <Rect height="100" width="200">
         <stroke>
              <SolidColorStroke color="#000000" weight="2"/>
         </stroke>
         <fill>
              <SolidColor color="#00FF00" alpha=".5"/>
         </fill>
   </Rect>
</Graphic>
```

MXML graphics example

The following example draws a rectangle and fills it with a SolidColor fill at 50% opacity:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/SolidColorExampleMXML.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
     <mx:Panel title="Solid Color MXML Graphics Example"
        height="75%" width="75%" layout="horizontal"
        paddingTop="10" paddingBottom="10" paddingLeft="10" paddingRight="10">
           <s:Group>
                <!-- Draw rectangle that is filled with a SolidColor. -->
               <s:Rect height="100" width="200">
                     <s:stroke>
                          <s:SolidColorStroke color="0x000000" weight="2"/>
                     </s:stroke>
                     <s:fill>
                          <s:SolidColor color="0x00FF00" alpha=".5"/>
                     </s:fill>
               </s:Rect>
           </s:Group>
     </mx:Panel>
</s:Application>
```

For more information, see the SolidColor class in the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

LinearGradient fills

A linear gradient fills a path or shape with a continuously smooth color transition between a list of colors along a vector. With gradient fills, you can use the `spreadMethod` property to define a repetition of the patterns.

In FXG, you use the `<LinearGradient>` tag to define a linear gradient. In MXML graphics, you use the `<s:LinearGradient>` tag, or the mx.graphics.LinearGradient class.

FXG example

The following FXG-based example uses a LinearGradient fill:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/LinearGradientExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:comps="comps.*">
     <mx:Panel title="Linear Gradient Example"
        height="75%" width="75%" layout="horizontal"
        paddingTop="10" paddingBottom="10" paddingLeft="10" paddingRight="10">
           <s:Group>
                <comps:LinearGradientComp/>
            </s:Group>
     </mx:Panel>
</s:Application>
```

The following FXG file defines the LinearGradientComp FXG component used in the previous example:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/comps/LinearGradientComp.fxg -->
<Graphic xmlns="http://ns.adobe.com/fxg/2008" version="2">
    <!-- Draw rectangle that is filled with a LinearGradient. -->
   <Rect height="100" width="200">
         <stroke>
              <SolidColorStroke color="#000000" weight="2"/>
         </stroke>
         <fill>
              <LinearGradient>
                <GradientEntry color="#0056FF" ratio="0" alpha=".5"/>
                <GradientEntry color="#00CC99" ratio=".33" alpha=".5"/>
                <GradientEntry color="#ECEC21" ratio=".66" alpha=".5"/>
              </LinearGradient>
         </fill>
   </Rect>
</Graphic>
```

MXML graphics example

The following MXML graphics example draws a rectangle and fills it with a LinearGradient fill:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/LinearGradientExampleMXML.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:comps="comps.*">
     <mx:Panel title="Linear Gradient MXML Graphic Example"
        height="75%" width="75%" layout="horizontal"
        paddingTop="10" paddingBottom="10" paddingLeft="10" paddingRight="10">
           <s:Group>
                <!-- Draw rectangle that is filled with a LinearGradient. -->
               <s:Rect height="100" width="200">
                     <s:stroke>
                          <s:SolidColorStroke color="0x000000" weight="2"/>
                     </s:stroke>
                     <s:fill>
                          <s:LinearGradient>
                            <s:GradientEntry color="0x0056FF" ratio="0" alpha=".5"/>
                            <s:GradientEntry color="0x00CC99" ratio=".33" alpha=".5"/>
                            <s:GradientEntry color="0xECEC21" ratio=".66" alpha=".5"/>
                          </s:LinearGradient>
                     </s:fill>
               </s:Rect>
            </s:Group>
     </mx:Panel>
</s:Application>
```

RadialGradient fills

A radial gradient specifies a gradual color transition in the fill color. A radial gradient defines a fill pattern that radiates out from the center of a graphical element.

In FXG, you use the `<RadialGradient>` tag to define a radial gradient. you add a series of GradientEntry objects to the `<RadialGradient>` tag's `entries` Array to define the colors that make up the gradient fill.

In MXML graphics, you use the `<s:RadialGradient>` tag, or the mx.graphics.RadialGradient class. You then define an array of entries, and add to it GradientEntry objects.

FXG example

The following FXG-based example uses a radial gradient in an FXG component:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/RadialGradientExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:comps="comps.*">
     <mx:Panel title="Radial Gradient Example"
        height="75%" width="75%" layout="horizontal"
        paddingTop="10" paddingBottom="10" paddingLeft="10" paddingRight="10">
           <s:Group>
                <comps:RadialGradientComp/>
            </s:Group>
     </mx:Panel>
</s:Application>
```

The following FXG file defines the RadialGradientComp FXG component used in the previous example:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/comps/RadialGradientComp.fxg -->
<Graphic xmlns="http://ns.adobe.com/fxg/2008" version="2">
    <!-- Draw rectangle that is filled with a RadialGradient. -->
    <Rect height="100" width="200">
         <stroke>
              <SolidColorStroke color="#000000" weight="2"/>
         </stroke>
         <fill>
              <RadialGradient>
                <GradientEntry color="#0056FF" ratio="0" alpha=".5"/>
                <GradientEntry color="#00CC99" ratio=".33" alpha=".5"/>
                <GradientEntry color="#ECEC21" ratio=".66" alpha=".5"/>
              </RadialGradient>
         </fill>
   </Rect>
</Graphic>
```

MXML graphics example

The following MXML graphics example draws a rectangle and fills it with a RadialGradient fill:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/RadialGradientExampleMXML.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
     <mx:Panel title="Radial Gradient MXML Graphics Example"
        height="75%" width="75%" layout="horizontal"
        paddingTop="10" paddingBottom="10" paddingLeft="10" paddingRight="10">
        <s:Group>
            <s:Rect height="100" width="200">
                 <s:stroke>
                      <s:SolidColorStroke color="0x000000" weight="2"/>
                 </s:stroke>
                 <s:fill>
                      <s:RadialGradient>
                        <s:GradientEntry color="0x0056FF" ratio="0" alpha=".5"/>
                        <s:GradientEntry color="0x00CC99" ratio=".33" alpha=".5"/>
                        <s:GradientEntry color="0xECEC21" ratio=".66" alpha=".5"/>
                      </s:RadialGradient>
                 </s:fill>
           </s:Rect>
        </s:Group>
     </mx:Panel>
</s:Application>
```

BitmapFill fills

In FXG, you use the `<BitmapFill>` tag to fill an area with the specified bitmap data. In MXML graphics, you use the `<s:BitmapFill>` tag, or the mx.graphics.BitmapFill class.

A bitmap fill can scale or repeat its contents to fit the area. The default behavior is to scale the bitmap data to fill the available area. To prevent scaling, set the fillMode property to clip. If the fill is larger than the available area, the bitmap data is clipped. To scale the bitmap data to the available area, set the `fillMode` property to `scale`. To repeat the bitmap data in the available area, set the `fillMode` property to `repeat`.

When you set the value of the `fillMode` property in ActionScript (for MXML graphics), use the constants defined on the BitmapFillMode class.

You can offset the position of the bitmap data inside the specified fill area by using the `offset` and `origin` position properties. You can rotate the bitmap data with the `rotation` property.

The properties that are supported by the FXG `<BitmapFill>` tag are listed in “Graphics classes and elements” on page 1715.

A fill’s bitmap data is affected by matrix transformations that you can define on the fill.

To specify the source of a bitmap fill, use the `@Embed` directive inside the `source` property. This embeds the source of the fill into the application at compile time.

You cannot specify the source of a bitmap fill at runtime.

FXG example

The following FXG-based example defines a BitmapFill for a rectangle:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/FXGBitmapFillExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:comps="comps.*">

     <mx:Panel title="BitmapFill Example"
        height="75%" width="75%" layout="horizontal"
        paddingTop="10" paddingBottom="10" paddingLeft="10" paddingRight="10">
           <s:Group>
                <comps:BitmapFillComp/>
            </s:Group>
     </mx:Panel>
</s:Application>
```

The following file defines the BitmapFillComp FXG component used in the previous example:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/comps/BitmapFillComp.fxg -->
<Graphic xmlns="http://ns.adobe.com/fxg/2008" version="2">
   <!-- Draw rectangle that is filled with a repeating bitmap. -->
   <Rect height="100" width="200">
         <stroke>
              <SolidColorStroke color="#000000" weight="2"/>
         </stroke>
         <fill>
              <BitmapFill
                source="@Embed('../../assets/AirIcon12x12.gif')"
                fillMode="repeat"/>
         </fill>
   </Rect>
</Graphic>
```

MXML graphics example

The following MXML graphics example defines a bitmap fill:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/BitmapFillExampleMXML.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:comps="comps.*">

     <mx:Panel title="BitmapFill MXML Graphic Example"
        height="75%" width="75%" layout="horizontal"
        paddingTop="10" paddingBottom="10" paddingLeft="10" paddingRight="10">
        <s:Graphic>
           <!-- Draw rectangle that is filled with a repeating bitmap. -->
           <s:Rect height="100" width="200">
                 <s:stroke>
                      <s:SolidColorStroke color="0x000000" weight="2"/>
                 </s:stroke>
                 <s:fill>
                      <s:BitmapFill
                        source="@Embed('../assets/AirIcon12x12.gif')"
                        fillMode="repeat"/>
                 </s:fill>
           </s:Rect>
        </s:Graphic>
     </mx:Panel>
</s:Application>
```

For more information, see the BitmapFill class in *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Bitmap graphics in FXG and MXML graphics

A bitmap graphic defines a rectangular region that is filled with bitmap data from a source file.

In FXG, you use the `<BitmapImage>` tag to draw a bitmap graphic. In MXML graphics, you use the `<s:BitmapImage>` tag, or the spark.primitives.BitmapImage class.

A bitmap image can be optionally scaled or repeated to fit the available area. The default behavior is to scale the image to fill the available area. To prevent scaling, set the `fillMode` property to `clip`. If the image is larger than the available area, the fill is clipped. To scale the image to the available area, set the `fillMode` property to `scale`. To repeat the image in the available area, set the `fillMode` property to `repeat`.

The properties that are supported by the FXG `<BitmapImage>` tag are listed in "Graphics classes and elements" on page 1715.

Bitmap graphics support the following types of images:

- PNG
- GIF
- JPG

When used in a clip mask, bitmap graphics are treated as bitmap-filled rectangles. As a result, the alpha channel of the source bitmap is not relevant when it is part of a mask. The bitmap affects the mask in the same manner as the solid filled rectangle.

FXG examples

The following FXG-based example displays bitmap images in FXG:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/BitmapGraphicExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:comps="comps.*">

     <mx:Panel title="BitmapGraphic Example"
        height="75%" width="75%" layout="horizontal"
        paddingTop="10" paddingBottom="10" paddingLeft="10" paddingRight="10">

        <s:HGroup>
               <!-- Single image, not resized, not repeated. -->
                    <comps:BitmapGraphicComp/>

               <!-- Single image, scaled to fit specified dimensions. -->
                    <comps:ScaledBitmapGraphicComp/>

               <!-- Repeated image to fit specified dimensions. -->
                    <comps:RepeatedBitmapGraphicComp/>
        </s:HGroup>
     </mx:Panel>
</s:Application>
```

The following FXG file defines the BitmapGraphicComp FXG component used in the previous example:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/comps/BitmapGraphicComp.fxg -->
<Graphic xmlns="http://ns.adobe.com/fxg/2008" version="2">
    <BitmapImage
         height="120"
         width="120"
         fillMode="clip"
         source="@Embed('../../assets/AirIcon12x12.gif')"/>
</Graphic>
```

The following FXG file defines the ScaledBitmapGraphicComp FXG component used in the previous example:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/comps/ScaledBitmapGraphicComp.fxg -->
<Graphic xmlns="http://ns.adobe.com/fxg/2008" version="2">
    <BitmapImage
         source="@Embed('../../assets/AirIcon12x12.gif')"
         height="120"
         width="120"
         fillMode="scale"
     />
</Graphic>
```

The following FXG file defines the RepeatedBitmapGraphicComp FXG component used in the previous example:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/comps/RepeatedBitmapGraphicComp.fxg -->
<Graphic xmlns="http://ns.adobe.com/fxg/2008" version="2">
    <BitmapImage
         source="@Embed('../../assets/AirIcon12x12.gif')"
         width="120"
         height="120"
         fillMode="repeat"/>
</Graphic>
```

MXML graphics examples

The following MXML graphics example embeds an image and displays it in three different ways, original size, resized, and tiled:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/BitmapGraphicExampleMXML.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:comps="comps.*">

     <mx:Panel title="Bitmap MXML Graphic Example"
        height="75%" width="75%" layout="horizontal"
        paddingTop="10" paddingBottom="10" paddingLeft="10" paddingRight="10">

        <s:HGroup>
           <!-- Single image, not resized, not repeated. -->
            <s:Graphic>
                <s:BitmapImage
                     width="120"
                     height="120"
                     fillMode="clip"
                     source="@Embed('../assets/AirIcon12x12.gif')"/>
            </s:Graphic>
           <!-- Single image, scaled to fit specified dimensions. -->
            <s:Graphic>
                <s:BitmapImage
                     source="@Embed('../assets/AirIcon12x12.gif')"
                     width="120"
                     height="120"
                     fillMode="scale"
                 />
            </s:Graphic>
           <!-- Repeated image to fit specified dimensions. -->
            <s:Graphic>
                <s:BitmapImage
                     source="@Embed('../assets/AirIcon12x12.gif')"
                     width="120"
                     height="120"
                     fillMode="repeat"/>
            </s:Graphic>
        </s:HGroup>
     </mx:Panel>
</s:Application>
```

The following MXML graphics example embeds the image once, and reuses that embedded class for each of the BitmapImage instances. It also uses the BitmapFillMode class's constants to define the fill mode for each image.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/BitmapGraphicExampleAS.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp()">

    <fx:Script>
        <![CDATA[
            import mx.graphics.BitmapFillMode;

            [Embed(source="../assets/AirIcon12x12.gif")]
            [Bindable]
            public var airLogo:Class;

            private function initApp():void {
                clippedImage.fillMode = BitmapFillMode.CLIP;
                repeatedImage.fillMode = BitmapFillMode.REPEAT;
                scaledImage.fillMode = BitmapFillMode.SCALE;
            }
        ]]>
    </fx:Script>

     <mx:Panel title="Bitmap MXML Graphic Example"
        height="75%" width="75%" layout="horizontal"
        paddingTop="10" paddingBottom="10" paddingLeft="10" paddingRight="10">

        <s:HGroup>
           <!-- Single image, not resized, not repeated. -->
            <s:Graphic>
                <s:BitmapImage id="clippedImage"
                     width="120" height="120"
                     source="{airLogo}"/>
            </s:Graphic>

           <!-- Single image, scaled to fit specified dimensions. -->
            <s:Graphic>
                <s:BitmapImage id="scaledImage"
                     width="120" height="120"
                     source="{airLogo}"/>
            </s:Graphic>

           <!-- Repeated image to fit specified dimensions. -->
            <s:Graphic>
                <s:BitmapImage id="repeatedImage"
                     width="120" height="120"
                     source="{airLogo}"/>
            </s:Graphic>
        </s:HGroup>
     </mx:Panel>
</s:Application>
```

For more information on embedding images in MXML, see "Embedding assets" on page 1699.

For more information on using the BitmapImage class, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Effects in FXG and MXML graphics

You can add effects such as masks, alpha, and blend modes to graphic elements and groups.

Flash Player renders graphic elements and effects on those elements in the following order:

1. GraphicElement or Group
2. Alpha
3. Masks
4. Filters
5. Blend modes

Masks in FXG and MXML graphics

You can add masks to any instance group element. A mask defines the region in which the group's content is rendered. There are two kinds of masking: clipping and alpha.

In *clip masking*, only the actual path, shapes, and fills defined by the mask are used to determine the effect on the source content. Strokes and bitmap filters on the mask are ignored. Filled regions in the mask are considered filled, and Flash Player renders the source content. The type of fill is not relevant: solid color, gradient fill, or bitmap fills in a mask all render the underlying source content, regardless of the alpha values of the mask fill.

In *alpha masking*, the opacity of each pixel in the source content is multiplied by the opacity of the corresponding region of the mask.

To specify a mask, you add a mask as a child of a group or graphic element. A mask must contain a single child tag, either a Group instance or a locally-defined tag from the library. The mask defines its child to be the clipping mask for its parent.

You set the type of masking to use with the `maskType` property on the mask's parent graphical element. You can set the value of this property to either `alpha` or `clip`.

In FXG, if the `<mask>` tag is a child of the root tag, then it must be the first tag. If there is a `<Library>` tag, then it must be the second tag.

FXG example

The following example uses FXG components to define masks:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/SimpleMaskExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:comps="comps.*">
      <s:VGroup gap="10" left="10" top="10">
            <s:RichText text="Ellipse.maskType = 'alpha'"/>
            <comps:AlphaMaskComp/>
            <s:RichText text="Ellipse.maskType = 'clip'"/>
            <comps:ClipMaskComp/>
      </s:VGroup>
</s:Application>
```

The following FXG file defines the AlphaMaskComp FXG component used in the previous example:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/comps/AlphaMaskComp.fxg -->
<Graphic xmlns="http://ns.adobe.com/fxg/2008" version="2">
    <Ellipse width="400" height="200" maskType="alpha">
          <mask>
                <Group>
                      <Rect width="100" height="100">
                            <fill>
                                  <SolidColor alpha="0.1"/>
                            </fill>
                      </Rect>
                </Group>
          </mask>
          <fill>
                <SolidColor color="#FF00FF"/>
          </fill>
    </Ellipse>
</Graphic>
```

The following FXG file defines the ClipMaskComp FXG component used in the previous example:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/comps/ClipMaskComp.fxg -->
<Graphic xmlns="http://ns.adobe.com/fxg/2008" version="2">
    <Ellipse width="400" height="200" maskType="clip">
          <mask>
                <Group>
                      <Rect width="100" height="100">
                            <fill>
                                  <SolidColor/>
                            </fill>
                      </Rect>
                </Group>
          </mask>
          <fill>
                <SolidColor color="#FF00FF"/>
          </fill>
    </Ellipse>
</Graphic>
```

MXML graphics example

The following MXML graphics example shows the two types of masks, and their effect on the underlying graphic:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/SimpleMaskExampleMXML.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
      <s:VGroup gap="10" left="10" top="10">
            <s:RichText text="Ellipse.maskType = 'alpha'"/>
            <s:Ellipse width="400" height="200" maskType="alpha">
                  <s:mask>
                        <s:Group>
                              <s:Rect width="100" height="100">
                                    <s:fill>
                                          <s:SolidColor alpha="0.1"/>
                                    </s:fill>
                              </s:Rect>
                        </s:Group>
                  </s:mask>
                  <s:fill>
                        <s:SolidColor color="#FF00FF"/>
                  </s:fill>
            </s:Ellipse>
            <s:RichText text="Ellipse.maskType = 'clip'"/>
            <s:Ellipse width="400" height="200" maskType="clip">
                  <s:mask>
                        <s:Group>
                              <s:Rect width="100" height="100">
                                    <s:fill>
                                          <s:SolidColor/>
                                    </s:fill>
                              </s:Rect>
                        </s:Group>
                  </s:mask>
                  <s:fill>
                        <s:SolidColor color="#FF00FF"/>
                  </s:fill>
            </s:Ellipse>
      </s:VGroup>
</s:Application>
```

Filters in FXG and MXML graphics

A filter effect consists of a series of graphic operations applied to the rendered graphic of a grouping element and its children before compositing it into the background.

Filters can only be defined on shapes and group instances, not group definitions. That means they can be defined on a Group tag placed as an immediate child of a Graphic or other Group tag, or as a child of a library object that references a defined group.

To define a filter in FXG, add the `<filters>` child tag to the Group or shape you want to apply the filter to. To define a filter in MXML graphics, you add a `<s:filters>` tag to the Group or shape you want to apply the filter to. The filters are defined in the spark.filters package.

The FXG `<filters>` child tag and the `<s:filters>` MXML tag must contain one or more of the bitmap filter types.

Flash Player applies filters to the rendered content of the tag in the order that they appear in the document: the first filter modifies the rendered content, the second filter modifies the output of the first filter, and so on.

The following table lists the filters that are supported by FXG and MXML graphics. It also lists the FXG attributes and children. For the supported properties of the MXML graphics equivalents, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

FXG tag	Equivalent MXML graphics tag and ActionScript class	FXG tag attributes	Children
BevelFilter	<s:BevelFilter> spark.filters.BevelFilter	angle blurX blurY highlightAlpha highlightColor distance knockout quality shadowAlpha shadowColor strength type	None.
BlurFilter	<s:BlurFilter> spark.filters.BlurFilter	blurX blurY quality	None.
ColorMatrixFilter	<s:ColorMatrixFilter> spark.filters.ColorMatrixFilter	matrix	None.
DropShadowFilter	<s:DropShadowFilter> spark.filters.DropShadowFilter	alpha angle blurX blurY color distance inner hideObject knockout quality strength	None.

FXG tag	**Equivalent MXML graphics tag and ActionScript class**	**FXG tag attributes**	**Children**
GlowFilter	<s:GlowFilter> spark.filters.GlowFilter	alpha blurX blurY color inner knockout quality strength	None.
GradientGlowFilter	<s:GradientGlowFilter> spark.filters.GradientGlowFilter	angle blurX blurY distance inner knockout quality strength	GradientEntry
GradientBevelFilter	<s:GradientBevelFilter> spark.filters.GradientBevelFilter	angle blurX blurY distance knockout quality strength type	GradientEntry

MXML graphics also support an AnimateFilter effect, that lets you animate a filter at runtime. Unlike effects that animate properties of the target, the AnimateFilter effect animates properties of the filter applied to the target. For more information, see “Spark filter effects” on page 1823.

In some cases, you can use the RectangularDropShadow class to apply a drop shadow to a graphic element, rather than using the DropShadowFilter effect. It is more efficient, but limited in some ways.

FXG examples

The following FXG-based example applies a drop shadow filter to a rectangle:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/FilteredRectExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:comps="comps.*">

     <mx:Panel title="Rectangle With DropShadowFilter Example"
        height="75%" width="75%" layout="horizontal"
        paddingTop="10" paddingBottom="10" paddingLeft="10" paddingRight="10">
        <s:Group>
            <comps:FilteredRectComp/>
        </s:Group>
     </mx:Panel>
</s:Application>
```

The following file defines the FilteredRectComp FXG component used in the previous example:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/comps/FilteredRectComp.fxg -->
<Graphic xmlns="http://ns.adobe.com/fxg/2008" version="2">
   <Group>
        <filters>
            <DropShadowFilter distance="12" alpha=".5" strength=".33"/>
        </filters>
        <Rect height="100" width="200">
             <stroke>
                  <SolidColorStroke color="#000000" weight="1"/>
             </stroke>
             <fill>
                  <SolidColor color="#FF0000"/>
             </fill>
        </Rect>
   </Group>
</Graphic>
```

You can also apply filters to the RichText element, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/FilteredTextExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:comps="comps.*">

     <mx:Panel title="TextGraphic with BlurFilter Example"
        height="75%" width="75%" layout="horizontal"
        paddingTop="10" paddingBottom="10" paddingLeft="10" paddingRight="10">
        <s:Group>
            <comps:TextFilterComp/>
        </s:Group>
     </mx:Panel>
</s:Application>
```

The following file defines the TextFilterComp FXG component used in the previous example:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/comps/TextFilterComp.fxg -->
<Graphic xmlns="http://ns.adobe.com/fxg/2008" version="2">
   <Group>
        <filters>
            <BlurFilter/>
        </filters>
        <RichText>
           <content>Hello World!</content>
        </RichText>
   </Group>
</Graphic>
```

MXML graphics examples

The following MXML graphics example applies a drop shadow filter to a rectangle:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/FilteredRectExampleMXML.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:comps="comps.*">

     <mx:Panel title="Rectangle With DropShadowFilter MXML Graphics Example"
        height="75%" width="75%" layout="horizontal"
        paddingTop="10" paddingBottom="10" paddingLeft="10" paddingRight="10">
        <s:Group>
            <s:filters>
                <s:DropShadowFilter distance="12" alpha=".5" strength=".33"/>
            </s:filters>
            <s:Rect height="100" width="200">
                 <s:stroke>
                      <s:SolidColorStroke color="0x000000" weight="1"/>
                 </s:stroke>
                 <s:fill>
                      <s:SolidColor color="0xFF0000"/>
                 </s:fill>
            </s:Rect>
        </s:Group>
     </mx:Panel>
</s:Application>
```

Blend modes in FXG and MXML graphics

Graphical elements can control how their content is composited with the background by specifying a `blendMode` attribute. A grouping element with the `blendMode` property set to `normal` acts only as a transformation on the elements contained within. Its 2D transform, color transform, and opacity are multiplied down into its child elements, where they are combined with any local values to render the child element into the current surface.

In FXG, you specify a blend mode by setting the value of the `blendMode` attribute on the `<Group>` or graphic element (like `<Rect>`).

In MXML graphics, you specify a blend mode by setting the value of the `blendMode` attribute on the `<s:Group>` tag or graphic tag (like `<s:Rect>`). The possible values are defined by the flash.display.BlendMode class.

The following table describes the available blend modes in FXG:

Blend mode	Description
add	Adds the values of the constituent colors of the element to the colors of its background, applying a ceiling of 0xFF.
alpha	Applies the alpha value of each pixel of the element to the background.
auto	For grouping elements, acts the same as setting the blend mode to normal when the alpha of the group is 0 or 1, and the blend mode is layer when the alpha of the group is strictly between 0 and 1. For shape elements, acts the same as setting the blend mode to normal.
color	Creates a resulting color with the luminance of the base color and the hue and saturation of the blend color. This preserves the gray levels in the artwork and is useful for coloring monochrome artwork and for tinting color artwork.
colordodge	Brightens the base color to reflect the blend color. Blending with black produces no change.
colorburn	Darkens the base color to reflect the blend color. Blending with white produces no change.
darken	Selects the darker of the constituent colors of the element and the colors of the background (the colors with the smaller values).
difference	Compares the constituent colors of the element with the colors of its background, and subtracts the darker of the values of the two constituent colors from the lighter value.
erase	Erases the background based on the alpha value of the element.
exclusion	Creates an effect similar to but lower in contrast than the Difference mode. Blending with white inverts the base-color components. Blending with black produces no change.
hardlight	Adjusts the color of each pixel based on the darkness of the element. If the element is lighter than 50% gray, the element and background colors are screened, which results in a lighter color. If the element is darker than 50% gray, the colors are multiplied, which results in a darker color. This setting is commonly used for shading effects.
hue	Creates a resulting color with the luminance and saturation of the base color and the hue of the blend color.
invert	Inverts the background.
layer	The element content is pre-composed in a temporary buffer before it is processed further.
lighten	Selects the lighter of the constituent colors of the element and the color of the background (the colors with the larger values).
luminosity	Creates a resulting color with the hue and saturation of the base color and the luminance of the blend color. This mode creates an inverse effect from that of the Color mode.
multiply	Multiplies the values of the element's constituent colors by the colors of the background color, and then normalizes by dividing by 0xFF, resulting in darker colors.
normal	The element content appears in front of the background. Pixel values of the element override those of the background. Where the element is transparent, the background is visible.
overlay	Adjusts the color of each pixel based on the darkness of the background. If the background is lighter than 50% gray, the element and background colors are screened, which results in a lighter color. If the background is darker than 50% gray, the colors are multiplied, which results in a darker color.
saturation	Creates a resulting color with the luminance and hue of the base color and the saturation of the blend color. Painting with this mode in an area with no saturation (gray) causes no change.
screen	Multiplies the complement (inverse) of the display object color by the complement of the background color, resulting in a bleaching effect. This setting is commonly used for highlights or to remove black areas of the display object.
softlight	Darkens or lightens the colors, depending on the blend color. The effect is similar to shining a diffused spotlight on the artwork.If the blend color (light source) is lighter than 50% gray, the artwork is lightened, as if it were dodged. If the blend color is darker than 50% gray, the artwork is darkened, as if it were burned in. Painting with pure black or white produces a distinctly darker or lighter area but does not result in pure black or white.
subtract	Subtracts the values of the constituent colors in the element from the values of the background color, applying a floor of 0.

You can also set the blend mode of a shape.

For more information about using blend modes in FXG, see the FXG 2.0 specification.

Color transformations in FXG and MXML graphics

Color transformations are a high performance way to modify the color of a group or shape element. A color transform can be used, for example, to tint a group, adjust its brightness, or modify its opacity.

Color transforms are applied to the rendering of a group or shape element after any bitmap filters are applied; color transforms affect the *output* of a filter (such as tinting the drop shadow). They are applied before the group element is composited with its background. Blend modes use the transformed color value when combining the group with the background content.

In FXG, you specify a color transformation by adding a `<transform>` tag as a child tag of a group. The `<transform>` tag must have a single child tag `<Transform>`. The `<Transform>` tag can have a child tag `<colorTransform>`. The `<colorTransform>` tag must have a single child tag `<ColorTransform>`. The supported attributes of the `<ColorTransform>` tag are shown in "Graphics classes and elements" on page 1715.

In MXML graphics, you specify a color transformation with the flash.geom.ColorTransform class.

Transformations are considered instanced group properties, and can only be defined on shape elements and Groups whose parent tag is another grouping element, or on instances of symbols. Specifically, transformations cannot be defined on Groups whose parent tag is a `<Definition>` tag, or on the topmost `<Graphic>` tag of an FXG document.

Transformations can be defined on an element in one of two ways: through discrete transform attributes, or through a child Transformation and Matrix element. It is illegal to specify both a child element matrix transformation and one or more transform attributes on the same Group instance.

Discrete transforms can be specified with the attributes `x`,`y`, `scaleX`, `scaleY`, and `rotation`. These attributes are combined to create a 2D transform matrix to define the Group's coordinate space as follows:

- Scale by `scaleX`, `scaleY`
- Rotate by `rotation`
- Translate by `x`, `y`

For more information about using color transformations in FXG, see the FXG 2.0 specification.

Introduction to effects

Effects let you add animation to your application in response to user or programmatic action. For example, you can use effects to cause a dialog box to bounce slightly when it receives focus, or to slowly fade in when it becomes visible. You build effects into your applications by using MXML and ActionScript.

About effects

An *effect* is a visible or audible change to the target component that occurs over a time, measured in milliseconds. Examples of effects are fading, resizing, or moving a component.

Effects are initiated in response to an event, where the event is often is initiated by a user action, such as a button click. However, you can initiate effects programmatically or in response to events that are not triggered by the user.

You can define multiple effects to play in response to a single event. For example, when the user clicks a Button control, a window becomes visible. As the window becomes visible, it uses effects to move to the lower-left corner of the screen, and resize itself from 100 by 100 pixels to 300 by 300 pixels.

Flex ships with two types of effects: Spark effects and MX effects. Spark effects are designed to work with all Flex components, including MX components, Spark components, and the Flex graphics components. Because Spark effects can be applied to any component, Adobe recommends that you use the Spark effects in your application when possible.

The MX effects are designed to work with the MX components, and in some cases might work with the Spark components. However, for best results, you should use the Spark effects.

Blogger Brian Telintelo blogged about Flex: Effects on a Mobile Device.

About applying Spark effects

Spark effects are defined in the spark.effects package. To apply a Spark effect, you first define it in the `<fx:Declarations>`, and then invoke the effect by calling the `Effect.play()` method. The following example uses the event listener of a Button control's `click` event to invoke a Resize effect on an Image control:

```
<?xml version="1.0"?>
<!-- behaviors\SparkResizeEffect.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Declarations>
        <s:Resize id="myResizeEffect"
            target="{myImage}"
            widthBy="10" heightBy="10"/>
    </fx:Declarations>
    <s:Image id="myImage"
        source="@Embed(source='assets/logo.jpg')"/>
    <s:Button label="Resize Me"
        click="myResizeEffect.end();myResizeEffect.play();"/>
</s:Application>
```

Notice that this example first calls the `Effect.end()` method before it calls the `play()` method. Call the `end()` method to ensure that any previous instance of the effect has ended before you start a new one.

In the next example, you create two Resize effects for a Button control. One Resize effect expands the size of the button by 10 pixels when the user clicks down on the button, and the second resizes it back to its original size when the user releases the mouse button. The duration of each effect is 200 ms:

```
<?xml version="1.0"?>
<!-- behaviorExamples\SparkResizeEffectReverse.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Declarations>
        <s:Resize id="myResizeEffectUp"
            target="{myImage}"
            widthBy="10" heightBy="10"/>
        <s:Resize id="myResizeEffectDown"
            target="{myImage}"
            widthBy="-10" heightBy="-10"/>
    </fx:Declarations>
    <s:Image id="myImage"
        source="@Embed(source='assets/logo.jpg')"/>
    <s:Button label="Resize Me Up"
        click="myResizeEffectUp.end();myResizeEffectUp.play();"/>
    <s:Button label="Resize Me Down"
        click="myResizeEffectDown.end();myResizeEffectDown.play();"/>
</s:Application>
```

About applying MX effects

MX effects are defined in the mx.effects package. With MX effects, you typically use a trigger to initiate the effect. A *trigger* is an action, such as a mouse click on a component, a component getting focus, or a component becoming visible. To configure a component to use an effect, you associate an effect with a trigger.

The MX effects are designed to work with the MX components, and in some cases might work with the Spark components.

***Note:** Triggers are not the same as events. For example, a Button control has both a `mouseDown` event and a `mouseDownEffect` trigger. The event initiates the corresponding effect trigger when a user clicks on a component. You use the `mouseDown` event property to specify the event listener that executes when the user clicks on the component. You use the `mouseDownEffect` trigger property to associate an effect with the trigger.*

You associate MX effects with triggers as part of defining the basic behavior for your application, as the following example shows:

```
<?xml version="1.0"?>
<!-- behaviors\ButtonWL.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Declarations>
        <!-- Define effect. -->
        <mx:WipeLeft id="myWL" duration="1000"/>
    </fx:Declarations>
    <!-- Assign effect to targets. -->
    <mx:Button id="myButton" label="Click Me"
        mouseDownEffect="{myWL}"/>
    <mx:Button id="myOtherButton" label="Click Me"
        mouseDownEffect="{myWL}"/>
</s:Application>
```

In this example, the effect is a WipeLeft effect with a duration of 1000 milliseconds (ms). That means it takes 1000 ms for the effect to play from start to finish.

You use data binding to assign the effect to the `mouseDownEffect` property of each Button control. The `mouseDownEffect` property is the effect trigger that specifies to play the effect when the user clicks the control using the mouse. In the previous example, the effect makes the Button control appear as if it is being wiped onto the screen from right to left.

About factory and instance classes

Flex implements effects using an architecture in which each effect is represented by two classes: a factory class and an instance class.

Factory class You use factory classes in your application. The factory class creates an object of the instance class to perform the effect on the target. The factory classes are defined in the spark.effects and mx.effects packages.

You define a factory class in your application, and configure it with the necessary properties to control the effect, such as the zoom size or effect duration, as the following example shows:

```
<fx:Declarations>
    <!-- Factory class. -->
    <s:Resize id="myResizeEffect"
        target="{myImage}"
        widthBy="50" heightBy="50"/>
</fx:Declarations>
<!-- Effect target.-->
<s:Image id="myImage"/>
<s:Button label="Resize Image"
    click="myResizeEffect.end();myResizeEffect.play();"/>
```

By convention, the name of a factory class is the name of the effect, such as Resize, Move, or Fade.

Instance class The instance class implements the effect logic. When an effect plays, the factory class creates an object of the instance class to perform the effect on the target. When the effect ends, Flex destroys the instance object. If the effect has multiple target components, the factory class creates multiple instance objects, one per target.

The factory classes are defined in the spark.effects.supportClasses and mx.effects.effectClasses packages. By convention, the name of an instance class is the name of the factory class with the suffix *Instance*, such as ResizeInstance, MoveInstance, or FadeInstance.

When you use effects, you perform the following steps.

1 Create a factory class object in your application.

2 Configure the factory class object.

When Flex plays an effect, Flex performs the following actions:

1 Creates one object of the instance class for each target component of the effect.

2 Copies configuration information from the factory object to the instance object.

3 Plays the effect on the target using the instance object.

4 Deletes the instance object when the effect completes.

Any changes that you make to the factory object are not propagated to a currently playing instance object. However, the next time the effect plays, the instance object uses your new settings.

When you use effects in your application, you are concerned only with the factory class; the instance class is an implementation detail. However, if you want to create custom effects classes, you must implement a factory and an instance class.

For more information, see “Custom effects” on page 2525.

Available effects

The following table lists the Spark and MX effects:

Spark Effect	MX Effect	Description

`Animate`
`Animae3D`
`AnimateColor`
	`AnimateProperty`	Animates a numeric property of a component, such as `height`, `width`, `scaleX`, or `scaleY`. You specify the property name, start value, and end value of the property to animate. The effect first sets the property to the start value, and then updates the property value over the duration of the effect until it reaches the end value.
		For example, if you want to change the width of a Button control, you can specify width as the property to animate, and starting and ending width values to the effect.

`AnimateFilter`		Animates the properties of a filter applied to the target. This effect does not actually modify the properties of the target. For example, you can use this property to animate a filter, such as a DropShadowFilter, applied to the target.
	`Blur`	Applies a blur visual effect to a component. A Blur effect softens the details of an image. You can produce blurs that range from a softly unfocused look to a Gaussian blur, a hazy appearance like viewing an image through semi-opaque glass. If you apply a Blur effect to a component, you cannot apply a BlurFilter or a second Blur effect to the component. The Blur effect uses the Flash BlurFilter class as part of its implementation. For more information, see flash.filters.BlurFilter in the *ActionScript 3.0 Reference for the Adobe Flash Platform*. You can use the Spark AnimateFilter effect to replace the MX Blur effect.
`CallAction`		Animates the target by calling a function on the target. The effect lets you pass parameters to the function from the effect class.

Spark Effect	MX Effect	Description
	`Dissolve`	Modifies the `alpha` property of an overlay to gradually have to target component appear or disappear. If the target object is a container, only the children of the container dissolve. The container borders do not dissolve. Note: To use the MX Dissolve effect with the `creationCompleteEffect` trigger of a DataGrid control, you must define the data provider of the control inline using a child tag of the DataGrid control, or using data binding. This issue is a result of the data provider not being set until the `creationComplete` event is dispatched. Therefore, when the effect starts playing, Flex has not completed the sizing of the DataGrid control.
`Fade` `CrossFade`	`Fade`	Animate the component from transparent to opaque, or from opaque to transparent. If you specify the MX `Fade` effect for the `showEffect` or `hideEffect` trigger, and if you omit the `alphaFrom` and `alphaTo` properties, the effect automatically transitions from 0.0 to the targets' current `alpha` value for a show trigger, and from the targets' current `alpha` value to 0.0 for a hide trigger. Note: To use these effects with MX components that display text, the component must either support the Flash Text Engine or you must use an embedded font with the component, not a device font. For more information, see "Styles and themes" on page 1492.
	`Glow`	Applies a glow visual effect to a component. The Glow effect uses the Flash GlowFilter class as part of its implementation. For more information, see the flash.filters.GlowFilter class in the *ActionScript 3.0 Reference for the Adobe Flash Platform*. If you apply a Glow effect to a component, you cannot apply a GlowFilter or a second Glow effect to the component. You can use the Spark AnimateFilter effect to replace the MX Glow effect.
	`Iris`	Animates the effect target by expanding or contracting a rectangular mask centered on the target. The effect can either grow the mask from the center of the target to expose the target, or contract it toward the target center to obscure the component. For more information, see "Using MX mask effects" on page 1837.
`Move`	`Move`	Changes the position of a component over a specified time interval. You typically apply this effect to a target in a container that uses absolute positioning, such as a MX Canvas container, or a Spark container that uses BasicLayout. If you apply it to a target in a container that performs automatic layout, the move occurs, but the next time the container updates its layout, it moves the target back to its original position. You can set the container's `autoLayout` property to `false` to disable the move back, but that disables layout for all controls in the container.
	`Pause`	Does nothing for a specified period of time. This effect is useful when you need to composite effects. For more information, see "Creating composite effects" on page 1799.
`Resize`	`Resize`	Changes the width and height of a component over a specified time interval. When you apply a Resize effect, the layout manager resizes neighboring components based on the size changes to the target component. To run the effect without resizing other components, place the target component in a Canvas container, or a Spark container that uses BasicLayout. When you use the Resize effect with Panel containers, you can hide Panel children to improve performance. For more information, see "Improving performance when resizing Panel containers" on page 1842.

Spark Effect	**MX Effect**	**Description**
`Rotate` `Rotate3D`	`Rotate`	Rotates a component around a specified point. You can specify the coordinates of the center of the rotation, and the starting and ending angles of rotation. You can specify positive or negative values for the angles. Note: To use the rotate effects with MX components that display text, the component must either support the Flash Text Engine or you must use an embedded font with the component, not a device font. For more information, see "Styles and themes" on page 1492.
`Scale Scale3D`		Scale a component. You can specify properties to scale the target in the x and y directions.
	`SoundEffect`	Plays an mp3 audio file. For example, you could play a sound when a user clicks a Button control. This effect lets you repeat the sound, select the source file, and control the volume and pan. You specify the mp3 file using the `source` property. If you have already embedded the mp3 file, using the `Embed` keyword, then you can pass the Class object of the mp3 file to the source property. Otherwise, specify the full URL to the mp3 file. For more information, see "Using the MX sound effect" on page 1836.

`Wipe`	`WipeLeft`
	`WipeRight`
	`WipeUp`
	`WipeDown`
		Defines a bar Wipe effect. The before or after state of the component must be invisible.

	`Zoom`	Zooms a component in or out from its center point by scaling the component. Note: When you apply a Zoom effect to text rendered using a system font, Flex scales the text between whole point sizes. Although you do not have to use embedded fonts when you apply a Zoom effect to text, the Zoom will appear smoother when you apply it to embedded fonts. For more information, see "Styles and themes" on page 1492. You can use the Spark Scale effect to replace the MX Zoom effect.

Applying effects

To apply an effect to a target, you must specify the target, and then initiate the effect. Once the effect has started, you can pause, stop, resume, and end the effect epigrammatically.

Using the Effect.target and Effect.targets properties

Use the Effect.target or Effect.targets properties to specify the effect targets. You use the `Effect.target` property in MXML to specify a single target, and the `Effect.targets` property to specify an array of targets, as the following example shows:

```
<?xml version="1.0"?>
<!-- behaviors\TargetProp.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <fx:Declarations>
        <s:Resize id="myResize"
            heightBy="25"
            widthBy="50"
            target="{myButton}"/>
    </fx:Declarations>

    <s:Button id="myButton"
        label="Resize target"
        click="myResize.end();myResize.play();"/>
</s:Application>
```

In this example, you use data binding to the `target` property to specify that the Button control is the target of the Resize effect.

In the next example, you apply a Resize effect to multiple Button controls by using data binding with the effect's `targets` property:

```
<?xml version="1.0"?>
<!-- behaviors\TargetProp3Buttons.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Declarations>
        <s:Resize id="myResize"
            heightBy="25"
            widthBy="50"
            targets="{[myButton1, myButton2, myButton3]}"/>
    </fx:Declarations>
    <s:Button id="myButton1" label="Button 1"/>
    <s:Button id="myButton2" label="Button 2"/>
    <s:Button id="myButton3" label="Button 3"/>

    <s:Button id="myButton4"
        label="Zoom targets"
        click="myResize.end();myResize.play();"/>
</s:Application>
```

Because you specified three targets to the effect, the `play()` method invokes the effect on all three button controls.

If you use the `targets` property to define multiple event targets, calling the `end()` method with no arguments terminates the effect on all targets. If you pass an effect instance as an argument, just that instance is interrupted.

To obtain the effect instance, save the return value of the `play()` method, as the following example shows:

```
var myResizeArray:Array = myResize.play();
```

The Array contains EffectInstance objects, one per target of the effect. Pass the element from the Array to the `end()` method that corresponds to the effect to end, as the following example shows:

```
myResize.end(myResizeArray[1]);
```

You can define an effect that specifies no targets. Instead, you can pass an Array of targets to the `play()` method to invoke the effect on all components specified in the Array, as the following example shows:

```
myResize.play([comp1, comp2, comp3]);
```

This example invokes the Resize effect on three components.

Applying effects by using data binding

You can use data binding in MXML to set properties of an effect. For example, the following example lets the user set the `heightBy` and `widthBy` properties of the Resize effect using a TextInput control. The `heightBy` and `widthBy` properties specify the increase, of pixels, of the size of the target.

```
<?xml version="1.0"?>
<!-- behaviors\DatabindingEffects.mxml  -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Declarations>
        <s:Resize id="myResizeEffect"
            target="{myImage}"
            heightBy="{Number(resizeHeightInput.text)}"
            widthBy="{Number(resizeWidthInput.text)}"/>
    </fx:Declarations>
    <s:Form>
        <s:FormItem label="Resize Height:">
            <s:TextInput id="resizeHeightInput"
                text="0" width="30"/>
        </s:FormItem>
        <s:FormItem label="Resize Width:">
            <s:TextInput id="resizeWidthInput"
                text="0" width="30"/>
        </s:FormItem>
    </s:Form>
    <s:Image id="myImage"
        source="@Embed(source='assets/logo.jpg')"/>
    <s:Button label="Resize Image" click="myResizeEffect.play();"/>
</s:Application>
```

Playing an effect backward

You can pass an optional argument to the `play()` method to play the effect backward, as the following example shows:

```
resizeLarge.play([comp1, comp2, comp3], true);
```

In this example, you specify `true` as the second argument to play the effect backward. The default value is `false`.

You can also use the Effect.pause() method to pause an effect, the Effect.resume() method to resume a paused effect, and the Effect.reverse() method to play an effect backward.

Ending an effect

Use the end() method to terminate an effect at any time, as the following example shows:

```
<?xml version="1.0"?>
<!-- behaviors\ASend.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Declarations>
        <s:Resize id="resizeLarge"
            heightTo="150"
            widthTo="150"
            duration="5000"
            target="{myTA}"/>
    </fx:Declarations>

    <s:Group height="228" width="328">
        <s:Button label="Start"
            x="10" y="10"
            click="resizeLarge.end();resizeLarge.play();"/>
        <s:Button label="End"
            x="86" y="10"
            click="resizeLarge.end();"/>
        <s:Button label="Reset"
            click="myTA.height=100;myTA.width=100;"
            x="162" y="10"/>
        <s:TextArea id="myTA"
            x="10" y="40"
            height="100"
            width="100"
            text="Here is some text."/>
    </s:Group>
</s:Application>
```

In this example, you set the `duration` property of the Resize effect to 10 seconds, and use a Button control to call the `end()` method to terminate the effect when the user clicks the button.

When you call the `end()` method, the effect jumps to its end state and then terminates. For the Resize effect, the effect sets the final size of the expanded TextArea control before it terminates, just as if you had let the effect finish playing. If the effect was a move effect, the target component moves to its final position before terminating.

You can end all effects on a component by calling the `UIComponent.endEffectsStarted()` method on the component. The `endEffectsStarted()` method calls the `end()` method on every effect currently playing on the component.

If you defined a listener for the `effectEnd` event, that listener gets invoked by the `end()` method, just as if you had let the effect finish playing. For more information on working with effect events, see "Handling effect events" on page 1796.

After the effect starts, you can use the `pause()` method to pause the effect at its current location. You can then call the `resume()` method to start the effect, or the `end()` method to terminate it.

Use the stop() method to stop the effect in its current state, but not jump to the end. A call to the `stop()` method dispatches the `effectEnd` event. Unlike a call to the `pause()` method, you cannot call the `resume()` method after calling the `stop()` method. However, you can call the `play()` method to restart the effect.

Creating effects in ActionScript

You can declare and play effects in ActionScript. The following example uses the event listener of a Button control's `click` event to invoke a Resize effect on an TextArea control:

```
<?xml version="1.0"?>
<!-- behaviors\ASplayVBox.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="createEffect(event);">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            // Import effect class.
            import spark.effects.Resize;
            // Create a resize effect
            private var resizeLarge:Resize = new Resize();
            private function createEffect(eventObj:Event):void {
                // Set the TextArea as the effect target.
                resizeLarge.target=myTA;

                // Set resized width and height, and effect duration.
                resizeLarge.widthTo=150;
                resizeLarge.heightTo=150;
                resizeLarge.duration=750;
            }
        ]]>
    </fx:Script>
    <s:Button label="Start"
        click="resizeLarge.end();resizeLarge.play();"/>
    <s:Button label="Reset"
        click="myTA.width=100;myTA.height=100;"/>
    <s:TextArea id="myTA"
        height="100" width="100"
        text="Here is some text."/>
</s:Application>
```

In this example, use the application's `creationComplete` event to configure the effect, and then invoke it by calling the `play()` method in response to a user clicking the Button control.

Working with effects

Effects have many configuration settings that you can use to control the effect. For example, you can set the effect duration and repeat behavior, or handle effect events. The effect target also has configuration settings that you can use to configure it for effects.

Setting effect durations

All effects take the `duration` property that you can use to specify the time, in milliseconds, over which the effect occurs. The following example creates two versions of the Fade effect. The slowFade effect uses a two-second duration; the reallySlowFade effect uses an eight-second duration:

```
<?xml version="1.0"?>
<!-- behaviors\FadeDuration.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Declarations>
        <s:Fade id="slowFade"
            duration="2000"
            target="{myButton1}"/>
        <s:Fade id="reallySlowFade"
            duration="8000"
            target="{myButton2}"/>
    </fx:Declarations>
    <s:Button id="myButton1"
        label="Button 1"
        creationCompleteEffect="{slowFade}"/>
    <s:Button id="myButton2"
        label="Button 2"
        creationCompleteEffect="{reallySlowFade}"/>
</s:Application>
```

Delaying effect start

The Effect.startDelay property specifies a value, in milliseconds, that the effect waits once it is triggered before it begins. You can specify an integer value greater than or equal to 0. If you have used the `Effect.repeatCount` property to specify the number of times to repeat the effect, the `startDelay` property is applied only to the first time the effect plays, but not to the repeated playing of the effect.

If you set the `startDelay` property for a Parallel effect, Flex inserts the delay between each effect of the parallel effect.

Repeating effects

All effects support the Effect.repeatCount and Effect.repeatDelay properties that let you configure whether effects repeat, where:

- `repeatCount` Specifies the number of times to play the effect. A value of 0 means to play the effect indefinitely until stopped by a call to the `end()` method. The default value is 1. For a repeated effect, the `duration` property specifies the duration of a single instance of the effect. Therefore, if an effect has a `duration` property set to 2000, and a `repeatCount` property set to 3, then the effect takes a total of 6000 ms (6 seconds) to play.
- `repeatDelay` Specifies the amount of time, in milliseconds, to pause before repeating the effect. The default value is 0.
- `repeatBehavior` (Spark effects only) Specifies `RepeatBehavior.LOOP` (default) to repeat the effect each time, or `RepeatBehavior.REVERSE` to reverse direction of the effect on each iteration.

For example, the following example repeats the Rotate effect until the user clicks a Button control:

```
<?xml version="1.0"?>
<!-- behaviors\RepeatEff.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Declarations>
        <s:Rotate id="myRotate"
            angleBy="360"
            repeatCount="0"
            target="{myImage}"/>
    </fx:Declarations>
    <s:Label text="Click the image to start rotation."/>
    <s:Button id="myButton"
        label="Stop Rotation"
        click="myRotate.end();"/>
    <s:Image id="myImage"
        source="@Embed(source='assets/logo.jpg')"
        mouseDown="myRotate.end(); myRotate.play();"/>
</s:Application>
```

All effects dispatch an `effectEnd` event when the effect completes. If you repeat the effect, the effect dispatches the `effectEnd` event after the final repetition.

If the effect is a tween effect, such as a MX Fade or MX Move effect, the effect dispatches both the `tweenEnd` effect and the `endEffect` when the effect completes. If you configure the tween effect to repeat, the `tweenEnd` effect occurs at the end of every repetition of the effect, and the `endEffect` event occurs after the final repetition.

Handling effect events

Every Spark and MX effect class supports the following events:

- effectStart Dispatched when the effect starts playing. The `type` property of the event object for this event is set to `EffectEvent.EFFECT_START`.
- effectEnd Dispatched after the effect ends, either when the effect finishes playing or when the effect has been interrupted by a call to the `end()` method. The `type` property of the event object for this event is set to `EffectEvent.EFFECT_END`.
- effectStop Dispatched after the effect stops by a call to the `stop()` method. The `type` property of the event object for this event is set to `EffectEvent.EFFECT_STOP`.

The event object passed to the event listener for these events is of type EffectEvent.

The previous list of events are dispatched by all effects. The Spark and MX effects dispatch additional events. For more information, see “Handling Spark effect events” on page 1826 and “Handling MX effect events” on page 1835.

Flex dispatches one event for each target of an effect. Therefore, if you define a single target for an effect, Flex dispatches a single `effectStart` event, and a single `effectEnd` event. If you define three targets for an effect, Flex dispatches three `effectStart` events, and three `effectEnd` events.

The EffectEvent class is a subclass of the Event class, and contains all of the properties inherited from Event, including `target`, and `type`, and defines a new property named `effectInstance`, where:

target Contains a reference to the Effect object that dispatched the event. This is the factory class of the effect.

type Either `EffectEvent.EFFECT_END` or `EffectEvent.EFFECT_START`, depending on the event.

effectInstance Contains a reference to the EffectInstance object. This is the object defined by the instance class for the effect. Flex creates one object of the instance class for each target of the effect. You access the target component of the effect using the `effectInstance.target` property.

The following example defines an event listener for the `endEffect` event:

```
<?xml version="1.0"?>
<!-- behaviors\EventEffects2.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[

            import mx.effects.*;
            import mx.events.EffectEvent;
            import mx.core.UIComponent;

            private function endEffectListener(eventObj:EffectEvent):void {
                // Access the effect object.
                var effectObj:Effect = Effect(eventObj.target);
                // Access the target component of the effect.
                var effectTarget:UIComponent =
                    UIComponent(eventObj.effectInstance.target);
                // Write the target id and event type to the TextArea control.
                myTA.text = effectTarget.id;
                myTA.text = myTA.text + " " + eventObj.type;
            }
        ]]>
    </fx:Script>

    <fx:Declarations>
        <s:Fade id="slowFade"
            duration="2000"
            effectEnd="endEffectListener(event);"
            target="{myButton1}"/>
    </fx:Declarations>
    <s:Button id="myButton1"
        label="Button 1"
        creationCompleteEffect="{slowFade}"/>
    <s:TextArea id="myTA" />
</s:Application>
```

If the effect has multiple targets, Flex dispatches an `effectStart` event and `effectEnd` event once per target, as the following example shows:

```
<?xml version="1.0"?>
<!-- behaviors\EventEffects.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[

            import mx.effects.*;
            import mx.events.EffectEvent;
            import mx.core.UIComponent;

            private function endSlowFadeEffectListener(eventObj:EffectEvent):void
            {
                // Access the effect object.
                var effectObj:Effect = Effect(eventObj.target);
                // Access the target component of the effect.
                var effectTarget:UIComponent =
                    UIComponent(eventObj.effectInstance.target);

                myTA.text = myTA.text + effectTarget.id + ' : ';
                myTA.text = myTA.text + " " + eventObj.type + '\n';
            }
        ]]>
    </fx:Script>
    <fx:Declarations>
        <s:Fade id="slowFade"
            duration="2000"
            effectEnd="endSlowFadeEffectListener(event);"
            targets="{[myButton1, myButton2, myButton3, myButton4]}"/>
    </fx:Declarations>

    <s:Button id="myButton1"
        label="Button 1"
        creationCompleteEffect="{slowFade}"/>
    <s:Button id="myButton2"
        label="Button 2"
        creationCompleteEffect="{slowFade}"/>
    <s:Button id="myButton3"
        label="Button 3"
        creationCompleteEffect="{slowFade}"/>
    <s:Button id="myButton4"
        label="Button 4"
        creationCompleteEffect="{slowFade}"/>

    <s:TextArea id="myTA" height="125" width="250"/>
</s:Application>
```

Flex dispatches an `effectEnd` event once per target; therefore, the `endSlowFadeEffectListener()` event listener is invoked four times, once per Button control.

Creating composite effects

Flex supports two ways to combine, or *composite*, effects:

Parallel The effects play at the same time. If you play effects in parallel, you must make sure that the effects do not modify the same property of the target. If two effects modify the same property, the effects conflict with each other and the results of the effects are undefined.

Sequence One effect must complete before the next effect starts.

To define a Parallel or Sequence effect, you use the `<mx:Parallel>` or `<,x:Sequence>` tag. The following example defines the Parallel effect, fadeResizeShow, which combines the Spark Fade and Resize effects in parallel, and fadeResizeHide, which combines the Fade and Resize effects in sequence:

```
<?xml version="1.0"?>
<!-- behaviors\CompositeEffects.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Declarations>
        <s:Sequence id="fadeResizeHide"
            target="{aTextArea}"
            duration="1000">
            <s:Fade id="fadeHide"
                alphaFrom="1.0"
                alphaTo="0.0"/>
            <s:Resize id="resizeHide"
                widthTo="0"
                heightTo="0"/>
        </s:Sequence>
        <s:Parallel id="fadeResizeShow"
            target="{aTextArea}"
            duration="1000">
            <s:Resize id="resizeShow"
                widthTo="100"
                heightTo="50"/>
            <s:Fade id="fadeShow"
                alphaFrom="0.0"
                alphaTo="1.0"/>
        </s:Parallel>
    </fx:Declarations>
    <s:TextArea id="aTextArea"
        width="100" height="50"
        text="Hello world."/>
    <s:Button id="myButton2"
        label="Hide!"
        click="fadeResizeHide.end();fadeResizeHide.play();"/>
    <s:Button id="myButton1"
        label="Show!"
        click="fadeResizeShow.end();fadeResizeShow.play();"/>
</s:Application>
```

The button controls alternates making the TextArea control visible and invisible. When the TextArea control becomes invisible, it uses the fadeResizeHide effect as its hide effect, and when it becomes invisible, it uses the fadeResizeShow effect.

As a modification to this example, you could disable the Show button when the TextArea control is visible, and disable the Hide button when the TextArea control is invisible, as the following example shows:

```
<?xml version="1.0"?>
<!-- behaviors\CompositeEffectsEnable.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            private function showHandler():void {
                myButton2.enabled=true;
                myButton1.enabled=false;
            }
            private function hideHandler():void {
                myButton2.enabled=false;
                myButton1.enabled=true;
            }
        ]]>
    </fx:Script>

    <fx:Declarations>
        <s:Sequence id="fadeResizeHide"
            target="{aTextArea}"
            duration="1000"
            effectEnd="hideHandler();">
            <s:Fade id="fadeHide"
                alphaFrom="1.0"
                alphaTo="0.0"/>
            <s:Resize id="resizeHide"
                widthTo="0"
                heightTo="0"/>
        </s:Sequence>
        <s:Parallel id="fadeResizeShow"
            target="{aTextArea}"
            duration="1000"
            effectEnd="showHandler();">
            <s:Resize id="resizeShow"
                widthTo="100"
                heightTo="50"/>
            <s:Fade id="fadeShow"
                alphaFrom="0.0"
                alphaTo="1.0"/>
        </s:Parallel>
    </fx:Declarations>
    <s:TextArea id="aTextArea"
        width="100" height="50"
        text="Hello world."/>
    <s:Button id="myButton2"
        label="Hide!"
        click="fadeResizeHide.end();fadeResizeHide.play();"/>
    <s:Button id="myButton1"
        label="Show!"
        enabled="false"
        click="fadeResizeShow.end();fadeResizeShow.play();"/>
</s:Application>
```

In this example, the Show button is initially disabled. Event handlers for the `effectEnd` event toggle the `enable` property for the two button based on the effect that played.

You can nest `<Parallel>` and `<Sequence>` tags inside each other. For example, two effects can run in parallel, followed by a third effect running in sequence.

In a Parallel or Sequence effect, the `duration` property sets the duration of each effect. For example, if the a Sequence effect has its `duration` property set to 3000, then each effect in the Sequence will take 3000 ms to play.

Using embedded fonts with effects

The fade and rotate effects only work with components that support the Flash Text Engine (FTE), or with components that use an embedded font. All Spark components, and some MX components, support the FTE. Therefore, the fade and rotate effects work with text in the components.

However, if you apply a fade and rotate effects to a MX component that uses a system font, nothing happens to the text in the component. You either have to embed a font, or use the appropriate Spark component instead of the MX component.

When you apply an MX Zoom effect to text rendered using a system font, Flex scales the text between whole point sizes. While you do not have to use embedded fonts when you apply a Zoom effect to text, the Zoom will appear smoother when you apply it to embedded fonts.

The following example rotates text area controls. The first text area control is defined using the Spark TextArea component, whish supports the FTE. Therefore the text rotates when you apply the Spark Rotate effect to it.

The second text area control is defined using the MX TextArea control. This TextArea control uses an embedded font and, therefore, the text rotates.

The third text area control uses the MX TextArea control with the default system font. Therefore, when you apply the Spark Rotate effect, the text disappears and reappears when you rotate the component back to its initial state:

```
<?xml version="1.0"?>
<!-- behaviors\EmbedFont.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    width="650">
    <s:layout>
        <s:HorizontalLayout/>
    </s:layout>
    <fx:Style>
        @namespace s "library://ns.adobe.com/flex/spark";
        @namespace mx "library://ns.adobe.com/flex/mx";
        @font-face {
            src:url("../assets/MyriadWebPro.ttf");
            font-family: myMyriadWebPro;
            embedAsCFF: true;
        }
        @font-face {
            src:url("../assets/MyriadWebPro.ttf");
            font-family: myMyriadWebProMX;
            embedAsCFF: false;
        }
</fx:Style>
    <fx:Declarations>
        <s:Rotate id="rotateForward"
            angleFrom="0" angleTo="45"/>
        <s:Rotate id="rotateBack"
            angleFrom="45" angleTo="0"/>
    </fx:Declarations>
    <s:VGroup>
        <s:Button label="Rotate Forward"
            click="rotateForward.end();rotateForward.play([l1]);"/>
        <s:Button label="Rotate Backward"
            click="rotateBack.end();rotateBack.play([l1]);"/>
        <s:TextArea id="l1" height="75"
            fontFamily="myMyriadWebPro"
            text="FTE supported. This text will rotate."/>
    </s:VGroup>
    <s:VGroup>
        <s:Button label="Rotate Forward"
            click="rotateForward.end();rotateForward.play([l2]);"/>
        <s:Button label="Rotate Backward"
            click="rotateBack.end();rotateBack.play([l2]);"/>
        <mx:TextArea id="l2" height="75"
            fontFamily="myMyriadWebProMX"
            text="Embedded font. This text will rotate."/>
    </s:VGroup>
    <s:VGroup>
        <s:Button label="Rotate Forward"
            click="rotateForward.end();rotateForward.play([l3]);"/>
        <s:Button label="Rotate Backward"
            click="rotateBack.end();rotateBack.play([l3]);"/>
        <mx:TextArea id="l3" height="75"
            text="System font. This text will not rotate."/>
    </s:VGroup>
</s:Application>
```

Notice that you had to embed the font twice: once for the Spark TextArea control and one for the MX TextArea control. For more information on embedding fonts for MX components, see "Embedding fonts with MX components" on page 1592.

Suspending background processing

To improve the performance of effects, you can disable background processing in your application for the duration of the effect by setting the Effect.suspendBackgroundProcessing property to `true`. The background processing that is blocked includes component measurement and layout, and responses to data services for the duration of the effect.

The default value of the `suspendBackgroundProcessing` property is `false`. You can set it to `true` in most cases. However, you should set it to `false` if either of the following conditions is true for your application:

- User input may arrive while the effect is playing, and the application must respond to the user input before the effect finishes playing.
- A response may arrive from the server while the effect is playing, and the application must process the response while the effect is still playing.

Disabling container layout for effects

By default, Flex updates the layout of a container's children when a new child is added to it, when a child is removed from it, when a child is resized, and when a child is moved. Because some effects, such as the move and resize effects, modify a child's position or size, they cause the container to update its layout.

However, when the container updates its layout, it can actually reverse the results of the effect. For example, you use a move effect to reposition a container child. At some time later, you change the size of another container child, which forces the container to update its layout. This layout update can cause the child that moved to be returned to its original position.

To prevent Flex from performing layout updates, you can set the autoLayout property of a container to `false`. Its default value is `true`, which configures Flex so that it always updates layouts. You always set the `autoLayout` property on the parent container of the component that uses the effect. For example, if you want to control the layout of a child of a Grid container, you set the `autoLayout` property for the parent GridItem container of the child, not for the Grid container.

You set the `autoLayout` property to `false` when you use a move effect in parallel with a resize or zoom effect. You must do this because the resize or zoom effect can cause an update to the container's layout, which can return the child to its original location.

When you use the Zoom effect on its own, you can set the `autoLayout` property to `false`, or you may leave it with its default value of `true`. For example, if you use a Zoom effect with the `autoLayout` property set to `true`, as the child grows or shrinks, Flex automatically updates the layout of the container to reposition its children based on the new size of the child. If you use a Zoom effect with the `autoLayout` property set to `false`, the child resizes around its center point, and the remaining children do not change position.

The container in the following example uses the default vertical alignment of `top` and the default horizontal alignment of `left`. If you apply a Zoom effect to the image, the container resizes to hold the image, and the image remains aligned with the upper-left corner of the container:

```
<s:SkinnableContainer>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:Image source="myImage.jpg"/>
</s:SkinnableContainer>
```

In the next example, the image is centered in the container. If you apply a Zoom effect to the image, as it resizes, it remains centered in the container.

```
<s:SkinnableContainer>
    <s:layout>
        <s:VerticalLayout horizontalAlign="center"/>
    </s:layout>
    <s:Image source="myImage.jpg"/>
</s:SkinnableContainer>
```

By default, the size of the container is big enough to hold the image at it original size. If you disable layout updates, and use the Zoom effect to enlarge the image, or use a move effect to reposition the image, the image might extend past the boundaries of the container, as the following example shows:

```
<s:SkinnableContainer autoLayout="false">
    <s:layout>
        <s:VerticalLayout horizontalAlign="center"/>
    </s:layout>
    <s:Image source="myImage.jpg"/>
</s:SkinnableContainer>
```

For a Spark container, if you set the `autoLayout` property to `false`, the container does not resize as the image resizes. The image can grow to a size so that it extends beyond the boundaries of the container. You can then decide to wrap the container in the Scroller component to add scroll bars rather than allowing the Image to extend past the container boundaries.

For an MX container, if you set the `autoLayout` property to `false`, the container does not resize as the image resizes. If the image grows to a size larger than the boundaries of the container, the container adds scroll bars and clips the image at its boundaries.

Setting UIComponent.cachePolicy on the effect target

An effect can use the bitmap caching feature in Adobe® Flash® Player to speed up animations. An effect typically uses bitmap caching when the target component’s drawing does not change while the effect is playing.

For example, the Fade effect works by modifying the `alpha` property of the target component. Changing the `alpha` property does not change the way the target component is drawn on the screen. Therefore, caching the target component as a bitmap can speed up the performance of the effect. The Move effect modifies the `x` and `y` properties of the target component. Modifying the values of these properties does not alter the way the target component is drawn, so it can take advantage of bitmap caching.

Not all effects can use bitmap caching. Effects such as Zoom, resize, and the wipe effects modify the target component in a way that alters the way it is drawn on the screen. The Zoom effect modifies the scale properties of the component, which changes its size. Caching the target component as a bitmap for such an effect would be counterproductive because the bitmap changes continuously while the effect plays.

The UIComponent.cachePolicy property controls the caching operation of a component during an effect. The `cachePolicy` property can have the following values:

CachePolicy.ON Specifies that the effect target is always cached.

CachePolicy.OFF Specifies that the effect target is never cached.

CachePolicy.AUTO Specifies that Flex determines whether the effect target should be cached. This is the default value.

Flex uses the following rules to set the `cacheAsBitmap` property:

- When at least one effect that does not support bitmap caching is playing on a target, set the target's `cacheAsBitmap` property to `false`.

- When one or more effects that supports bitmap caching are playing on a target, set the target's `cacheAsBitmap` property to `true`.

  Typically, you leave the `cachePolicy` property with its default value of `CachePolicy.AUTO`. However, you might want to set the property to `CachePolicy.OFF` because bitmap caching is interfering with your user interface, or because you know something about your application’s behavior such that disabling bitmap caching will have a beneficial effect on it.

Spark effects

Spark effects define a change to the target over time. The Spark effects ship in the spark.effects package.

While Flex ships with both Spark and MX effects, Adobe recommends that you use the Spark effects when possible.

For an introduction to effects, see “Introduction to effects” on page 1784.

About Spark effects

The Spark effects are divided into categories based on their implementation and target type, as the following table shows:

Type	Description
Property effects	Animates the change of one or more properties of the target.
Transform effects	Animates the change of one or more transform-related properties of the target, such as the scale, rotation, and position. The target can be modified in parallel with other transform effects with no interference among the effects.
Pixel-shader effects	Animates the change from one bitmap image to another, where the bitmap image represents the before and after states of the target.
Filter effects	Applies a filter to the target where the effect modifies the properties of the filter, not properties of the target.
3D effects	A subset of the transform effects that modify the 3D transform properties of the target.

Spark effects can be applied to:

- Any Spark or MX component.
- Any graphical component in the spark.primitives package, such as Rect, Ellipse, and path.
- Any object that contains the styles or properties modified by the effect.

Blogger Brian Telintelo blogged about Flex: Effects on a Mobile Device.

Spark property effects

The Spark property effects modify one or more properties of a component over time to animate the effect. The Spark property effects are subclasses of the Animate class, and include the following classes:

- Animate   Animates any properties of the target.
- Fade   Animates a change to the `alpha` property of the target.
- Resize   Animates a change to the `height` and `width` properties of the target.
- AnimateColor   Animates a change to any color property of the target, such as `color`, or `fontColor`.

The Animate effect

Use the Animate effect directly to animate any properties of the target. You create an instance of the SimpleMotionPath class for each property to animate, as the following example shows:

```
<?xml version="1.0"?>
<!-- behaviors\SparkAnimateProp.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Declarations>
        <s:Animate id="scaleUp"
            target="{myB1}">
            <s:SimpleMotionPath property="scaleX"
                valueFrom="1.0" valueTo="1.5"/>
        </s:Animate>
        <s:Animate id="scaleDown"
            target="{myB1}">
            <s:SimpleMotionPath property="scaleX"
                valueFrom="1.5" valueTo="1.0"/>
        </s:Animate>
    </fx:Declarations>
    <s:Button id="myB1"
        label="Scale Button"
        mouseDown="scaleUp.end(); scaleUp.play();"
        mouseUp="scaleDown.end(); scaleDown.play();"/>
</s:Application>
```

The SimpleMotionPath class defines the name of the property, the property’s starting value, and the property’s ending value.

You can define multiple instance of the SimpleMotionPath class to animate multiple properties, as the following example shows:

```
<?xml version="1.0"?>
<!-- behaviors\SparkAnimate2Prop.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Declarations>
        <s:Animate id="scaleIncrease"
            target="{myB1}">
            <s:SimpleMotionPath property="scaleX"
                valueFrom="1.0" valueTo="1.5"/>
            <s:SimpleMotionPath property="scaleY"
                valueFrom="1.0" valueTo="1.5"/>
        </s:Animate>
        <s:Animate id="scaleDecrease"
            target="{myB1}">
            <s:SimpleMotionPath property="scaleX"
                valueFrom="1.5" valueTo="1.0"/>
            <s:SimpleMotionPath property="scaleY"
                valueFrom="1.5" valueTo="1.0"/>
        </s:Animate>
    </fx:Declarations>
    <s:Button id="myB1"
        label="Scale Button"
        mouseDown="scaleDecrease.end(); scaleIncrease.play();"
        mouseUp="scaleIncrease.end(); scaleDecrease.play();"/>
</s:Application>
```

The Fade, Resize, and AnimateColor effects

The Fade, Resize, and AnimateColor effects modify specific properties of the target. These effects are predefined to modify specific properties. So, you do not need to use the SimpleMotionPath class to specify the property, as you do for the Animate effect.

The following example uses the Resize effect on an Image control:

```
<?xml version="1.0"?>
<!-- behaviors\SparkResizeEffect.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Declarations>
        <s:Resize id="myResizeEffect"
            target="{myImage}"
            widthBy="10" heightBy="10"/>
    </fx:Declarations>
    <s:Image id="myImage"
        source="@Embed(source='assets/logo.jpg')"/>
    <s:Button label="Resize Me"
        click="myResizeEffect.end();myResizeEffect.play();"/>
</s:Application>
```

This example resizes the Image control by increasing its height and width by 10 pixels when the user clicks the Button control.

The Resize effect defines six properties that you can use to configure it: `heightBy`, `widthBy`, `heightFrom`, `widthFrom`, `heightTo`, and `widthTo`. If omitted, Flex automatically calculates any values for these properties. In the previous example, `heightFrom` and `widthFrom` are set to the current size, and `heightTo` and `widthTo` are set to the final size.

Spark transform effects

The Spark property effects work by modifying one or more properties of the target over the duration of the effect. Using the property effects, you can define two effects that play in parallel but modify the same property of the target. In this situation, the two effects conflict with each other and the results of the effects are undefined.

The Spark transform effects are designed to work together. You can define multiple effects that, while playing in parallel, do not interfere with each other. When executing multiple transform effects in parallel, the effects are combined into a single transformation, rather than playing independently. By combining the transform effects, Flex eliminates the chance that one effect could interfere with another.

The Spark transform effects include the Move, Rotate, and Scale effects.

Applying transform effects

The following example applies the Rotate and Move effects in parallel to an Image control:

```
<?xml version="1.0"?>
<!-- behaviors\SparkXFormRotateMove.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Declarations>
        <s:Parallel id="parallelRMForward"
            target="{myImage}">
            <s:Rotate
                angleBy="180"/>
            <s:Move
                xBy="100"
                yBy="100"/>
        </s:Parallel>
        <s:Parallel id="parallelRMBack"
            target="{myImage}">
            <s:Rotate
                angleBy="180"/>
            <s:Move
                xBy="-100"
                yBy="-100"/>
        </s:Parallel>
    </fx:Declarations>
    <s:Button label="Play Effect Forward"
        x="10" y="10"
        click="parallelRMForward.end();parallelRMForward.play();"/>
    <s:Button label="Play Effect Backward"
        x="150" y="10"
        click="parallelRMBack.end();parallelRMBack.play();" />
    <s:Image id="myImage"
        x="10" y="50"
        source="@Embed(source='assets/logo.jpg')"/>
</s:Application>
```

Transform effects operate relative to the *transform center* of the target. By default, the transform center of the target is the upper-left corner of the target, corresponding to coordinates (0,0) in the target coordinate system.

For the Move effect, the change in position is measured by a change of the location of the transform center of the target. The Rotate effect rotates the target around the transform center, and the Scale effect scales the target while the transform center of the target stays stationary.

You do not have to use the upper-left corner of the target as the transform center. For example, instead of rotating the target around the upper-left corner, you rotate the target around its center point.

You can set the coordinates of the transform center either on the target itself, or on the effect class. If you set the transform center on the target, all transform effects use that transform center. Use the UIComponent properties `transformX`, `transformY`, and `transformZ` to define the transform center of the target.

If you set the transform center on the effect, the effect uses that transform center for the duration of the effect. Use the `transformX`, `transformY`, and `transformZ` properties on the transform effect classes to set the transform center for all effect targets. Setting these properties on the effect class overrides the corresponding setting on the target.

You do not have to specify all three properties. For example, if you only want to specify the x location of the transform center, set only the `transformX` property on the target or on the effect class.

You can also set the effect's `autoCenterTransform` property to `true` to configure the effect to play the transform around the center point of the target. If you apply the effect to multiple targets, Flex calculates the transform center independently for each target.

If you apply multiple transform effects in parallel to the same target, set the transform center to the same value for all the effects. For example, set the `autoCenterTransform` property to `true` for one transform effect, set it to the same value for all effects.

The next example modifies the previous example set the `autoCenterTransform` property to `true`. The effects now operate on the center of the target:

```
<?xml version="1.0"?>
<!-- behaviors\SparkXFormRotateMoveAutoCenter.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Declarations>
        <s:Parallel id="parallelRMForward"
            target="{myImage}">
            <s:Rotate
                angleBy="180"
                autoCenterTransform="true"/>
            <s:Move
                xBy="100"
                yBy="100"
                autoCenterTransform="true"/>
        </s:Parallel>
        <s:Parallel id="parallelRMBack"
            target="{myImage}">
            <s:Rotate
                angleBy="180"
                autoCenterTransform="true"/>
            <s:Move
                xBy="-100"
                yBy="-100"
                autoCenterTransform="true"/>
        </s:Parallel>
    </fx:Declarations>
    <s:Button label="Play Effect Forward"
        x="10" y="10"
        click="parallelRMForward.end();parallelRMForward.play();"/>
    <s:Button label="Play Effect Backward"
        x="150" y="10"
        click="parallelRMBack.end();parallelRMBack.play();" />
    <s:Image id="myImage"
        x="10" y="50"
        source="@Embed(source='assets/logo.jpg')"/>
</s:Application>
```

Limitations with transform effects

The only limitation of transform effects is that they cannot be played multiple times. Therefore, you cannot use the `repeatCount`, `repeatDelay`, and `repeatBehavior` properties with transform effects.

Spark 3D effects

Most effects manipulate the effect target in the x and y dimensions to create two-dimensional effects. In the two-dimensional coordinate system, the x, y coordinates of 0, 0 corresponds to the upper-left corner of the component's coordinate system. For example, if the Application container takes up your full computer screen, those coordinates correspond to the upper-left corner of the computer screen. Increasing values of x moves to the right of the compute screen, and increasing values of y move down the screen.

The 3D effects add support for the z-axis. The z = 0 coordinate corresponds to the plane of the computer screen. Increasing values of z moves an object into the screen, making the object look farther away from the viewer. Decreasing values of z move the object toward the viewer.

The spark 3D effects are transform effects designed to take advantage of the support for three-dimensional graphics in Flash Player. Flex includes the following 3D effects:

- Move3D

  Moves the effect target in the x, y, and z coordinate system. Moving the target to increasing values in the z direction makes it appear to move back away from the viewer, so the target shrinks. Moving the target to decreasing values in the z direction makes it appear to move toward the viewer, so the target grows.

- Rotate3D

  Rotates the effect target around the x, y, or z-axis. For example, rotating the target around the y-axis rotates the object vertically through the x and z planes, similar to a door opening and closing on vertical hinges. Rotating the target around the z-axis makes the object rotate through the x and y planes, which is the same as a two-dimensional rotation.

- Scale3D

  Scales the effect target in the x, y, and z directions by setting the appropriate scale properties on the target. A scale of 2.0 means the object has been magnified by a factor of 2. A scale of 0.5 means the object has been reduced by a factor of 2. A scale value of 0.0 is not allowed.

For an introduction to transform effects, see "Spark transform effects" on page 1808.

Applying 3D effects

The following example applies the Move3D effect to an image:

```
<?xml version="1.0"?>
<!-- behaviors\Spark3DMoveEffect.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Declarations>
        <s:Move3D id="moveEffect" target="{targetImg}"
            xBy="100" zBy="100"
            repeatCount="2" repeatBehavior="reverse"
            effectStart="playButton.enabled=false;"
            effectEnd="playButton.enabled=true;"/>
    </fx:Declarations>
    <s:Panel title="Move3D Effect Example"
        width="75%" height="75%" >

        <s:Image id="targetImg"
            horizontalCenter="0"
            verticalCenter="0"
            source="@Embed(source='assets/Nokia_6630.png')"/>

        <s:Button id="playButton"
            left="5" bottom="5"
            label="Move3D"
            click="moveEffect.play();"/>
    </s:Panel>
</s:Application>
```

In this example, the Move3D effect moves the target by increasing the value of the x and z coordinates by 100. It then reverses, and moves the component back to its original x and z coordinates. To the user, the image moves to the left and shrinks, then moves back to the right and grows to its original size.

The following example uses the Rotate3D effect to rotate the image around the y-axis:

```
<?xml version="1.0"?>
<!-- behaviors\Spark3DRotateEffect.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Declarations>
        <s:Rotate3D id="rotateEffect" target="{targetImg}"
            angleYFrom="0" angleYTo="360"
            repeatCount="2" repeatBehavior="reverse"
            effectStart="playButton.enabled=false;"
            effectEnd="playButton.enabled=true;"/>
    </fx:Declarations>
    <s:Panel title="Rotate 3D Effect Example"
        width="75%" height="75%" >

        <s:Image id="targetImg"
            horizontalCenter="0"
            verticalCenter="0"
            source="@Embed(source='assets/Nokia_6630.png')"/>
        <s:Button id="playButton"
            left="5" bottom="5"
            label="Rotate3D"
            click="rotateEffect.play();"/>
    </s:Panel>
</s:Application>
```

Setting the transform center of a 3D effect

By default, the transform center of the target of a 3D transform effect is the upper-left corner of the target component. This point corresponds to coordinates (0, 0, 0) in the target component's coordinate system. You can set the transform center to a different location. For an introduction to setting the transform center for two-dimensional effects, see "Applying transform effects" on page 1808.

If you run the example in the previous section, you notice that the target object rotates around its left edge. That is because the effects, by default, operates around the default transform center of the target object.

Often, you want to rotate the target component around its center point instead of around the default transform center. One option is to set the transform center to the center point of the component by setting the `autoCenterTransform` property to `true`. The following example modifies the example from the previous section to rotate the image around its center point:

```
<?xml version="1.0"?>
<!-- behaviors\Spark3DRotateLayoutCenterTransform.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Declarations>
        <s:Rotate3D id="rotateEffect" target="{targetImg}"
            angleYFrom="0" angleYTo="360"
            duration="3000"
            autoCenterTransform="true"
            repeatCount="2" repeatBehavior="reverse"
            effectStart="playButton.enabled=false;"
            effectEnd="playButton.enabled=true;"/>
    </fx:Declarations>
    <s:Panel title="Rotate 3D Effect Example"
        width="75%" height="75%" >

        <s:HGroup
            horizontalCenter="0"
            verticalCenter="0">
            <s:Image
                source="@Embed(source='assets/Nokia_6630.png')"/>
            <s:Image id="targetImg"
                source="@Embed(source='assets/Nokia_6630.png')"/>
            <s:Image
                source="@Embed(source='assets/Nokia_6630.png')"/>
        </s:HGroup>
        <s:Button id="playButton"
            left="5" bottom="5"
            label="Rotate3D"
            click="rotateEffect.play();"/>
    </s:Panel>
</s:Application>
```

Alternatively, you can set the `transormX`, `transformY`, and `transformZ` properties on the effect target to define the transform center. In the following example, you set the transform center of the image to the right edge, corresponding to the `transormX` property having a value of 100:

```
<?xml version="1.0"?>
<!-- behaviors\Spark3DRotateLayoutRightTransform.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Declarations>
        <s:Rotate3D id="rotateEffect" target="{targetImg}"
            angleYFrom="0" angleYTo="360"
            duration="3000"
            repeatCount="2" repeatBehavior="reverse"
            effectStart="playButton.enabled=false;"
            effectEnd="playButton.enabled=true;"/>
    </fx:Declarations>
    <s:Panel title="Rotate 3D Effect Example"
        width="75%" height="75%" >

            left="5" bottom="5"
            label="Rotate3D"
            click="rotateEffect.play();"/>
    </s:Panel>
</s:Application>
```

Component layout and 3D effects

Effects can modify the layout of the parent container of the effect target. For example, suppose the effect target is in a container that uses vertical layout. You then use the two-dimensional Rotate effect to rotate the target through 360°. As the effect plays, the parent container modifies the layout of its other children to accommodate the rotating child. Therefore, container children can change position during the effect.

Flex has the concept of layering of the children of a container. Children are drawn on the screen in the order in which they are defined in the container. If children overlap, the child defined later in the container appears on top because it is drawn last.

Flex provides a set of built-in layout classes, such as the VerticalLayout class, to control child layout in a container. These layout classes assume that all children are in the z = 0 plane. That means a container always lays out children in the two-dimensional x, y plane.

However, a 3D effect can modify the effect target in the x, y, and z dimensions. If your 3D effect uses the z dimension, the built-in layout classes do not consider it during layout. If you then allow the parent container to update its layout by taking only the x and y dimensions into consideration, your application might not appear correctly. Therefore, you typically disable the parent container from performing layout while the 3D effect plays.

All effects support the `disableLayout` property. When set to `true`, this property disables layout in the parent container of the effect target for the duration of the effect. The default value is `false`. For effects though, you typically do not want to disable layout of the parent container entirely.

All transform effects define the `applyChangesPostLayout` property which, by default, is set to `true` for the 3D effects. This setting lets the 3D effect modify the target component, but the parent container ignores the changes and does not update its layout while the effect plays. Changes to other container children still cause a layout update.

Note: *For the 2D transform effects Move, Rotate, and Scale, the affectLayout property is true by default.*

You can think of the 3D effects as not playing until after the container for the effect target has completed its layout. Because the effect plays post layout, the parent container does not modify its layout for changes to the target component caused by the effect.

In the following example, the application contains three images in an HGroup container. The Rotate3D effect then plays on the middle image to rotate it around the y-axis. Because the `applyChangesPostLayout` property is `true` by default, no layout occurs as the image rotates, and the target image overlaps the image on its left:

```
<?xml version="1.0"?>
<!-- behaviors\Spark3DRotateLayout.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Declarations>
        <s:Rotate3D id="rotateEffect" target="{targetImg}"
            angleYFrom="0" angleYTo="360"
            duration="3000"
            repeatCount="2" repeatBehavior="reverse"
            effectStart="playButton.enabled=false;"
            effectEnd="playButton.enabled=true;"/>
    </fx:Declarations>
    <s:Panel title="Rotate 3D Effect Example"
        width="75%" height="75%" >

        <s:HGroup
            horizontalCenter="0"
            verticalCenter="0">
            <s:Image
                source="@Embed(source='assets/Nokia_6630.png')"/>
            <s:Image id="targetImg"
                source="@Embed(source='assets/Nokia_6630.png')"/>
            <s:Image
                source="@Embed(source='assets/Nokia_6630.png')"/>
        </s:HGroup>
        <s:Button id="playButton"
            left="5" bottom="5"
            label="Rotate3D"
            click="rotateEffect.play();"/>
    </s:Panel>
</s:Application>
```

For example, set the `transformX` property to 100 on the effect target in the previous example to rotate the middle image so that it overlaps the image on the right. The image on the right appears on top of the middle image because it was drawn last.

You can override the default of disabling layout on the effect target by setting the `applyChangesPostLayout` property of the effect to `false`. In the following example, you rotate the image around the z-axis, with the `applyChangesPostLayout` property set to `false`. A 3D rotation around the z-axis is essentially a 2D rotation in the x and y plane. Because the `applyChangesPostLayout` property is `false`, the parent container updates the layout of the other two images as the effect plays:

```
<?xml version="1.0"?>
<!-- behaviors\Spark3DRotateWithLayout.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Declarations>
        <s:Rotate3D id="rotateEffect" target="{targetImg}"
            angleZFrom="0" angleZTo="360"
            applyChangesPostLayout="false"
            duration="5000"
            repeatCount="2" repeatBehavior="reverse"
            effectStart="playButton.enabled=false;"
            effectEnd="playButton.enabled=true;"/>
    </fx:Declarations>
    <s:Panel title="Rotate 3D Effect Example"
        width="75%" height="75%" >

        <s:HGroup
            horizontalCenter="0"
            verticalCenter="0">
            <s:Image
                source="@Embed(source='assets/Nokia_6630.png')"/>
            <s:Image id="targetImg"
                source="@Embed(source='assets/Nokia_6630.png')"/>
            <s:Image
                source="@Embed(source='assets/Nokia_6630.png')"/>
        </s:HGroup>
        <s:Button id="playButton"
            left="5" bottom="5"
            label="Rotate3D"
            click="rotateEffect.play();"/>
    </s:Panel>
</s:Application>
```

Setting the postLayoutTransformOffsets property on a component

You can directly modify the position, rotation, and scale of a component post layout without using a 3D effect. Instead, use the `postLayoutTransformOffsets` property, of type mx.geom:TransformOffsets, of the UIComponent class. By setting the `postLayoutTransformOffsets` property directly, you modify the target without causing the parent container to update its layout.

In the following example, you use the `postLayoutTransformOffsets` property to modify the position and scale of a component. As you modify it, notice that the parent container does not update its layout:

```
<?xml version="1.0"?>
<!-- behaviors\Spark3DOffset.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            import mx.geom.TransformOffsets;

            // Define an instance of TransformOffsets.
            private var myXForm:TransformOffsets = new TransformOffsets();

            // Initialize the postLayoutTransformOffsets property of the target.
            private function initOffsets():void {
                targetImg.postLayoutTransformOffsets = myXForm;
            }

            // Move the target 20 pixels to the left and
            // increase its x and y scale by 0.1.
            private function nudgeImageLeft():void {
                targetImg.postLayoutTransformOffsets.x =
                    targetImg.postLayoutTransformOffsets.x - 20;
                targetImg.postLayoutTransformOffsets.scaleX =
                    targetImg.postLayoutTransformOffsets.scaleX + 0.1;
                targetImg.postLayoutTransformOffsets.scaleY =
                    targetImg.postLayoutTransformOffsets.scaleY + 0.1;
            }
            // Move the target 20 pixels to the right and
            // decrease its x and y scale by 0.1.
            private function nudgeImageRight():void {
                targetImg.postLayoutTransformOffsets.x =
                    targetImg.postLayoutTransformOffsets.x + 20;
                targetImg.postLayoutTransformOffsets.scaleX =
                    targetImg.postLayoutTransformOffsets.scaleX - 0.1;
                targetImg.postLayoutTransformOffsets.scaleY =
                    targetImg.postLayoutTransformOffsets.scaleY - 0.1;
            }
            // Reset the transform.
            private function resetImage():void {
                targetImg.postLayoutTransformOffsets.x = 0;
                targetImg.postLayoutTransformOffsets.scaleX = 1.0;
                targetImg.postLayoutTransformOffsets.scaleY = 1.0;
            }
        ]]>
    </fx:Script>
    <s:Panel title="Offset Example"
        width="75%" height="75%" >

        <s:HGroup
            horizontalCenter="0"
            verticalCenter="0">
            <s:Image
```

```
                source="@Embed(source='assets/Nokia_6630.png')"/>
            <s:Image id="targetImg"
                source="@Embed(source='assets/Nokia_6630.png')"
                creationComplete="initOffsets();"/>
            <s:Image
                source="@Embed(source='assets/Nokia_6630.png')"/>
        </s:HGroup>
        <s:HGroup left="5" bottom="5">
            <s:Button id="nudgeLeftButton"
                label="Nudge Left"
                click="nudgeImageLeft();"/>
             <s:Button id="nudgeRightButton"
                label="Nudge Right"
                click="nudgeImageRight();"/>
             <s:Button id="resetButton"
                label="Reset"
                click="resetImage();"/>
        </s:HGroup>
    </s:Panel>
</s:Application>
```

Notice in this example that as you nudge the image to the left, it overlaps the image to its left. As you nudge the image to the right, it moves behind the image on the right. This overlap is because the image on the right is defined later in the container, and is therefore drawn last on the screen.

Setting the center of the projection

The 3D effects work by mapping a three-dimensional image onto a two-dimensional representation for display on a computer screen. The *projection point* defines the center of the field of view, and controls how the target is projected from three dimensions onto the screen.

By default, when you apply a 3D effect, the effect automatically sets the projection point to the center of the target. You can set the `autoCenterProjection` property of the effect to `false` to disable this default. You then use the `projectionX` and `projectionY` properties to explicitly set the projection point. These properties specify the offset of the projection point from the (0, 0) coordinate of the target.

Spark pixel-shader effects

The Spark pixel-shader effects apply an animation to a target that has a before and after bitmap representation, rather than by animating a change to the value of a property. The effect works by capturing a before bitmap image of the component, capturing an after bitmap image of the component, and then applying the animation between the two images.

While the use of pixel-shader effects might seem obvious when working with Image components, you can use them with any component.

The bitmaps are represented by an instance of the flash.display.BitmapData class. The animation from the initial to the final bitmap is defined by a pixel-shader program created by using Adobe® Pixel Bender™ Toolkit. A pixel-shader program used with the pixel-shader effects operates on two bitmap inputs to animate from one to the other.

The Spark pixel-shader effects, CrossFade and Wipe, use their own internal pixel-shaders. However, you can use a custom pixel-shader defined by using the Pixel Bender Toolkit. For an example of a custom pixel-shader, see “Creating a custom pixel shader” on page 1821.

You can use pixel-shader effects on their own, just as you can use the Spark effects such as Fade and Resize. However, since they are designed to by applied to a component with a before and after bitmap, they are often used as part of a transition.

Using a pixel-shader effect in a transition

View states let you change the appearance of an application, typically in response to a user action. Transitions define how a change of view state looks as it occurs on the screen. You define a transition by using the effect classes, in combination with several effects designed explicitly for handling transitions. For more information on view states, see "View states" on page 1847. For more information on transitions, see "Transitions" on page 1870.

When using a pixel-shader effect with a transition, you use one view state to represent the before image of the target, and another view state to represent the after image. The following example uses the Wipe effect as part of a transition that changes the font color of a button control from black to red:

```
<?xml version="1.0"?>
<!-- behaviors\SparkWipeEffect.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <!-- Define two view states.-->
    <s:states>
        <s:State name="default"/>
        <s:State name="red"/>
    </s:states>
    <!-- Define the transition that applies the Wipe effect
        whenever the view state changes.-->
    <s:transitions>
        <s:Transition fromState="*" toState="*">
            <s:Sequence target="{myB}">
                <s:Wipe id="wipeEffect"
                    direction="right"
                    duration="1000"/>
            </s:Sequence>
        </s:Transition>
    </s:transitions>
    <s:Button id="myB" label="Wipe"
        color="black" color.red="red"/>
    <!-- Define two buttons to change the view state. -->
    <s:Button label="Set Default State"
        click="currentState='default'"/>
    <s:Button label="Set Red State"
        click="currentState='red'"/>
</s:Application>
```

The transition automatically captures the bitmap of the button in the initial and final states, then plays the Wipe effect on the button to animate the change.

Applying a pixel-shader effect

To use a pixel-shader effect outside a transition, create the bitmaps that define the initial state of the target and the final state of the target, as the following example shows:

```
<?xml version="1.0"?>
<!-- behaviors\SparkShaderBitmap.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[

        import mx.core.BitmapAsset;

        [Embed(source='assets/logo.jpg')]
        [Bindable]
        public var beforeImage:Class;
        [Bindable]
        public var beforeImageBitmap:BitmapAsset = new beforeImage();
        [Embed(source='assets/flexLogo.jpg')]
        [Bindable]
        public var afterImage:Class;
        [Bindable]
        public var afterImageBitmap:BitmapAsset = new afterImage();

        ]]>
    </fx:Script>

    <fx:Declarations>
        <s:CrossFade id="forwardCF"
            target="{myImage}"
            bitmapFrom="{beforeImageBitmap.bitmapData}"
            bitmapTo="{afterImageBitmap.bitmapData}"
            effectEnd="myImage.source=afterImage;"/>
        <s:CrossFade id="backwardCF"
            target="{myImage}"
            bitmapFrom="{afterImageBitmap.bitmapData}"
            bitmapTo="{beforeImageBitmap.bitmapData}"
            effectEnd="myImage.source=beforeImage;"/>
    </fx:Declarations>
    <s:Image id="myImage"
        source="{beforeImage}"/>
    <s:Button id="fwd" label="Forward"
        click="forwardCF.end();forwardCF.play();"/>
    <s:Button id="bwd" label="Backward"
        click="backwardCF.end();backwardCF.play();"/>
</s:Application>
```

In this example, you embed two JPEG images, logo.jpg and flexLogo.jpg. When you embed JPEG files into Flex, they are represented as instances of the mx.core.BitmapAsset class. Use the `bitmapData` property of the BitmapAsset class to access the BitmapData object that contains the actual image data. For more information on embedding JPEG files, see "Embedding JPEG, GIF, and PNG images" on page 1707.

Note: *As written, this example causes the compiler to issue warnings for the binding to the* `bitmapData` *property. To remove these warnings, compile the application with the* `show-binding-warnings` *compiler flag set to* `false`*. Or, create a custom object to represent the image. For more information, see "Using data binding with Objects" on page 309.*

The first CrossFade effect, forwardCF, uses logo.jpg file to define the before state and the flexLogo.jpg to define the final state of the effect. When it plays, the effect animates the transition from the logo.jpg file to the linelogo.jpg file. After the effect plays, it loads flexLogo.jpg into the Image control. The backwardCF effect does the opposite.

The target of the effect is the Image control. When the effect plays, the following occurs:

1 The effect target, the Image control, is hidden.

2 The bitmap for the initial state displays.

3 The pixel-shader plays to animate the change from the initial state to the final state.

4 When the effect ends, hide the bitmap for the final state and make the Image control visible.

Creating a custom pixel shader

You can use the Pixel Bender Toolkit to create a custom pixel shader, and then pass it to the AnimateTransitionShader effect, as the following example shows:

```
<?xml version="1.0"?>
<!-- behaviors\SparkCustomPBTransform.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

     <fx:Script>
          <![CDATA[
            // Embed the .pbj file.
            [Embed(source="assets/twist.pbj", mimeType="application/octet-stream")]
            private static var CustomShaderClass:Class;
            [Bindable]
            private static var customShaderCode:ByteArray = new CustomShaderClass();
          ]]>
     </fx:Script>

     <fx:Declarations>
        <!-- Use the custom pixel shader with an effect. -->
        <s:AnimateTransitionShader  id="shadeAnim"
            shaderByteCode="{customShaderCode}"
            target="{btn2}"
            repeatCount="2"
            repeatBehavior="reverse"/>
     </fx:Declarations>
     <s:Button id="btn2" label="Click Me" click="shadeAnim.play();"/>
</s:Application>
```

A custom pixel shader is represented by a .pbj file created by using the Pixel Bender Toolkit. To use the .pbj file in your application, you embed it, and then assign it to a property of type ByteArray. You then specify the ByteArray object as the value of the `shaderByteCode` property of the AnimateTransitionShader effect.

The AnimateTransitionShader effect also supports the `shaderProperties` property that lets you pass properties directly to the pixel shader.

The .pbj file has the following requirements:

- Define three `image4` inputs. The first input is unused but must be defined and referenced in the code. If the input is not referenced, the compiler in the Pixel Bender Toolkit removes it as part of optimizing the code.

  One `image4` input must be called `from`, and one named `to`. These inputs represent the initial and final states of the target.

- Define one parameter named `progress` of type float. This parameter represents the current fraction of the animation completed from 0.0, animating started, to 1.0, animation completed.

The following example shows the source .pbk file for the twist.pbj file used in the previous example:

```
<languageVersion : 1.0;>
kernel FxTwist
<   namespace : "flex";
    vendor : "Adobe";
    version : 1;
    description : "Twisty Effect";
>
{
    input image4 src0;
    input image4 from;
    input image4 to;
    output pixel4 dst;

    parameter float progress<
        minValue: 0.00;
        maxValue: 1.00;
        defaultValue: 0.0;
    >;

    parameter float width<
        minValue: 0.0;
        maxValue: 1024.0;
        defaultValue: 180.0;
    >;

    parameter float height<
        minValue: 0.00;
        maxValue: 1024.0;
        defaultValue: 275.0;
    >;

    void
    evaluatePixel()
    {

        // Common initialization
        float2 outCoord = outCoord();
        pixel4 color1 = sampleNearest(src0, outCoord);
        const float _height = 2.0;
        const float scale = 1.0 + _height;
        float start = progress * scale - _height;
        float end   = start + _height;

        float yfrac = outCoord.y / height;
        float angle = (yfrac - start) / (end - start);
        float _width = cos(angle * 3.141592653589);

        if (yfrac < start) {
            dst = sampleLinear(to, outCoord());
        }
        else if (yfrac > end) {
            dst = sampleLinear(from, outCoord());
        }
        else {
        if (_width > 0.0) {

            float xstep  = (65536.0 / _width);
            float xval   = 0.0;
            float startx = (width - width * _width) / 2.0;
            float xcount = startx;

            float sampleWidth = (width * 65536.0) / (xstep);

            if (outCoord.x < startx)
                dst = float4(0.0,0.0,0.0,0.0);
            else if (outCoord.x < (startx + sampleWidth)) {
                float perc = (outCoord.x - startx) / sampleWidth;
                dst = sampleLinear(to, float2(width * perc, outCoord.y));
            }
            else
                dst = float4(0.0,0.0,0.0,0.0);
        }

        else if (_width < 0.0) {
            float xstep  = (65536.0 / -_width);
            float xval   = 0.0;
            float startx = (width + width * _width) / 2.0;
            float xcount = startx;
            float sampleWidth = (width * 65536.0) / (xstep);

            if (outCoord.x < startx)
                dst = float4(0.0,0.0,0.0,0.0);
            else if (outCoord.x < (startx + sampleWidth)) {
                float perc = (outCoord.x - startx) / sampleWidth;
                dst = sampleLinear(from, float2( width * perc, outCoord.y));
            }
            else
                dst = float4(0.0,0.0,0.0,0.0);
        }

        }
    }
}
```

You can also look at the source code for the CrossFade.pbk file in the frameworks\projects\spark\src\spark\effects directory of the Flex source code.

Spark filter effects

Filters let you modify the visual appearance of your components not by modifying properties of the component but by applying a visual filter to the component. The filters are defined in the spark.filters. package. Common filters include the DropShadowFilter, GlowFilter, BlurFilter, and the other filter classes in the spark.filters. package.

Filters define a static change to the component where the properties of the filter are fixed unless you explicitly modify them at runtime. You can use the AnimateFilter effect to animate a filter at runtime. Unlike effects that animate properties of the target, the AnimateFilter effect animates properties of the filter applied to the target.

For example, if you apply the DropShadowFilter to a component, it has a static value for the filter properties such as `color`, `distance`, and `angle`. If you use the AnimateFilter effect to apply the filter to the target, you can animate these properties, as the following example shows:

```
<?xml version="1.0"?>
<!-- behaviors\SparkAnimateDropShadowFilter.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <fx:Declarations>
        <s:DropShadowFilter id="myDSF"
            color="0x0000FF"
            distance="5"
            angle="315"/>
        <s:AnimateFilter id="myFilter"
            target="{myB2}"
            repeatCount="0"
            duration="500"
            repeatBehavior="reverse"
            bitmapFilter="{new spark.filters.DropShadowFilter()}">
            <s:SimpleMotionPath property="color" valueFrom="0" valueTo="0x0000FF"/>
            <s:SimpleMotionPath property="distance" valueFrom="0" valueTo="10"/>
            <s:SimpleMotionPath property="angle" valueFrom="270" valueTo="360"/>
        </s:AnimateFilter>
    </fx:Declarations>

    <s:Button id="myB1"
        x="50" y="50"
        label="Show a DropShadowFilter"
        filters="{[myDSF]}"/>
    <s:Button id="myB2"
        x="50" y="95"
        label="Animate a DropShadowFilter"
        click="myFilter.end();myFilter.play();"/>
</s:Application>
```

In this example, the first button uses a static DropShadowFilter. The second button uses the AnimateFilter effect to animate the filter. Because the effect sets the `repeatCount` to 0, the effect plays continuously.

To use the AnimateFilter effect, you specify the filter to animate, and then use the SimpleMotionPath class to specify the properties of the filter to animate. In this example, the effect animate the `color`, `distance`, and `angle` properties.

Motion paths and keyframes

The Spark effect classes are designed to make it easy to specify the property to animate, and the starting and ending values of the property for the animation. These classes hide much of the underlying effects implementation to simplify the use of effects.

However, you might want to create an effect that animates a property over a set of values, rather than over just a starting and ending value. To create these effect, use keyframes and motion paths.

A *keyframe* defines the value of a property at a specific time during the effect. For example, you can create three keyframes that define the value of a property at the beginning of the effect, at the midpoint of the effect, and at the end of the effect. The effect animates the property change on the target from keyframe to keyframe over the effect duration.

If your effect has just two keyframes, use the Animate effect. The Animate effect takes a starting an ending value for the property, corresponding to two keyframes. For more information, see “The Animate effect” on page 1806.

The collection of keyframes for an effect is called the effect’s motion path. A *motion path* can define any number of keyframes. The effect then calculates the value of the property by interpolating between the values specified by two keyframes.

Applying an effect using keyframes and motion paths

Use the Keyframe class to define a keyframe. You typically define a keyframe by specifying the value of the property, and the time during the duration of the effect when the property has that value.

The MotionPath class contains a Vector of Keyframe objects. The MotionPath class also defines the name of the property that is modified by the effect, as the following example shows:

```
<?xml version="1.0"?>
<!-- behaviors\SparkKeyFrame.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Declarations>
        <fx:Vector id="kf" type="spark.effects.animation.MotionPath">
            <s:MotionPath property="scaleX">
                <s:Keyframe time="250" value="0.5"/>
                <s:Keyframe time="500" value="1.0"/>
                <s:Keyframe time="750" value="0.5"/>
                <s:Keyframe time="1000" value="1.0"/>
                <s:Keyframe time="1250" value="0.5"/>
                <s:Keyframe time="1500" value="1.0"/>
            </s:MotionPath>
            <s:MotionPath property="scaleY">
                <s:Keyframe time="250" value="0.5"/>
                <s:Keyframe time="500" value="1.0"/>
                <s:Keyframe time="750" value="0.5"/>
                <s:Keyframe time="1000" value="1.0"/>
                <s:Keyframe time="1250" value="0.5"/>
                <s:Keyframe time="1500" value="1.0"/>
            </s:MotionPath>
        </fx:Vector>

        <s:Animate id="shrinkEffect"
            motionPaths="{kf}"
            target="{myImage}"/>
    </fx:Declarations>
    <s:Image id="myImage"
        source="@Embed(source='assets/logo.jpg')"
        click="shrinkEffect.end();shrinkEffect.play();"/>
</s:Application>
```

Each MotionPath object defines the property of the target to animate, and contains six Keyframe objects. The Keyframe objects define the values of the `scaleX` and `scaleY` properties of the target at different times during the effect. The Animate class takes as the value of the `motionPaths` property a Vector of MotionPath objects.

In most situations, you do not have to work with keyframes and motion paths; the Spark effect classes handles the creating and use of keyframes internally. For example, the Animate class can take as the value of the `motionPaths` property a Vector of SimpleMotionPath objects. Each SimpleMotionPath object defines the property to animate, the starting property value, and the ending property value.

The SimpleMotionPath class is a subclass of the MotionPath class. When you create an instance of the SimpleMotionPath class, it creates two instances of the Keyframe class to represent the beginning and ending values of the property on the target. The effect then animates the property change on the target between the values specified by the two Keyframe objects.

Handling Spark effect events

Spark effects support all the general events, such as `effectStart`, `effectStop`, and `effectEnd`. For more information on handling these events, see "Handling effect events" on page 1796.

In addition, the Spark effect classes support the following additional events:

- `effectRepeat` For any effect that is repeated more than once, dispatched when the effect begins a new repetition. The `type` property of the event object for this event is set to `EffectEvent.EFFECT_UPDATE`.
- `effectUpdate` Dispatched every time the effect updates the target. The `type` property of the event object for this event is set to `EffectEvent.EFFECT_UPDATE`.

Using Spark easing classes

You can change the acceleration of an effect animation by using an easing class with an effect. With easing, you can create a more realistic rate of acceleration and deceleration. You can also use an easing class to create a bounce effect or control other types of motion.

Flex supplies the Spark easing classes in the spark.effects.easing package. This package includes classes for the most common types of easing, including Bounce, Linear, and Sine easing. For more information on using these classes, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Easing class	Description
Bounce	The movement of the effect target accelerates toward the end value, and then bounces against the end value several times.
Elastic	The effect target decelerates toward the end value, and continues past the end value. It then oscillates around the end value in smaller and smaller increments, before reaching the end value.
Linear	Defines three phases of animation: acceleration, uniform motion, and deceleration. Acceleration and deceleration occur at a constant rate. Use the `easeinFraction` property to specify the percentage of the total animation duration for acceleration. Use the `easeOutFraction` property to specify the percentage of the total animation duration for deceleration.
Power	Defines easing as consisting of two phases: the acceleration, or ease in phase, followed by the deceleration, or ease out phase. The rate of acceleration and deceleration is based on the `exponent` property. The higher the value of the `exponent` property, the greater the acceleration and deceleration. Use the `easeInFraction` property to specify the percentage of an animation accelerating.
Sine	Defines easing as consisting of two phases: the acceleration, or ease in phase, followed by the deceleration, or ease out phase. Use the `easeInFraction` property to specify the percentage of an animation accelerating.

The following example uses the Sine and Power easing classes with the Move effect:

```
<?xml version="1.0"?>
<!-- behaviorExamples\SparkResizeEasing.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    width="750">
    <fx:Declarations>
        <s:Sine id="sineEasing"
            easeInFraction="0.3"/>
        <s:Power id="powerEasing"
            exponent="4"/>
        <s:Move id="moveRight"
            target="{myImage}"
            xBy="500"
            duration="2000"
            easer="{powerEasing}"/>
        <s:Move id="moveLeft"
            target="{myImage}"
            xBy="-500"
            duration="2000"
            easer="{sineEasing}"/>
    </fx:Declarations>
    <s:Image id="myImage"
        source="@Embed(source='assets/logo.jpg')"/>
    <s:Button label="Move Right"
         x="0" y="100"
        click="moveRight.end();moveRight.play();"/>
    <s:Button label="Move Left"
         x="0" y="125"
        click="moveLeft.end();moveLeft.play();"/>
</s:Application>
```

The Sine effect specifies a short acceleration phase for the move effect, followed by a longer deceleration. The Power effect specifies a rapid acceleration for the move.

The following example uses the Bounce and Elastic easing classes:

```
<?xml version="1.0"?>
<!-- behaviorExamples\SparkBounceEasing.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    width="750">
    <fx:Declarations>
        <s:Bounce id="bounceEasing"/>
        <s:Elastic id="elasticEasing"/>
        <s:Move id="moveRight"
            target="{myImage}"
            xBy="500"
            duration="2000"
            easer="{elasticEasing}"/>
        <s:Move id="moveLeft"
            target="{myImage}"
            xBy="-500"
            duration="2000"
            easer="{bounceEasing}"/>
    </fx:Declarations>
    <s:Image id="myImage"
        source="@Embed(source='assets/logo.jpg')"/>
    <s:Button label="Move Right"
         x="0" y="100"
        click="moveRight.end();moveRight.play();"/>
    <s:Button label="Move Left"
         x="0" y="125"
        click="moveLeft.end();moveLeft.play();"/>
</s:Application>
```

Former Adobe engineer Chet Haase describes custom easing in Custom Easing in Flex 4 Effects and using transitions with easing classes in Transitions and Easing in Flex.

Using MX effects

In MX, an effect defines the visual or audible change to the target component, and a trigger initiates the effect. A trigger is an action, such as a mouse click on a component, a component getting focus, or a component becoming visible. The MX effects are shipped in the mx.effects package.

While Flex ships with both Spark and MX effects, Adobe recommends that you use the Spark effects when possible.

For an introduction to effects, see “Introduction to effects” on page 1784.

Available MX triggers

You use a trigger name to assign an effect to a target component. You can reference a trigger name as a property of an MXML tag, in the `<fx:Style>` tag, or in an ActionScript `setStyle()` and `getStyle()` function. Trigger names use the following naming convention:

triggerEvent`Effect`

where *triggerEvent* is the event that invokes the effect.

For example, the `focusIn` event occurs when a component gains focus; you use the `focusInEffect` trigger property to specify the effect to invoke for the `focusIn` event. The `focusOut` event occurs when a component loses focus; the corresponding trigger property is `focusOutEffect`.

The following table lists the effect name that corresponds to each trigger:

Trigger name	Triggering event
`addedEffect`	Component is added as a child to a container.
`creationCompleteEffect`	Component is created.
`focusInEffect`	Component gains keyboard focus.
`focusOutEffect`	Component loses keyboard focus.
`hideEffect`	Component becomes invisible by changing the `visible` property of the component from `true` to `false`.
`mouseDownEffect`	User presses the mouse button while the mouse pointer is over the component.
`mouseUpEffect`	User releases the mouse button.
`moveEffect`	Component is moved.
`removedEffect`	Component is removed from a container.
`resizeEffect`	Component is resized.
`rollOutEffect`	User rolls the mouse pointer off the component.
`rollOverEffect`	User rolls the mouse pointer over the component.
`showEffect`	Component becomes visible by changing the `visible` property of the component from `false` to `true`.

Applying MX effects in MXML

Associate MX effects with triggers as part of defining the basic behavior for your application, as the following example shows:

```
<?xml version="1.0"?>
<!-- behaviors\ButtonWL.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Declarations>
        <!-- Define effect. -->
        <mx:WipeLeft id="myWL" duration="1000"/>
    </fx:Declarations>
    <!-- Assign effect to targets. -->
    <mx:Button id="myButton" label="Click Me"
        mouseDownEffect="{myWL}"/>
    <mx:Button id="myOtherButton" label="Click Me"
        mouseDownEffect="{myWL}"/>
</s:Application>
```

In this example, the effect is a WipeLeft effect with a duration of 1000 milliseconds (ms). That means it takes 1000 ms for the effect to play from start to finish.

You use data binding to assign the effect to the `mouseDownEffect` property of each Button control. The `mouseDownEffect` property is the effect trigger that specifies to play the effect when the user clicks the control using the mouse pointer. In the previous example, the effect makes the Button control appear as if it is being wiped onto the screen from right to left.

Using ActionScript, you can create, modify, or play an effect. With ActionScript, you can configure the effect to play in response to an effect trigger, or you can explicitly invoke it by calling the `play()` method of the effect's class. ActionScript gives you control of effects so that you can configure them as part of a user preferences setting, or modify them based on user actions. The following example creates the WipeLeft effect in ActionScript:

```
<?xml version="1.0"?>
<!-- behaviors\AsEffect.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="createEffect(event);" >
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <!-- Define effect. -->
    <fx:Script>
        <![CDATA[
            // Import the effect class.
            import mx.effects.*;

            // Define effect variable.
            private var myWL:WipeLeft;
            private function createEffect(eventObj:Event):void {
                // Create the WipeLeft effect object.
                myWL=new WipeLeft();

                // Set the effect duration.
                myWL.duration=1000;

                // Assign the effects to the targets.
                myButton.setStyle('mouseDownEffect', myWL);
                myOtherButton.setStyle('mouseDownEffect', myWL);
            }
        ]]>
    </fx:Script>
    <mx:Button id="myButton" label="Click Me"/>
    <mx:Button id="myOtherButton" label="Click Me"/>
</s:Application>
```

This example still uses an event to invoke the effect. To play an effect programmatically, you call the effect's `play()` method. For information on using ActionScript to configure and invoke effects, and for more information on using MXML, see "Applying behaviors in MXML" on page 130.

Applying MX effects in MXML using styles

All MXML properties corresponding to effect triggers are implemented as CSS styles. Therefore, you can also apply an effect using the `<fx:Style>` tag. For example, to set the `mouseDownEffect` property for all TextArea controls in an application, you can use a CSS type selector, as the following example shows:

```
<?xml version="1.0"?>
<!-- behaviors\MxmlTypeSel.mxml-->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Style>
        @namespace mx "library://ns.adobe.com/flex/mx";
        mx|TextArea {mouseDownEffect: slowWipe;}
    </fx:Style>
    <fx:Declarations>
        <mx:WipeLeft id="slowWipe" duration="5000"/>
    </fx:Declarations>
    <mx:TextArea id="myTA"
        text="This TextArea slowly wipes in on mouseDown."/>
    <mx:TextArea id="myTA2"
        text="This TextArea control has no effect."
        mouseDownEffect="none"/>
</s:Application>
```

Setting the `mouseDownEffect` property in a component tag overrides any settings that you make in an `<fx:Style>` tag. If you want to remove the associated effect defined in a type selector, you can explicitly set the value of any trigger to `none`, as the following example shows:

```
<mx:TextArea id="myTA" mouseDownEffect="none"/>
```

You can also use a class selector to apply effects, as the following example shows:

```
<?xml version="1.0"?>
<!-- behaviors\ButtonWLClassSel.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <!-- Define a class selector for a TextArea control -->
    <fx:Style>
        .textAreaStyle { mouseDownEffect: WipeLeft; }
    </fx:Style>
    <fx:Declarations>
        <mx:WipeLeft id="slowWipe" duration="5000"/>
    </fx:Declarations>
    <mx:TextArea id="myTA"
        styleName="textAreaStyle"
        text="This TextArea control quickly wipes in."/>
</s:Application>
```

Using setStyle() and getStyle() with MX effects defined in MXML

Trigger properties are implemented as styles; therefore, you can use the setStyle() and getStyle() methods to manipulate triggers and their associated effects. The `setStyle()` method has the following signature:

```
setStyle("trigger_name", effect)
```

trigger_name String indicating the name of the trigger property; for example, `mouseDownEffect` or `focusInEffect`.

effect The effect associated with the trigger. The data type of `effect` is an Effect object, or an object of a subclass of the Effect class.

The `getStyle()` method has the following signature:

```
getStyle("trigger_name"):return_type
```

trigger_name String indicating the name of the trigger property.

return_type An Effect object, or an object of a subclass of the Effect class.

The following scenarios show how to use `getStyle()` with effects defined in MXML:

When you use MXML tag properties or the `<fx:Style>` tag to apply effects to a target, `getStyle()` returns an Effect object. The type of the object depends on the type of the effect that you specified. In the following example, you use the `setStyle()` method to set the duration of an effect, and the `getStyle()` method to return the duration:

```
<?xml version="1.0"?>
<!-- behaviors\ButtonWLGetStyleMXML.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            private function displayStyle():void {
                var s:String = String(myB.getStyle('mouseDownEffect').duration)
                myTA.text = "mouseDownEffect duration: " + s;
            }

            private function changeStyle(n:Number):void {
                myB.getStyle('mouseDownEffect').duration = n;
            }
        ]]>
    </fx:Script>
    <fx:Declarations>
        <mx:WipeLeft id="slowWipe" duration="5000"/>
    </fx:Declarations>
    <!-- Set the behavior in MXML. -->
    <mx:Button id="myB" label="Click Me"
        mouseDownEffect="{slowWipe}"/>
    <mx:TextArea id="myTA" width="200"/>

    <!-- Call getStyle() to return an object of type WipeLeft. -->
    <mx:HBox>
        <mx:Button label="Get Style" click="displayStyle();"/>
        <mx:Button label="Set Duration" click="changeStyle(1000);"/>
        <mx:Button label="Reset Duration" click="changeStyle(5000);"/>
    </mx:HBox>
</s:Application>
```

For more information on working with styles, see “Styles and themes” on page 1492.

Applying MX effects in ActionScript using styles

Because Flex implements the properties corresponding to effect triggers as styles, you can use style sheets and the setStyle() and getStyle() methods to apply effects. Therefore, you can create an effect in ActionScript, and then use the `setStyle()` method to associate it with a trigger, as the following example shows:

```
<?xml version="1.0"?>
<!-- behaviors\BehaviorsASStyles.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp();">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import mx.effects.Zoom;
            // Define a new Zoom effect.
            private var zEffect:Zoom = new Zoom();
            private function initApp():void {
                // Set duration of zoom effect.
                zEffect.duration = 1000;
                // Define zoom in ratio.
                zEffect.zoomHeightTo = 1.0;
                zEffect.zoomWidthTo = 1.0;
            }

            private function applyZoomEffect(newZoom:Number):void {
                zEffect.zoomHeightTo = newZoom;
                zEffect.zoomWidthTo = newZoom;
                // Apply or re-apply the Zoom effect to the Button control.
                b1.setStyle("mouseDownEffect", zEffect);
            }

            private function resizeButton():void {
                var newZoom:Number;
                var n:Number = zEffect.zoomHeightTo;
                if (n == 1.0) {
                    newZoom = 2.0;
                } else {
                    newZoom = 1.0;
                }
                applyZoomEffect(newZoom);
            }
        ]]>
    </fx:Script>
    <mx:HBox>
        <mx:Button id="b1" label="Click Me" click="resizeButton();"/>
    </mx:HBox>
</s:Application>
```

You can also define the effect in MXML, then use ActionScript to apply it, as the following example shows:

```
<?xml version="1.0"?>
<!-- behaviors\ASStylesMXML.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initializeEffect(event);">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import flash.events.Event;

            private function initializeEffect(eventObj:Event):void {
                myB.setStyle("mouseDownEffect", myWL);
            }
        ]]>
    </fx:Script>
    <fx:Declarations>
        <mx:WipeLeft id="myWL" duration="1000"/>
    </fx:Declarations>
    <mx:Button id="myB" label="Click Me"/>
</s:Application>
```

The code in the following example alternates the WipeRight and WipeLeft effects for the `mouseDownEffect` style of a Button control:

```
<?xml version="1.0"?>
<!-- behaviors\ASStyleGetStyleMXML.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            private function changeEffect():void {
                if (myButton.getStyle("mouseUpEffect") == myWR) {
                    myButton.setStyle("mouseUpEffect", myWL);
                }
                else if (myButton.getStyle("mouseUpEffect") == myWL) {
                    myButton.setStyle("mouseUpEffect", myWR);
                }
            }
        ]]>
    </fx:Script>
    <fx:Declarations>
        <mx:WipeRight id="myWR" duration="1000"/>
        <mx:WipeLeft id="myWL" duration="1000"/>
    </fx:Declarations>
    <mx:Button id="myButton"
        label="Click Me"
        click="changeEffect();"
        mouseUpEffect="{myWL}"/>
</s:Application>
```

Handling MX effect events

MX effects support all of the general events, such as `effectStart`, `effectStop`, and `effectEnd`. For more information on handling these events, see “Handling effect events” on page 1796.

In addition, every MX effect that is a subclass of the TweenEffect class, such as the Fade and Move effects, supports the following events:

- tweenStart   Dispatched when the tween effect starts. The `type` property of the event object for this event is set to `TweenEvent.TWEEN_START`. The `Effect.effectStart` event is dispatched before the `tweenStart` event.
- tweenUpdate   Dispatched every time a TweenEffect class calculates a new value. The `type` property of the event object for this event is set to `TweenEvent.TWEEN_UPDATE`.
- tweenEnd   Dispatched when the tween effect ends. The `type` property of the event object for this event is set to `TweenEvent.TWEEN_END`.

The event object passed to the event listener for these events is of type TweenEvent. The TweenEvent class is a subclass of the Event class, and contains all of the properties inherited from Event, including `target`, and `type`, and defines the following new property:

value Contains the tween value calculated by the effect. For example, for the Fade effect, the `value` property contains a single Number between the values of the `Fade.alphaFrom` and `Fade.alphaTo` properties. For the Move effect, the `value` property contains a two item Array, where the first value is the current `x` value of the effect target and the second value is the current `y` value of the effect target. For more information on the `value` property, see the instance class for each effect that is a subclass of the TweenEffect class.

Using the MX AnimateProperty effect

You use the AnimateProperty effect to animate a numeric property of a component. For example, you can use this effect to animate the `scaleX` property of a control, as the following example shows:

```
<?xml version="1.0"?>
<!-- behaviors\AnimateHScrollPos.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Declarations>
        <mx:Sequence id="animateScaleXUpDown" >
            <mx:AnimateProperty
                property="scaleX"
                fromValue="1.0"
                toValue="1.5"/>
            <mx:AnimateProperty
                property="scaleX"
                fromValue="1.5"
                toValue="1.0"/>
        </mx:Sequence>
    </fx:Declarations>
    <mx:Button label="Scale Button"
        mouseDownEffect="{animateScaleXUpDown}"/>
</s:Application>
```

In this example, clicking on the Button control starts the Sequence effect, which is made up of two AnimateProperty effects. The first AnimateProperty effect scales the control to 150% of its width, and the second scrolls it back to its original width.

Using the MX sound effect

You use the SoundEffect class to play a sound represented as an MP3 file. You specify the MP3 file using the `source` property. If you have already embedded the MP3 file, using the `Embed` keyword, you can pass the Class object of the MP3 file to the source property. Otherwise, specify the full URL to the MP3 file.

The following example shows both methods of specifying the MP3 file:

```
<?xml version="1.0"?>
<!-- behaviors\Sound.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            // Embed MP3 file.
            [Bindable]
            [Embed(source="../assets/sound1.mp3")]
            public var soundClass:Class;
        ]]>
    </fx:Script>

    <fx:Declarations>
        <mx:SoundEffect id="soundEmbed"
            useDuration="false"
            loops="0"
            source="{soundClass}"/>
    </fx:Declarations>
    <mx:Button id="myButton2"
        label="Sound Embed"
        mouseDownEffect="{soundEmbed}"/>
</s:Application>
```

In this example, you embed the sound1.mp3 file in your application. That means the file is compiled into the SWF file.

The SoundEffect class has several properties that you can use to control the playback of the MP3 file, including `useDuration` and `loops`. The `useDuration` property specifies whether to use the `duration` property to control the play time of the MP3 file. If the `useDuration` property is `true`, the MP3 file will play for as long as the time specified by the `duration` property, which defaults to 500 ms. If you set `useDuration` to `false`, the MP3 file plays to completion.

The `loops` property specifies the number of times to repeat the MP3 file, where a value of 0 means play the effect once, a value of 1 means play the effect twice, and so on. If you repeat the MP3 file, it still uses the setting of the `useDuration` property to determine the playback time.

The `duration` property takes precedence over the `loops` property. If the effect duration is not long enough to play the sound at least once, then the sound will not loop.

The SoundEffect class also defines the following events:

complete Dispatched when the sound file completes loading.

id3 Dispatched when ID3 data is available for an MP3 sound file.

ioError Dispatched when an error occurs during the loading of the sound file.

progress Dispatched periodically as the sound file loads. Within the event object, you can access the number of bytes currently loaded and the total number of bytes to load. The event is not guaranteed to be dispatched, which means that the `complete` event might be dispatched without any `progress` events being dispatched.

For more information, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Using MX mask effects

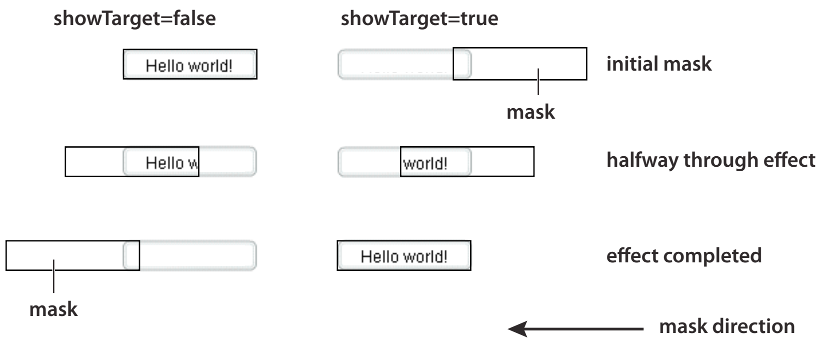
A mask effect is any effect that is a subclass of the MaskEffect class, which includes the wipe effects and the Iris effect. A mask effect uses an overlay, called a mask, to perform the effect. By default, for the wipe effects, the mask is a rectangle with the same size as the target component. For the Iris effect, the default mask is a rectangle centered on the component.

The before or after state of the target component of a mask effect must be invisible. That means a mask effect always makes a target component appear on the screen, or disappear from the screen.

To control the mask effect, you set the `MaskEffect.showTarget` property to correspond to the action of the component. If the target component is becoming visible, set `showTarget` to `true`. If the target is becoming invisible, set `showTarget` to `false`. The default value is `true`.

Often, you use these effects with the `showEffect` and `hideEffect` triggers. The `showEffect` trigger occurs when a component becomes visible by changing its `visible` property from `false` to `true`. The `hideEffect` trigger occurs when the component becomes invisible by changing its `visible` property from `true` to `false`. When using a mask effect with the `showEffect` or `hideEffect` triggers, you can ignore the `showTarget` property; Flex sets it for you automatically.

As the mask effect executes, the effect either covers the target component or uncovers it, based on the setting of the `showTarget` property. The following diagram shows the action of the WipeLeft effect for the two different settings of the `showTarget` property:



You can use several properties of the MaskEffect class to control the location and size of the mask, including the following:

scaleXFrom, scaleYFrom, scaleXTo, and scaleX Specify the initial and final scale of the mask where a value of 1.0 corresponds to scaling the mask to the size of the target component, 2.0 scales the mask to twice the size of the component, 0.5 scales the mask to half the size of the component, and so on. To use any one of these properties, you must specify all four.

xFrom, yFrom, xTo, and yTo Specify the coordinates of the initial position and final position of the mask relative to the target component, where (0, 0) corresponds to the upper-left corner of the target. To use any one of these properties, you must specify all four.

The coordinates of the initial and final position of the mask depend on the type of effect and whether the `showTarget` property is `true` or `false`. For example, for the WipeLeft effect with a `showTarget` value of `false`, the coordinates of the initial mask position are (0, 0), corresponding to the upper-left corner of the target, and the coordinates of the final position are the upper-right corner of the target (`-width`, 0), where `width` is the width of the target.

For a `showTarget` value of `true` for the WipeLeft effect, the coordinates of the initial mask position are (`width`, 0), and the coordinates of the final position are (0, 0).

Creating a custom mask function

You can supply a custom mask function to a mask effect using the createMaskFunction property. A custom mask function lets you create a mask with a custom shape, color, or other attributes for your application requirements.

The custom mask function has the following signature:

```
public function funcName(targ:Object, bounds:Rectangle):Shape
    var myMask:Shape = new Shape();
    // Create mask.

    return myMask;
}
```

Your custom mask function takes an argument that corresponds to the target component of the effect, and a second argument that defines the dimensions of the target so that you can correctly size the mask. The function returns a single Shape object that defines the mask.

The following example uses a custom mask with a WipeLeft effect:

```
<?xml version="1.0"?>
<!-- behaviors\CustomMaskSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            // Import the effect class.
            import mx.effects.*;

            public function createLargeMask(targ:Object,
                    bounds:Rectangle):Shape {
                // Create the Shape object.
                var largeMask:Shape = new Shape();
                // Access the Graphics object of the
                // Shape object to draw the mask.
                largeMask.graphics.beginFill(0x00FFFF, 0.5);
                largeMask.graphics.drawRoundRect(0, 0, bounds.width + 10,
                    bounds.height - 10, 3);
                largeMask.graphics.endFill();
                // Return the mask.
                return largeMask;
            }
        ]]>
    </fx:Script>
    <fx:Declarations>
        <mx:WipeLeft id="customWL"
            createMaskFunction="createLargeMask"
            showTarget="false"/>

        <mx:WipeLeft id="standardWL"
            showTarget="false"/>
    </fx:Declarations>
    <mx:HBox borderStyle="solid"
        paddingLeft="10" paddingRight="10"
        paddingTop="10" paddingBottom="10">
        <mx:Button label="Custom Mask"
            mouseDownEffect="{customWL}"
            height="100" width="150"/>
    </mx:HBox>
</s:Application>
```

Using MX data effects

The MX List and MX TileList controls take input from a *data provider*, an object that contains the data displayed by the control. To provide this data, you assign a collection, which is usually an ArrayCollection or XMLListCollection object, to the control's `dataProvider` property. Each item in the control is then displayed by using an item renderer.

MX data effects make it possible to apply effects to the item renderers in List and TileList controls when the data provider for the control changes. For example, when an item is deleted from the data provider of a List control, the item renderer for that item might fade out and shrink.

For more information about data providers and controls that use data providers, see "Data providers and collections" on page 898. For more information about item renderers, see "MX item renderers and item editors" on page 1006.

By default, the List and TileList control do not use a data effect. To specify the effect to apply to the control, use the control's `itemsChangeEffect` style property. For the List control, use the DefaultListEffect class to configure the data effect. For the TileList control, use the DefaultTileListEffect class.

You can also create custom data effects. For more information, see "Custom effects" on page 2525.

Example: Applying a MX data effect to a MX List or MX TileList control

The following example applies the MX DefaultListEffect effect to the MX List control when items are added to or removed from the control. When an item in the List control is removed, this effect first fades out the item, then collapses the size of the item to 0. When you add an item to the List control, this effect expands the slot for the item, then fades in the new item.

Because the DefaultListEffect effect grows and shrinks item renderers as it plays, you must set the `List.variableRowHeight` property to `true` to enable the List control to dynamically change its row height, as the following example shows:

```
<?xml version="1.0"?>
<!-- dataEffects\ListEffectCustomDefaultEffect.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            import mx.effects.DefaultListEffect;
            import mx.collections.ArrayCollection;

            [Bindable]
            private var myDP:ArrayCollection = new ArrayCollection(
                ['A','B','C','D','E']);

            private function deleteItem():void {
                // As each item is removed, the index of the other items changes.
                // So first get the items to delete, and then determine their indices
                // as you remove them.
                var toRemove:Array = [];
                for (var i:int = 0; i < list0.selectedItems.length; i++)
                    toRemove.push(list0.selectedItems[i]);
                for (i = 0; i < toRemove.length; i++)
                    myDP.removeItemAt(myDP.getItemIndex(toRemove[i]));
            }
            private var zcount:int = 0;
            private function addItem():void {
                // Always add the new item after the third item,
                // or after the last item if the length is less than 3.
                myDP.addItemAt("Z"+zcount++,Math.min(3,myDP.length));
            }
        ]]>
    </fx:Script>
    <fx:Declarations>
        <!-- Define an instance of the DefaultListEffect effect,
             and set its fadeOutDuration and color properties. -->
        <mx:DefaultListEffect id="myDLE"
            fadeOutDuration="1000"/>
    </fx:Declarations>
    <mx:List id="list0"
        width="150"
        dataProvider="{myDP}"
        variableRowHeight="true"
        fontSize="24"
        allowMultipleSelection="true"
        itemsChangeEffect="{myDLE}"/>
    <mx:Button
        label="Delete Item"
        click="deleteItem();"/>
    <mx:Button
        label="Add Item"
        click="addItem();"/>
</s:Application>
```

To use a MX data effect with the TileList class, apply the DefaultTileListEffect effect to the control. When an item in the TileList control is removed, this effect first fades out the item, and then moves the remaining items to their new position. When you add an item to the TileList control, this effect moves the existing items to their new position, and then fades in the new item.

You typically set the `offscreenExtraRowsOrColumns` property of the TileList control when you apply a data effect. This property specifies the number of extra rows or columns of offscreen item renderers used in the layout of the control. This property is useful because data effects work by first determining a *before* layout of the list-based control, then determining an *after* layout, and finally setting the properties of the effect to create an animation from the before layout to the after layout. Because many effects cause currently invisible items to become visible, or currently visible items to become invisible, this property configures the control to create the offscreen item renderers so that they already exist when the data effect plays.

You typically set the `offscreenExtraRowsOrColumns` property to a nonzero, even value, such as 2 or 4, for a TileList control, as the following example shows:

```
<?xml version="1.0"?>
<!-- dataEffects\TileListEffectCustomDefaultEffect.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    height="500">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            import mx.effects.DefaultTileListEffect;
            import mx.effects.easing.Elastic;
            import mx.collections.ArrayCollection;
            import mx.effects.Move;

            [Bindable]
            private var myDP:ArrayCollection = new ArrayCollection(
                ["A","B",'C','D','E','F','G','H','I','J','K','L','M','N','O','P']);
            private function deleteItems():void {
                // As each item is removed, the index of the other items changes.
                // So first get the items to delete, and then determine their indices
                // as you remove them.
                var toRemove:Array = [];
                for (var i:int = 0; i < tlist0.selectedItems.length; i++)
                    toRemove.push(tlist0.selectedItems[i]);
                for (i = 0; i < toRemove.length; i++)
                    myDP.removeItemAt(myDP.getItemIndex(toRemove[i]));
            }
            private var zcount:int = 0;
            private function addItems():void {
                myDP.addItemAt("Z"+zcount++,Math.min(2,myDP.length));
            }
        ]]>
    </fx:Script>

    <fx:Declarations>
        <!-- Define an instance of the DefaultTileListEffect effect,
             and set its moveDuration and color properties. -->
        <mx:DefaultTileListEffect id="myDTLE"
            moveDuration="100"/>
    </fx:Declarations>
    <mx:TileList id="tlist0"
        height="400" width="400"
        columnCount="4" rowCount="4"
        fontSize="30" fontWeight="bold"
        direction="horizontal"
        dataProvider="{myDP}"
        allowMultipleSelection="true"
        offscreenExtraRowsOrColumns="2"
        itemsChangeEffect="{myDTLE}" />
    <mx:Button
        label="Delete Selected Item(s)"
        click="deleteItems();"/>
    <mx:Button
        label="Add Item"
        click="addItems();"/>
</s:Application>
```

Improving performance when resizing Panel containers

When you apply a Resize effect to a MX Panel container, the measurement and layout algorithm for the effect executes repeatedly over the duration of the effect. When a Panel container has many children, the animation can be jerky because Flex cannot update the screen quickly enough.

To solve this problem, you can use the Resize effect's `hideChildrenTargets` property to hide the children of panel containers while the Resize effect is playing. The value of the `hideChildrenTargets` property is an Array of Panel containers that should include the Panel containers that resize during the animation. Before the Resize effect plays, Flex iterates through the Array and hides the children of each of the specified Panel containers.

In the following example, the children of the panelOne and panelTwo containers are hidden while the containers resize:

```
<?xml version="1.0"?>
<!-- behaviors\PanelResize.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:HorizontalLayout/>
    </s:layout>
    <fx:Declarations>
        <mx:Resize id="myResizeOne" heightTo="300"
            target="{panelOne}"
            hideChildrenTargets="{[panelOne]}"/>
        <mx:Resize id="myResizeTwo" heightTo="300"
            target="{panelTwo}"/>
    </fx:Declarations>
    <s:Button id="b1"
        label="Reset"
        click="panelOne.height=200;panelTwo.height=200;"/>
    <mx:Panel id="panelOne" title="Panel 1" height="200"
        mouseDown="myResizeOne.end();myResizeOne.play();">
        <s:Button label="Click Me"/>
        <s:Button label="Click Me"/>
        <s:Button label="Click Me"/>
        <s:Button label="Click Me"/>
        <s:Button label="Click Me"/>
    </mx:Panel>

    <mx:Panel id="panelTwo" title="Panel 2" height="200"
        mouseDown="myResizeTwo.end();myResizeTwo.play();">
        <s:Button label="Click Me"/>
        <s:Button label="Click Me"/>
        <s:Button label="Click Me"/>
        <s:Button label="Click Me"/>
        <s:Button label="Click Me"/>
    </mx:Panel>
</s:Application>
```

For the MX Panel container, you can control the effect used to hide the container children. For each panel container in the `hideChildrenTargets` Array, the following effect triggers execute:

- `resizeStartEffect` Delivered before the Resize effect begins playing.
- `resizeEndEffect` Delivered after the Resize effect finishes playing.

  If the `resizeStartEffect` trigger specifies an effect to play, the Resize effect is delayed until the effect finishes playing.

The default value for the MX Panel container's `resizeStartEffect` and `resizeEndEffect` triggers is `Dissolve`, which plays the Dissolve effect. To disable the Dissolve effect so that a Panel container's children are hidden immediately, you must set the value of the `resizeStartEffect` and `resizeEndEffect` triggers to `none`.

Using the MX Dissolve effect with the MX Panel, TitleWindow, and Accordion containers

The MX Dissolve effects is only applied to the content area of the Panel, TitleWindow, and Accordion containers. Therefore, the title bar of the Panel and TitleWindow containers, and the navigation buttons of the Accordion container are not modified by this effect.

To apply the Dissolve effect to the entire container, create a RoundedRectange instance that is the same size as the container, and then use the `targetArea` property of the effect to specify the area on which to apply the effect. In the following example, you apply a Dissolve effect to the first Panel container, and apply a Dissolve effect to a RoundedRectange instance overlaid on top of the second Panel container:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- behaviors\PanelDissolve.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="init();">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
           import mx.geom.*;
            // Define a bounding box for the target area of the effect.
           [Bindable]
           public var tArea:RoundedRectangle;
            // Size the bounding box to the size of Panel 2.
           private function init():void
           {
              tArea = new RoundedRectangle(0,0, panel2.width, panel2.height, 5);
           }
        ]]>
    </fx:Script>
    <fx:Declarations>
        <mx:Dissolve id="dissolveP1"
            duration="1000"
            target="{panel1}"
            alphaFrom="1.0" alphaTo="0.0"/>
        <!-- Apply the effect to the bounding box, not to Panel 2. -->
        <mx:Dissolve id="dissolveP2"
            duration="1000"
            target="{panel2}"
            alphaFrom="1.0" alphaTo="0.0"
            targetArea="{tArea}"/>
    </fx:Declarations>
    <mx:Panel id="panel1" title="Panel 1"
        width="100" height="140" >
       <mx:Button label="Orange" />
    </mx:Panel>
    <mx:Panel id="panel2" title="Panel 2"
        width="100" height="140" >
       <mx:Button label="Red" />
    </mx:Panel>
    <mx:Button label="Dissolve Panel 1"
        click="dissolveP1.end();dissolveP1.play();"/>
    <mx:Button label="Dissolve Panel 2"
        click="dissolveP2.end();dissolveP2.play();"/>
</s:Application>
```

Using MX easing functions

You can change the speed of an animation by defining an easing function for an effect. With easing, you can create a more realistic rate of acceleration and deceleration. You can also use an easing function to create a bounce effect or control other types of motion.

Flex supplies MX easing functions in the mx.effects.easing package. This package includes functions for the most common types of easing, including Bounce, Linear, and Sine easing. For more information on using these functions, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

The following code shows the basic format of an easing function:

```
function myEasingFunction(t:Number, b:Number, c:Number, d:Number):Number {
    ...
}
```

You specify the following arguments of an easing function:

- `t` specifies time.
- `b` specifies the initial position of a component.
- `c` specifies the total change in position of the component.
- `d` specifies the duration of the effect, in milliseconds.

Configuring a MX easing function

You specify an easing function to a component by passing a reference to the function to a component property. You pass only the name of the easing function; Flex automatically sets the values for the arguments of the easing function.

All tween effects, meaning effect classes that are child classes of the TweenEffect class, support the `easingFunction` property, which lets you specify an easing function to the effect. Mask effects, those effect classes that are child classes of the MaskEffect class, also support easing functions. Other components support easing functions as well. For example, the Accordion and Tree components let you use the `openEasingFunction` style property to specify an easing function, and the ComboBox component supports a `closeEasingFunction` style property.

For example, you can specify the `mx.effects.easing.Bounce.easeOut()` method to the Accordion container using the `openEasingFunction` property, as the following code shows.

```
<?xml version="1.0"?>
<!-- behaviors\EasingFuncExample.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    height="550">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        import mx.effects.easing.*;
    </fx:Script>
    <mx:Accordion
        openEasingFunction="{Bounce.easeOut}"
        openDuration="2000">
        <mx:VBox label="Pane 1" width="400" height="400"/>
        <mx:VBox label="Pane 2" width="400" height="400"/>
    </mx:Accordion>
</s:Application>
```

Creating a custom easing function

In the following example, you create a custom easing function that creates a bounce motion when combined with the Flex Move effect:

```
<?xml version="1.0"?>
<!-- behaviors\Easing.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    width="650">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            private function myEasingFunction(t:Number, b:Number,
                    c:Number, d:Number):Number {
              if ((t /= d) < (1 / 2.75)) {
                  return c * (7.5625 * t * t) + b;
              }
              else if (t < (2 / 2.75)) {
                  return c * (7.5625 * (t-=(1.5/2.75)) * t + .75) + b;
              }
              else if (t < (2.5 / 2.75)) {
                  return c * (7.5625 * (t-=(2.25/2.75)) * t + .9375) + b;
              }
              else {
                  return c * (7.5625 * (t-=(2.625/2.75)) * t + .984375) + b;
              }
            };
        ]]>
    </fx:Script>
    <fx:Declarations>
        <mx:Move id="moveLeftShow"
            xFrom="600" xTo="0" yTo="0"
            duration="3000"
            easingFunction="myEasingFunction"/>
        <mx:Move id="moveRightHide"
            xFrom="0" xTo="600"
            duration="3000"
            easingFunction="myEasingFunction"/>
    </fx:Declarations>

    <mx:LinkBar dataProvider="myVS"/>
    <mx:ViewStack id="myVS" borderStyle="solid">
        <mx:Canvas id="Canvas0" label="Canvas0"
            creationCompleteEffect="{moveLeftShow}"
            showEffect="{moveLeftShow}"
            hideEffect="{moveRightHide}" >
                <mx:Box height="300" width="600" backgroundColor="#00FF00">
                    <mx:Label text="Screen 0" color="#FFFFFF" fontSize="40"/>
                </mx:Box>
        </mx:Canvas>
        <mx:Canvas id="Canvas1" label="Canvas1"
            showEffect="{moveLeftShow}" hideEffect="{moveRightHide}" >
                <mx:Box height="300" width="600" backgroundColor="#0033CC">
                    <mx:Label text="Screen 1" color="#FFFFFF" fontSize="40"/>
                </mx:Box>
            </mx:Canvas>
    </mx:ViewStack>
</s:Application>
```

In this example, you use the custom effects in the `showEffect` and `hideEffect` properties of the children of a ViewStack container. When you click a label in the LinkBar control, the corresponding child of the ViewStack container slides in from the right, and bounces to a stop against the left margin of the ViewStack container, while the previously visible child of the ViewStack container slides off to the right.

The custom effect for the `showEffect` property is only triggered when the child's visibility changes from `false` to `true`. Therefore, the first child of the ViewStack container also includes a `creationCompleteEffect` property. This is necessary to trigger the effect when Flex first creates the component. If you omit the `creationCompleteEffect` property, you do not see the `moveLeftShow` effect when the application starts.

View states

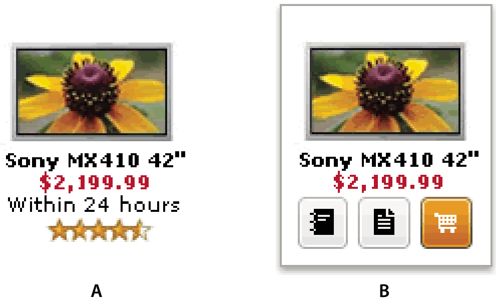
View states let you vary the content and appearance of a component or application, typically in response to a user action. When changing the view state, you can change the value of a property or style, change an event handler, or change the parent of a component.

Transitions define how a change of view state looks as it occurs on the screen. For information on transitions, see "Transitions" on page 1870.

About view states

In many rich Internet applications, the interface changes based on the task the user is performing. A simple example is an image that changes when the user rolls the mouse over it. More complex examples include user interfaces whose contents change depending on the user's progress through a task, such as changing from a browse view to a detail view. View states let you easily implement such applications.

At its simplest, a view state defines a particular view of a component. For example, a product thumbnail could have two view states; a default view state with minimal information, and a "rich" state with links for more information. The following figure shows two view states for a component:



A. *Default view state* ***B.*** *Rich view state*

To create a view state, you define a default view state, and then define a set of changes, or *overrides*, that modify the default view state to define the new view state. Each additional view state can modify the default view state by adding or removing child components, by setting style and property values, or by defining state-specific event handlers.

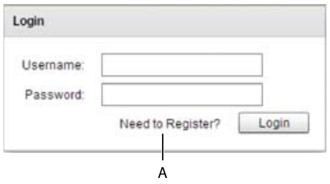
For example, the default view state of the application could be the home page and include a logo, a sidebar, and some welcome content. When the user clicks a button in the sidebar, the application dynamically changes its appearance, meaning its view state, by replacing the main content area with a purchase order form but leaving the logo and sidebar in place.

Two places in your application where you must use view states is when defining skins and item renderers for Spark components. For more information, see “Spark Skinning” on page 1602 and “Custom Spark item renderers” on page 470.

Adobe Flash Builder also has built-in support for view states. For more information on using Flash Builder, see Add View states and transitions.

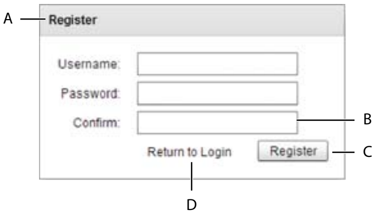
Defining a login interface by using view states

One use of view states is to implement a login and registration form. In this example, the default view state prompts the user to log in, and includes a LinkButton control that lets the user register, if necessary, as the following image shows:



LinkButton control (A)

If the user selects the Need to Register link, the form changes view state to display registration information, as the following image shows:



A. *Modified title of Panel container* ***B.*** *New form item* ***C.*** *Modified label of Button control* ***D.*** *New LinkButton control*

Notice the following changes to the default view state to create this view state:

- The title of the Panel container is set to Register
- The Form container has a new TextInput control for confirming the password
- The label of the Button control is set to Register
- The LinkButton control has been replaced with a new LinkButton control that lets the user change state back to the default view state

When the user clicks the Return to Login link, the view state changes back to the default view state to display the Login form. This change reverses all the changes made when changing to the register view state.

To see the code that creates this example, see “Example: Login form application” on page 1859.

Comparing view states to MX navigator containers

View states give you one way to change the appearance of an application or component in response to a user action. You can also use MX navigator containers, such as the Accordion, Tab Navigator, and ViewStack containers when you perform changes that affect several components.

Your choice of using navigator containers or states depends on your application requirements and user-interface design. For example, if you want to use a tabbed interface, use a TabNavigator container. You might decide to use the Accordion container to let the user navigate through a complex form, rather than using view states to perform this action.

When comparing view states to ViewStack containers, one thing to consider is that you cannot easily share components between the different views of a ViewStack container. That means you have to recreate a component each time you change views. For example, if you want to show a search component in all views of a View Stack container, you must define it in each view.

When using view states, you can easily share components across multiple view states by defining the component once, and then including it in each view state. For more information about sharing components among view states, see “Controlling when to create added children” on page 1856. For more information on navigator containers, see “MX navigator containers” on page 628.

Example: Creating a simple view state

The following example shows an application with a default view state, and one additional view state named "NewButton". In this example, changing to the NewButton view state adds button b2 to the Group container, and disables button b1. Switching back to the default view state removes b2 and enables b1:

```
<?xml version="1.0"?>
<!-- states\StatesSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:states>
        <!-- Define the new view states. -->
        <s:State name="default"/>
        <s:State name="NewButton"/>
    </s:states>
    <s:VGroup id="g1">
        <s:HGroup>
            <!-- Disable Button in the NewButton view state. -->
            <s:Button id="b1" label="Click Me"
                enabled.NewButton="false"/>
            <!-- Add a new child control to the VBox. -->
            <s:Button id="b2" label="New Button"
                includeIn="NewButton"/>
        </s:HGroup>

        <!-- Define Button control to switch to NewButton view state. -->
        <s:Button label="Change to NewButton state"
            click="currentState='NewButton';"/>
        <!-- Define Button control to switch to default view state. -->
        <s:Button label="Change to default view state"
            click="currentState='default';"/>
    </s:VGroup>
</s:Application>
```

Create and apply view states

The properties, styles, event handlers, and components that you define for an application or custom component specify its default view state. Any additional view state specify changes to the default view state.

For each additional view state, define overrides of the default view state. Overrides modify the properties, styles, and event handlers for a component, add a component to a view state, remove a component from a view state, or change the parent container of a component in a view state.

Creating view states

Consider the following when you define a view state.

- Define view states at the root of an application or at the root of a custom component; that is, as a property of the Application container of an application file, or of the root tag of an MXML component.
- Define states by using a component's `states` property, normally by using the `<s:states>` tag in MXML.
- Populate the `states` property with an Array of one or more State objects, where each State object corresponds to a view state.
- Use the `name` property of the State object to specify its identifier. To change to that view state, you set a component's `currentState` property to the value of the `name` property.

  ***Note:** View state definitions are processed at compile time. Therefore, you cannot use data binding to set the `State.name` property because data binding occurs at run time.*

The following MXML code shows this structure:

```
<s:Application>
    <!-- Define the view states.
        The <s:states> tag can also be a child tag of
        the root tag of a custom component.
    -->
    <s:states>
        <s:State name="State1"/>
        <s:State name="State2"/>
        <s:State name="State3"/>
        .
        .
    </s:states>
    <!-- Application definition. -->
    .
    .
</s:Application>
```

The default view state is defined as the first view state in the `<s:states>` Array. An application uses the default view state when it loads. The name of the default view state is not reserved, so it is not required to be "default".

Changing view state

The UIComponent class defines the `currentState` property that you use to set the current view state. When the application starts, the default value of the `currentState` property is the name of the first view state defined by the `<s:states>` tag.

In the next example, you use a Button control to set the `currentState` property of the Application object to "State1" or "State2", the names of a view state specified by the `<s:State>` tag:

```
<s:Button id="b1" label="Change to State 1" click="currentState='State2';"/>
<s:Button id="b2" label="Change to the default" click="currentState='State1';"/>
```

The second button in the previous example sets the current state to "State1" so that you can switch back to the default view state from "State2".

You can also set the `currentState` property to an empty String to set it to the default state, as the following example shows:

```
<s:Button id="b2" label="Change to the default" click="currentState='';"/>
```

You can change a component's view state by calling the `setCurrentState()` method of the UIComponent class. Use this method when you do *not* want to apply a transition that you have defined between two view states. For more information on transitions, see "Transitions" on page 1870.

Setting properties, styles, and events for a view state

Define state-specific property and style values by using the dot (.) operator with any writable MXML tag attribute. The dot notation has the following format:

`propertyOrStyleName.stateName`

For example, specify the value of the `label` property of a Button control for the default view state and for one additional view state, as the following example shows:

```
<s:Button label="Default State" label.State2="New State"/>
```

The value of the `label` property qualified by "State2" specifies the value for the property in that view state. The unqualified property definition, the one that omits the dot notation, defines the value of the property for all view states where you do not explicitly define an override.

Do not define an override for every property, style, and event for all view states. Only define the override for those view states where you want to change the value of the element.

You can also use child tags with the dot notation to define property overrides, as the following example shows for the b1 button control:

```
<?xml version="1.0"?>
<!-- states\StatesSimpleChildTags.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:states>
        <!-- Define the new view states. -->
        <s:State name="default"/>
        <s:State name="NewButton"/>
    </s:states>

    <s:VGroup >
        <s:HGroup>
            <!-- Disable Button in the NewButton view state. -->
            <s:Button id="b1">
                <s:label>Click Me</s:label>
                <s:label.NewButton>Disabled</s:label.NewButton>
                <s:enabled.NewButton>false</s:enabled.NewButton>
            </s:Button>

            <!-- Add a new child control to the VBox. -->
            <s:Button id="b2" label="New Button"
                includeIn="NewButton"/>
        </s:HGroup>
        <!-- Define Button control to switch to NewButton view state. -->
        <s:Button label="Change to NewButton state"
            click="currentState='NewButton';"/>
        <!-- Define Button control to switch to default view state. -->
        <s:Button label="Change to default view state"
            click="currentState='default';"/>
    </s:VGroup>
</s:Application>
```

To clear the value of a property in a view state, set the property to the value `@Clear()`, as the following example shows:

```
<s:Button color="0xFF0000" color.State1="@Clear()"/>
```

For a style property, setting the value to `@Clear()` corresponds to calling the `clearStyle()` method on the property.

Use the dot operator to change the event handler for a specific view state, as the following example shows. In this example, the handler for the `click` event for button b1 is set based on the view state:

```
<?xml version="1.0"?>
<!-- states\StatesEventHandlersSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:states>
        <s:State name="default"/>
        <s:State name="logout"/>
    </s:states>

    <s:VGroup >
        <s:Button id="b1" label="Click Me"
            click="ta1.text='hello';"
            click.logout="ta1.text='goodbye'"/>
        <s:TextArea id="ta1" height="100" width ="50%"/>

        <s:Button label="Default State"
            click="currentState='';"
            enabled="false"
            enabled.logout="true"/>
        <s:Button label="Logout State"
            click="currentState='logout';"
            enabled="true"
            enabled.logout="false"/>
    </s:VGroup>
</s:Application>
```

Adding or removing components for a view state

Use the `includeIn` and `excludeFrom` MXML attributes to specify the set of view states in which a component is included, where:

- The `includeIn` attribute specifies the list of view states where the component appears. This attribute takes a comma delimited list of view state names, all which must have been previously declared in the `<s:states>` Array.
- The `excludeFrom` attribute specifies the list of view states where the component is omitted. This attribute takes a comma delimited list of view state names.
- The `excludeFrom` and `includeIn` attributes are mutually exclusive; it is an error to define both on a single MXML tag.

The following example uses view states to add components to the application based on the current state:

```
<?xml version="1.0"?>
<!-- states\StatesSimpleIncExc.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:states>
        <s:State name="default"/>
        <s:State name="addCheckBox"/>
        <s:State name="addTextInput"/>
        <s:State name="addCheckBoxandButton"/>
    </s:states>

    <s:HGroup >
        <!-- Included in the addCheckBox and addCheckBoxandButton view states. -->
        <s:CheckBox id="myCB" label="Checkbox"
           includeIn="addCheckBox, addCheckBoxandButton"/>

        <!-- Included in the addTextInput view state. -->
        <s:TextInput id="myTI"
           includeIn="addTextInput"/>
        <!-- Included in the addCheckBoxandButton view state. -->
        <s:Button id="myB"
           includeIn="addCheckBoxandButton"/>

        <!-- Exclude from addTextInput view state. -->
        <s:TextArea text="Exclude from addTextInput"
            excludeFrom="addTextInput"/>
    </s:HGroup>
    <s:HGroup>
        <s:Button label="Add CheckBox"
            click="currentState='addCheckBox'"/>
        <s:Button label="Show Textinput Only"
            click="currentState='addTextInput'"/>
        <s:Button label="Add CheckBox and Button"
            click="currentState='addCheckBoxandButton'"/>
        <s:Button label="Default"
            click="currentState='default'"/>
    </s:HGroup>
</s:Application>
```

You can specify the `includeIn` and `excludeFrom` attributes on any MXML object within an MXML document, with the exception of the following tags:

- The root tag of an MXML document, such as the Application tag or the root tag in an MXML component.
- Tags that represent properties of their parent tag. For example, the `<s:label>` tag of the `<s:Button>` tag.
- Descendants of the `<fx:XML>`, `<fx:XMLList>`, or `<fx:Model>` tags.
- Any language tags, such as the `<fx:Binding>`, `<fx:Declarations>`, `<fx:Metadata>`, `<fx:Script>`, and `<fx:Style>` tags.

Restriction on modifying container children when using view states

When you use view states to control the children of a container, do not add or remove container children, or change the order of children in the container, at runtime. For example, the following container defines a Button control that appear only in State2:

```
<s:Group id="myGroup">
    <s:Button/>
    <s:Button includeIn="State2"/>
    <s:Button/>
</s:Group>
```

The view states infrastructure relies on the structure of the container as defined by the MXML file. Changing the child order of the container at runtime can cause your application to fail. Therefore, do not call the `addElement()`, `removeElement()`, `setElementIndex()` method on the Group container at runtime, or any other method that changes the child order of the container.

Changing the parent of a component

A view state can change the parent container of a component. Changing the parent container of a component is called *reparenting* the component.

Use the `<fx:Reparent>` tag to change the parent container of a component. The `<fx:Reparent>` tag has the following syntax:

```
<fx:Reparent target="targetComp" includeIn="stateName">
```

The `target` property specifies the target component, and the `includeIn` property specifies a view state. When the current view state is set to *stateName*, the target component becomes a child of the parent component of the `<fx:Reparent>` tag. You can think of the `<fx:Reparent>` tag as a placeholder for the component for a specific view state.

You can use the `<fx:Reparent>` tag in any component that can hold a child component, and the child can use the `includeIn` or `excludeFrom` keywords.

The following example uses the `<fx:Reparent>` tag to switch a Button control between two Panel containers:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- states\NewStatesReparent.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:states>
        <s:State name="Parent1"/>
        <s:State name="Parent2"/>
    </s:states>

    <s:HGroup>
        <s:Panel id="Panel1"
            height="100" width="100"
            title="Panel 1">
            <s:Button id="setCB" includeIn="Parent1"/>
        </s:Panel>
        <s:Panel id="Panel2"
            height="100" width="100"
            title="Panel 2">
            <fx:Reparent target="setCB" includeIn="Parent2"/>
        </s:Panel>
    </s:HGroup>

    <s:HGroup>
        <s:Button label="Parent 1"
            click="currentState='Parent1'"
            enabled.Parent1="false"/>
        <s:Button label="Parent 2"
            click="currentState='Parent2'"
            enabled.Parent2="false"/>
    </s:HGroup>
</s:Application>
```

Two `<fx:Reparent>` tags cannot target the same component for the same view state. That means a component can only have a single parent in each view state.

Controlling when to create added children

When you remove a component as part of a change of view state, you remove the component from the application's display list, which means that it no longer appears on the screen. Even though the component is no longer visible, the component still exists and you can access it from within your application.

When you add a component as part of a change of view state, you can either create the component before the first change to the view state, or create it at the time of the first change. If you create the component before the first change, you can access the component from within your application even though you have not yet changed view states. If you create the component when you perform the first change to the view state, you cannot access it until you perform that first change.

By default Flex creates container children when they are first required as part of a change of view state. However, if a child requires a long time to create, users might see a delay when the view state changes. Therefore, you can choose to create the child before the state changes to improve your application's apparent speed and responsiveness.

Regardless of when you create a component, the component remains in memory after you change out of the view state that creates it. Therefore, after the first change to a view state, you can always access the component even if that view state is no longer the current view state.

The specification of when the child is created is called its *creation policy*. For more general information on creation policies and controlling how children are created, see "Improving startup performance" on page 2333.

Use the `itemCreationPolicy` property to specify the creation policy. The `itemCreationPolicy` property supports the following values:

`deferred` Creates the component instance when it is first added by a change to the view state. This is the default value.

`immediate` Creates the component instance at application startup.

The following example uses the Immediate view state to add a Button control named newButtonImmediate. You set the `itemCreationPolicy` property for this button to `immediate` to create the button at application startup. Therefore, the application can access it to set its `label` property before it switches to the Immediate view state.

The application also uses the Deferred view state to create the button named newButtonDeferred with the `itemCreationPolicy` property set to `deferred`. Therefore, this button is created when you first change to the Deferred view state, and you cannot access it until after the first switch to the Deferred view state:

```
<?xml version="1.0"?>
<!-- states\StatesCreationPolicy.mxml  -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initButton();">

    <fx:Script>
        <![CDATA[
            // Because the Immediate view state creates the Button control
            // at application startup, you can access the control to
            // set the label before the first switch
            // to the Immediate view state.
            public function initButton():void {
                newButtonImmediate.label="Immediate Button";
                // Uncommenting this line to access the label causes a
                // Run Time Exception because newButtonDeferred does not exist yet.
                // newButtonDeferred.label="Deferred Button";
            }
        ]]>
    </fx:Script>
    <s:states>
        <s:State name="default"/>
        <s:State name="Immediate"/>
        <s:State name="Deferred"/>
    </s:states>

    <s:Panel id="myPanel"
        title="Static and dynamic states"
        width="300" height="150">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <!-- Create the Button control at application startup. -->
        <s:Button id="newButtonImmediate"
```

```
            includeIn="Immediate"
            itemCreationPolicy="immediate"/>
        <!-- Create the Button control when you switch to this view state. -->
        <s:Button id="newButtonDeferred"
            label="Deferred button"
            includeIn="Deferred"
            itemCreationPolicy="deferred"/>

        <!-- Change to the Immediate view state. -->
        <s:Button label="Change to Immediate state"
            click="currentState='Immediate';"/>

        <!-- Change to the Deferred view state. -->
        <s:Button label="Change to Deferred state"
          click="currentState='Deferred';"/>
        <!-- Change to the default view state. -->
        <s:Button label="Change to default state"
          click="currentState='default';"/>
    </s:Panel>
</s:Application>
```

Controlling caching of objects created in a view state

A change to a view state can cause Flex to create an object. By default, after Flex creates the object, the object is cached indefinitely, even after you switch to another view state. The item is cached even if the destination view state excludes the object.

Use the `itemDestructionPolicy` attribute with the `includeIn` and `excludeFrom` attributes configure Flex to completely destroy the object when leaving a view state, including deleting it from the cache. Typically it is more efficient to allow items to be cached because it improves performance when switching back to the view state that created the object, or to a view state that uses the object. However your application might define a view state that is rarely used, and you do not want to allocate memory for caching the object.

You can use the `itemDestructionPolicy` attribute on any object in MXML that supports the `includeIn` and `excludeFrom` attributes. The possible values for `itemDestructionPolicy` are `never` (default) and `auto`.

The value of `never` specifies that the object is cached indefinitely. A value of `auto` means that the object is destroyed when leaving a view state where the object exists. The following example sets the attribute to `auto`:

```
<s:TextInput includeIn="newTextInput" itemDestructionPolicy="auto"/>
```

Defining view state groups

The `stateGroups` attribute of the `<s:States>` tag lets you group one or more states together. For example, if multiple components appear in the same set of view states, create a view state group that contains all these view states. Then, when you set the `currentState` property to any view state in the group, the components appears.

In the following example, the CheckBox control named myCB appears when you change to any view state in Group1:

```
<?xml version="1.0"?>
<!-- states\StatesSimpleGroups.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <s:states>
        <s:State name="default"/>
        <s:State name="addCheckBox" stateGroups="Group1"/>
        <s:State name="addTextInput"/>
        <s:State name="addCheckBoxandButton" stateGroups="Group1"/>
    </s:states>

    <s:HGroup>
        <!-- Included in the addCheckBox and addCheckBoxandButton view states. -->
        <s:CheckBox id="myCB" label="Checkbox"
            includeIn="Group1"/>

       <!-- Included in the addTextInput view state. -->
       <s:TextInput id="myTI"
            includeIn="addTextInput"/>
        <!-- Included in the addCheckBoxandButton view state. -->
        <s:Button id="myB"
           includeIn="addCheckBoxandButton"/>

        <!-- Exclude from addTextInput view state. -->
        <s:TextArea text="Exclude from addTextInput"
           excludeFrom="addTextInput"/>
    </s:HGroup>
    <s:HGroup>
        <s:Button label="Add CheckBox"
            click="currentState='addCheckBox'"/>
        <s:Button label="Add Textinput"
            click="currentState='addTextInput'"/>
        <s:Button label="Add Group 1"
            click="currentState='addCheckBoxandButton'"/>
        <s:Button label="Default"
            click="currentState='default'"/>
    </s:HGroup>
</s:Application>
```

Example: Login form application

The following example creates the Login and Register forms shown in “About view states” on page 1847. This application has the following features:

- When the user clicks the Need to Register LinkButton control, the event handler for the `click` event sets the view state to Register.
- The Register state code adds a TextInput control, changes properties of the Panel container and Button control, removes the existing LinkButton controls, and adds a new LinkButton control.
- When the user clicks the Return to Login LinkButton control, the event handler for the `click` event resets the view state to the default view state.

***Note:** For an example that adds a transition to animate the change between view states, see "Example: Using transitions with a login form" on page 1871.*

```
<?xml version="1.0"?>
<!-- states\LoginExample.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <!-- The Application class states property defines the view states.-->
    <s:states>
        <s:State name="default"/>
        <s:State name="Register"/>
    </s:states>
    <!-- Set title of the Panel container based on the view state.-->
    <s:Panel id="loginPanel"
        title="Login" title.Register="Register">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <s:Form id="loginForm">
            <s:FormItem label="Username:">
                <s:TextInput/>
            </s:FormItem>

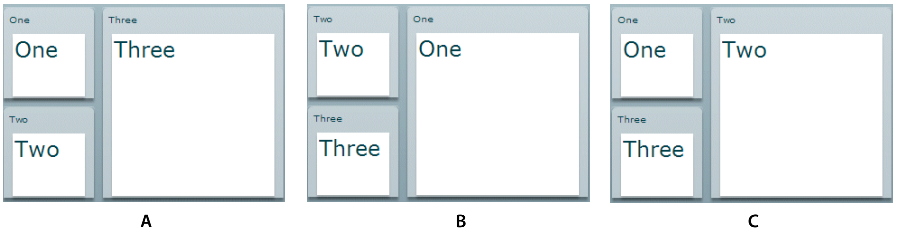
            <s:FormItem label="Password:">
                <s:TextInput/>
            </s:FormItem>

            <s:FormItem id="confirm" label="Confirm:" includeIn="Register">
             <!-- Add a TextInput control to the form for the Register view state. -->
                <s:TextInput/>
            </s:FormItem>

            <s:FormItem>
                <!-- Use the LinkButton to change view state.-->
                <s:HGroup>
                    <!-- Set label of the control based on the view state.-->
                    <mx:LinkButton id="registerLink"
                        label="Need to Register?"
                        label.Register="Return to Login"
                        click="currentState='Register'"
                        click.Register="currentState=''"/>
                    <s:Button id="loginButton"
                        label="Login" label.Register="Register"/>
                </s:HGroup>
            </s:FormItem>
        </s:Form>
    </s:Panel>
</s:Application>
```

Example: Controlling layout using view states groups

In this example, you define an application with three Panel containers and three view states, as the following example shows:



***A.** Default view state* ***B.** One view state* ***C.** Two view state*

To change view state, click the Panel container that you want to display in the expanded size. For a version of this example that adds a transition to animate the view state change, see “Defining transitions” on page 1872.

```
<?xml version="1.0"?>
<!-- states/ThreePanel.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark" width="400">
    <!-- Define the two view states, in addition to the default view state.-->
    <s:states>
        <s:State name="default"/>
        <s:State name="One"/>
        <s:State name="Two"/>
    </s:states>
    <!-- Define the Group container holding the three Panel containers.-->
    <s:Group width="100%" height="100%">
        <s:Panel id="p1" title="One"
                x="0" y="0"
                x.One="110" y.One="0"
                x.Two="0" y.Two="0"
                width="100" height="100"
                width.One="200" height.One="210"
                width.Two="100" height.Two="100"
                click="currentState='One'">
            <s:Label fontSize="24" text="One"/>
        </s:Panel>

        <s:Panel id="p2" title="Two"
                x="0" y="110"
                x.One="0" y.One="0"
                x.Two="110" y.Two="0"
                width="100" height="100"
                width.One="100" height.One="100"
                width.Two="200" height.Two="210"
                click="currentState='Two'">
            <s:Label fontSize="24" text="Two"/>
        </s:Panel>

        <s:Panel id="p3" title="Three"
                x="110" y="0"
                x.One="0" y.One="110"
                x.Two="0" y.Two="110"
                width="200" height="210"
                width.One="100" height.One="100"
                width.Two="100" height.Two="100"
                click="currentState='default'">
            <s:Label fontSize="24" text="Three"/>
        </s:Panel>
    </s:Group>
</s:Application>
```

You can optimize this application by using view state groups, as the following example shows:

```
<?xml version="1.0"?>
<!-- states/ThreePanelGroups.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark" width="400">
    <!-- Define the two view states, in addition to the default state.-->
    <s:states>
        <s:State name="default" stateGroups="grpDefaultOne, grpDefaultTwo"/>
        <s:State name="One" stateGroups="grpDefaultOne, grpOneTwo "/>
        <s:State name="Two" stateGroups="grpDefaultTwo, grpOneTwo"/>
    </s:states>
    <!-- Define the Group container holding the three Panel containers.-->
    <s:Group width="100%" height="100%">
        <s:Panel id="p1" title="One"
                x.grpDefaultTwo="0" y.grpDefaultTwo="0"
                x.One="110" y.One="0"
                width.grpDefaultTwo="100" height.grpDefaultTwo="100"
                width.One="200" height.One="210"
                click="currentState='One'">
            <s:Label fontSize="24" text="One"/>
        </s:Panel>
        <s:Panel id="p2" title="Two"
                x="0" y="110"
                x.One="0" y.One="0"
                x.Two="110" y.Two="0"
                width.grpDefaultOne="100" height.grpDefaultOne="100"
                width.Two="200" height.Two="210"
                click="currentState='Two'">
            <s:Label fontSize="24" text="Two"/>
        </s:Panel>

        <s:Panel id="p3" title="Three"
                x="110" y="0"
                x.grpOneTwo="0" y.grpOneTwo="110"
                width="200" height="210"
                width.grpOneTwo="100" height.grpOneTwo="100"
                click="currentState='default'">
            <s:Label fontSize="24" text="Three"/>
        </s:Panel>
    </s:Group>
</s:Application>
```

Using view state events

When a component's `currentState` property changes, the State object for the states being exited and entered dispatch the following events:

enterState Dispatched after a view state is entered. Dispatched by a State object and by a component.

exitState Dispatched when a view state is about to be exited. Dispatched by a State object before it is exited, and by a component before it exits the current view state.

The component on which you modify the `currentState` property to cause the state change dispatches the following events:

currentStateChanging Dispatched when the view state is about to change. It is dispatched by a component after its `currentState` property changes, but before the view state changes. You can use this event to request any data from the server required by the new view state.

currentStateChange Dispatched after the view state has completed changing. It is dispatched by a component after its `currentState` property changes. You can use this event to send data back to a server indicating the user's current view state.

The following example uses the `enterState` and `exitState` events to update two TextArea controls with the name of the new state and of the old state:

```
<?xml version="1.0"?>
<!-- states\StatesSimpleEvent.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    height="450">
    <s:states>
        <!-- Define the new view states. -->
        <s:State name="default"
            enterState="MyEnterTA.text = 'Enter state: default';"
            exitState="MyExitTA.text = 'Exit state: default';"/>
        <s:State name="NewButton"
            enterState="MyEnterTA.text = 'Enter state: NewButton';"
            exitState="MyExitTA.text = 'Exit state: NewButton';"/>
    </s:states>
    <s:VGroup id="g1">
        <s:HGroup>
            <s:Button id="b1" label="Click Me"
                enabled.NewButton="false"/>
            <s:Button id="b2" label="New Button"
                includeIn="NewButton"/>
        </s:HGroup>
        <s:Button label="Change to NewButton state"
            click="currentState='NewButton';"/>
        <s:Button label="Change to default view state"
            click="currentState='default';"/>
        <s:TextArea id="MyEnterTA"/>
        <s:TextArea id="MyExitTA"/>

    </s:VGroup>
</s:Application>
```

Defining view states in custom components

If a custom component has multiple view states, define the view states in the component code, not in the main application. You can then set the view state of the component independently of the view state of the enclosing application.

The following example shows a custom component that implements a login dialog box with two view states: Login and Register. The main application sets the `currentState` property of the component to Login. However, you can set it to Register if you want that to be the default view state, or use data binding to set it at run time:

```
<?xml version="1.0"?>
<!-- states\myComponents\LoginComponent.mxml -->
<!-- Set title of the Panel container based on the view state.-->
<s:Panel xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    title="Login" title.Register="Register">

    <!-- The states property defines the view states.-->
    <s:states>
        <s:State name="Login"/>
        <s:State name="Register"/>
    </s:states>
    <s:Form id="loginForm">
        <s:FormItem label="Username:">
            <s:TextInput/>
        </s:FormItem>
        <s:FormItem label="Password:">
            <s:TextInput/>
        </s:FormItem>
        <!-- Add a TextInput control to the form for the Register view state. -->
        <s:FormItem id="confirm" label="Confirm:" includeIn="Register">
            <s:TextInput/>
        </s:FormItem>
        <s:FormItem>
            <s:HGroup>
              <!-- Use the LinkButton to change to the Register view state.-->
               <!-- Exclude the LinkButton from the Register view state.-->
                <mx:LinkButton id="registerLink"
                    includeIn="Login"
                    label="Need to Register?"
                    click="currentState='Register'"/>
                <!-- Add a LinkButton to the form for the Register view state. -->
                <mx:LinkButton label="Return to Login"
                    includeIn="Register"
                    click="currentState=''"/>
                <mx:Spacer width="100%" id="spacer1"/>
                <!-- Set label of the control based on the view state.-->
                <s:Button id="loginButton"
                    label="Login" label.Register="Register" />
            </s:HGroup>
        </s:FormItem>
    </s:Form>
</s:Panel>
```

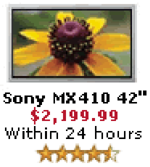
You can then use this component in an application, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- states\LoginMain.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:MyComp="myComponents.*">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:Label text="Login or Register"
        fontSize="14" fontWeight="bold"/>

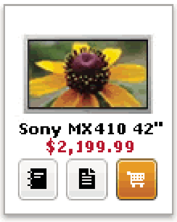
    <MyComp:LoginComponent currentState="Login"/>
</s:Application>
```

Using view states with a custom item renderer

A shopping application that displays multiple items on a page might have a custom thumbnail item renderer with two view states. In one view state, the item cell might look the following image:



When the user rolls the mouse over the item, the view state changes: the thumbnail no longer has the availability and rating information, but now has buttons that let the user get more information or add the item to the wish list or cart. In the new state, the cell also has a border and a drop shadow, as the following image shows:



In this example, the application item renderer's two view states have different child components and have different component styles. The summary state, for example, includes an availability label and a star rating image, and has no border. The rolled-over state replaces the label and rating components with three buttons, and has an outset border.

For information on item renderers, see "MX item renderers and item editors" on page 1006.

Example: Using view states with a custom item renderer

The following code shows an application that uses a custom item renderer to display catalog items. When the user moves the mouse over an item, the item renderer changes to a state where the picture is slightly enlarged, the price appears in the cell, and a text box shows a message about the item. All changes are made by the item renderer's state, including the change in the parent application.

```
<?xml version="1.0"?>
<!-- states\StatesRendererMain.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout horizontalAlign="center"/>
    </s:layout>

    <s:DataGroup itemRenderer="myComponents.ImageComp"
        width="300" height="400">
        <s:layout>
            <s:TileLayout columnWidth="150" rowHeight="175"
                requestedColumnCount="2" requestedRowCount="2" />
        </s:layout>
        <mx:ArrayCollection>
            <fx:Object
                name="Nokia 3595"
                data="1"
                price="129.99"
                image="assets/Nokia_3595.gif"
                description="Kids love it."/>
            <fx:Object
                name= "Nokia 3650"
                data="1"
                price="99.99"
                image="assets/Nokia_3650.gif"
                description="Impress your friends."/>
            <fx:Object
                name="Nokia 6010"
                data="1"
                price="49.99"
                image="assets/Nokia_6010.gif"
                description="Good for everyone."/>
            <fx:Object
                name="Nokia 6360"
                data="1"
                price="19.99"
                image="assets/Nokia_6360.gif"
                description="Great deal!"/>
        </mx:ArrayCollection>
    </s:DataGroup>
</s:Application>
```

The following code defines the item renderer, in the file ImageComp.mxml:

```
<?xml version="1.0" encoding="utf-8"?>
<s:ItemRenderer xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:states>
        <s:State name="normal"/>
        <s:State name="hovered"/>
        <s:State name="selected"/>
    </s:states>
    <s:Image id="img1"
        source="{data.image}"
        width="75" width.hovered="85"
        height="75" height.hovered="85"/>
    <s:Label text="{data.name}"
        color="blue"
        fontSize.hovered="16"/>
    <s:Label text.hovered="{data.price}"/>
    <s:TextArea id="t1"
        visible="false" visible.hovered="true"
        height="30" width="125"
        text.hovered="{data.description}"/>
</s:ItemRenderer>
```

Using view states with the browser manager

The Flex browser manager lets users navigate through an application by using the web browser's back and forward navigation commands. The browser manager can track when the application enters a state so that users can use the browser to navigate between states, such as states that correspond to different stages in an application process.

To use the browser manager, you first obtain a reference to the BrowserManager object by calling the `BrowserManager.getInstance()` method. This method returns the current instance of the manager, which implements IBrowserManager interface. You can then call methods on the browser manager such as `setTitle()` and `setFragment()`.

To save the current state of an application, you write the state name as a name-value pair to the application URL in the browser's address bar. When the user clicks the browser's Forward or Back button, extract the state from the browser's URL and set the `currentState` value appropriately. For more information the browser manager, see "Using the BrowserManager" on page 2024.

The following code shows how you can code a search interface so that the browser manager tracks the state of the application:

```
<?xml version="1.0"?>
<!-- states\StatesBrowserManager.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp();">

    <fx:Script>
        <![CDATA[
            import mx.managers.BrowserManager;
            import mx.managers.IBrowserManager;
            import mx.events.BrowserChangeEvent;
            import mx.utils.URLUtil;

            // The search string value.
            [Bindable]
            public var searchString:String;
            // The BrowserManager instance.
            private var browserManager:IBrowserManager;

            // Initialize the BrowserManager when the application is created.
            public function initApp():void {
                browserManager = BrowserManager.getInstance();
                browserManager.addEventListener(BrowserChangeEvent.BROWSER_URL_CHANGE, 
parseURL);
                browserManager.init("", "Browser Manager for View States");
                // Set the default state as a name/value pair in the URL.
                updateURL('default');
            }

            // Handle the event when the user clicks the Forward or Back button
            // in the browser. This event handler retrieves the value of the
            // state property from the new URL, and uses it to set currentState property.
            private var stateFromURL:String;
            private function parseURL(e:Event):void {
                var o:Object = URLUtil.stringToObject(browserManager.fragment);
                stateFromURL = o.state;
                currentState=stateFromURL;
            }
            // On a state change, save the value of the new
            // currentState property as name/value pair of the URL.
            private function updateURL(myCurrentState:String):void {
                var s:String = "state=" + myCurrentState;
                browserManager.setFragment(s);
            }

            // The method for doing the search.
            // For the sake of simplicity it doesn't do any searching.
            // It does change the state to display the results box,
            // and save the new state in the URL.
            public function doSearch():void {
                currentState = "results";
                updateURL('results');
                searchString = searchInput.text;
            }
            // Method to revert the state to the default state.
            // Saves the new state in in the URL.
            public function reset():void {
                currentState = '';
                searchInput.text = "";
                searchString = "";
                updateURL('default');
            }
        ]]>
    </fx:Script>

    <s:states>
        <!-- The state for displaying the search results -->
        <s:State name="default"/>
        <s:State name="results"/>
    </s:states>
    <!-- In the default state, just show a panel
        with a search text input and button. -->
    <s:Panel id="panel1"
        title="Search" title.results="Results"
        resizeEffect="Resize"
        width="10%" height="10%"
        width.results="100%" height.results="100%">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <s:SkinnableContainer id="searchFields" defaultButton="{b}">
            <s:layout>
                <s:HorizontalLayout/>
            </s:layout>
            <s:TextInput id="searchInput"/>
            <s:Button id="b"
                label="Go"
                click="doSearch();"/>
            <s:Button includeIn="results"
                label="Reset"
                click="reset();"/>
        </s:SkinnableContainer>
        <s:Label includeIn="results"
            text="Search results for {searchString}"/>
    </s:Panel>
</s:Application>
```

In this example, when the user changes state, the `updateURL()` method writes the current state to the browser's URL as a name/value pair. When the user clicks the browser's Forward or Back button, the `parseURL()` method extracts the state from the browser's URL and set the `currentState` value.

You can modify the `updateURL()` method to write more than just the current state to the URL. For example, you can write the search string to the URL. You then use the `parseURL()` method to extract it and update the TextInput control named searchInput.

Transitions

View states let you change the appearance of an application, typically in response to a user action. Transitions define how a change of view state looks as it occurs on the screen. You define a transition by using the effect classes, in combination with several effects designed explicitly for handling transitions.

To use transitions, you should be familiar with how effects and view states work. For more information on effects, see "Introduction to effects" on page 1784. For more information on view states, see "View states" on page 1847.

About transitions

View states let you vary the content and appearance of an application, typically in response to a user action. To use view states, you define the default view state of an application, and one or more additional view states.

When you change view states, Adobe® Flex® performs all the visual changes to the application at the same time. That means when you resize, move, or in some other way alter the appearance of the application, the application appears to jump from one view state to the next.

Instead, you might want to define a smooth visual change from one view state to the next, in which the change occurs over a period of time. A *transition* is one or more effects grouped together to play when a view state change occurs.

For example, your application defines a form that in its default view state shows only a few fields, but in an expanded view state shows additional fields. Rather than jumping from the base version of the form to the expanded version, you define a transition that uses the Resize effect to expand the form, and then uses the Fade effect to slowly make the new form elements appear on the screen.

When a user changes back to the base version of the form, your transition uses a Fade effect to make the fields of the expanded form disappear, and then uses the Resize effect to slowly shrink the form back to its original size.

By using a transition, you can apply one or more effects to the form, to the fields added to the form, and to fields removed from the form. You can apply the same effects to each form field, or apply different effects. You can also define one set of effects to play when you change state to the expanded form, and a different set of effects to play when changing from the expanded state back to the base state.

Example: Using transitions with a login form

The topic "View states" on page 1847 contains an example of a login form with two states: a base state and a register state. The following example adds a transition to this form to use a Wipe effect and a Resize effect with an easing function to animate the transition from view state to view state:

```
<?xml version="1.0" ?>
<!-- transitions\LoginFormTransition.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <!-- The Application class states property defines the view states.-->
    <s:states>
        <s:State name="default"/>
        <s:State name="Register"/>
    </s:states>

    <!-- Define the transition to animate the change of view state. -->
    <s:transitions>
       <s:Transition fromState="default">
            <s:Parallel>
                <s:Wipe direction="right" target="{confirm}"/>
                <s:Resize target="{loginPanel}" duration="100"/>
            </s:Parallel>
        </s:Transition>
       <s:Transition fromState="Register">
            <s:Sequence>
```

```
                <s:Resize target="{loginPanel}" duration="100"/>
            </s:Sequence>
        </s:Transition>
    </s:transitions>

    <!-- Set title of the Panel container based on the view state.-->
    <s:Panel id="loginPanel"
        title="Login" title.Register="Register">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <s:Form id="loginForm">
            <s:FormItem label="Username:">
                <s:TextInput/>
            </s:FormItem>
            <s:FormItem label="Password:">
                <s:TextInput/>
            </s:FormItem>
            <!-- Add a TextInput control to the form for the Register view state. -->
            <s:FormItem id="confirm" label="Confirm:" includeIn="Register">
                <s:TextInput id="myTI"/>
            </s:FormItem>
            <s:FormItem>
                <!-- Use the LinkButton to change to the Register view state.-->
                <!-- Exclude the LinkButton from the Register view state.-->
                <!-- Add a LinkButton to the form for the Register view state. -->
                <mx:LinkButton label="Return to Login"
                    includeIn="Register"
                    click="currentState=''"/>
                <mx:LinkButton id="registerLink"
                    includeIn="default"
                    label="Need to Register?"
                    click="currentState='Register'"/>
                <s:Button id="loginButton"
                    label="Login" label.Register="Register"/>
            </s:FormItem>
        </s:Form>
    </s:Panel>
</s:Application>
```

Comparing transitions to effects

Transitions do not replace effects; that is, you can still apply a single effect to a component. Transitions give you the ability to group multiple effects so that the effects are triggered together as part of a change of view states. Transitions are designed to work specifically with a change between view states, because a view state change typically means multiple components are modified at the same time.

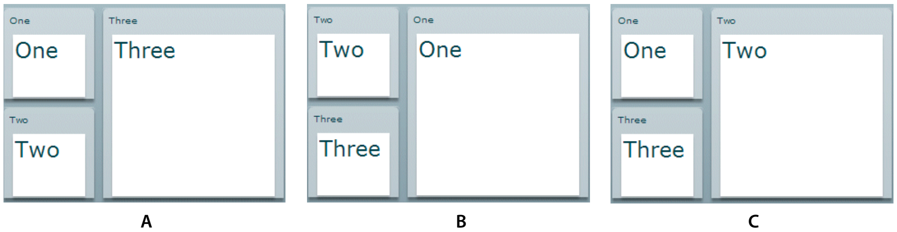
Transitions also support effect filters. A *filter* lets you conditionalize an effect so that it plays an effect only when the effect target changes in a certain way. For example, as part of the change to the view state, one or more components may change size. You can use a filter with an effect so that you apply the effect only to the components being resized. For an example using a filter, see “Filtering effects” on page 1882.

Defining transitions

You use the Transition class to create a transition. The following table defines the properties of the Transition class:

Property	Definition
`fromState`	A String that specifies the view state that you are changing from when you apply the transition. The default value is an asterisk, `"*"`, which means any view state.
`toState`	A String that specifies the view state that you are changing to when you apply the transition. The default value is an asterisk, `"*"`, which means any view state.
`effect`	The Effect object to play when you apply the transition. Typically, this is a composite effect, such as the Parallel or Sequence effect, that contains multiple effects.

You can define multiple Transition objects in an application. The UIComponent class includes a `transitions` property that you set to an Array of Transition objects. For example, you define an application with three Panel containers and three view states, as the following example shows:



A. Default view state B. One view state C. Two view state

You define the transitions for this example in MXML using the `<s:transitions>` tag, as the following example shows:

```
<?xml version="1.0" ?>
<!-- transitions/DefiningTrans.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark" width="400" >
    <!-- Define the two view states, in addition to the base state.-->
    <s:states>
        <s:State name="default"/>
        <s:State name="One"/>
        <s:State name="Two"/>
    </s:states>
    <!-- Define Transition array with one Transition object.-->
    <s:transitions>
        <!-- A transition for changing from any state to any state. -->
        <s:Transition id="myTransition" fromState="*" toState="*">
            <!-- Define a Parallel effect as the top-level effect.-->
            <s:Parallel id="t1" targets="{[p1,p2,p3]}">
                <!-- Define a Move and Resize effect.-->
                <s:Move  duration="400"/>
                <s:Resize duration="400"/>
            </s:Parallel>
        </s:Transition>
    </s:transitions>
    <!-- Define the container holding the three Panel containers.-->
    <s:Group id="pm" width="100%" height="100%">
        <s:Panel id="p1" title="One"
                x="0" y="0"
                x.One="110" y.One="0"
                x.Two="0" y.Two="0"
                width="100" height="100"
                width.One="200" height.One="210"
                width.Two="100" height.Two="100"
                click="currentState='One'">
            <s:Label fontSize="24" text="One"/>
        </s:Panel>

        <s:Panel id="p2" title="Two"
                x="0" y="110"
                x.One="0" y.One="0"
                x.Two="110" y.Two="0"
                width="100" height="100"
                width.One="100" height.One="100"
                width.Two="200" height.Two="210"
                click="currentState='Two'">
            <s:Label fontSize="24" text="Two"/>
        </s:Panel>

        <s:Panel id="p3" title="Three"
                x="110" y="0"
                x.One="0" y.One="110"
                x.Two="0" y.Two="110"
                width="200" height="210"
                width.One="100" height.One="100"
                width.Two="100" height.Two="100"
                click="currentState='default'">
            <s:Label fontSize="24" text="Three"/>
        </s:Panel>
    </s:Group>
</s:Application>
```

In this example:

1 You use the `click` event of each Panel container to change the view state.

2 When the application changes view state, Flex searches for a Transition object that matches the current and destination view state. In this example, you set the `fromState` and `toState` properties to `"*"`. Therefore, Flex applies myTransition to all state changes. For more information on setting the `fromState` and `toState` properties, see “Defining multiple transitions” on page 1875.

3 After Flex determines the transition that matches the change of view state, Flex applies the effects defined by the transition to the effect targets. In this example, you use the specification of the top-level Parallel effect in the transition to specify the targets as the three Panel containers. For more information on setting the effect targets, see “Defining effect targets” on page 1875.

The effects play in parallel on all effect targets, so the three Panel containers move to a new position and change size simultaneously. You can also define the top-level effect as a Sequence effect to make the effects occur sequentially, rather than in parallel.

Flex determines the start and end property values of the Move and Resize effect by using information from any properties that you specified to the effect, the current view state, and the destination view state. In this example, you omit any property specifications in the effect definitions, so Flex uses the current size and position of each Panel container to determine the values of the `Move.xFrom`, `Move.yFrom`, `Resize.widthFrom`, and `Resize.heightFrom` properties. Flex uses the destination view state to determine the values of the `Move.xTo`, `Move.yTo`, `Resize.widthTo`, and `Resize.heightTo` properties. For more information, see “Defining the effect start and end values” on page 1876.

Defining multiple transitions

You can define multiple transitions in your application so that you can associate a specific transition with a specific change to the view state. To specify the transition associated with a change to the view states, you use the fromState and toState properties.

By default, both the `fromState` and `toState` properties are set to `"*"`, which indicates that the transition should be applied to any changes in the view state. You can set either property to an empty string, `""`, which corresponds to the default view state.

You use the `fromState` property to explicitly specify the view state that your are changing from, and the `toState` property to explicitly specify the view state that you are changing to, as the following example shows:

```
<s:transitions>
    <!-- Play for a change to the login view state from any view state. -->
    <s:Transition id="toLoginFromAny" fromState="*" toState="login">
        ...
    </s:Transition>

    <!-- Play for a change to the login view state from the details view state. -->
    <s:Transition id="toLoginFromDetails" fromState="details" toState="login">
        ...
    </s:Transition>

    <!-- Play for a change from any view state to any other view state. -->
    <s:Transition id="toAnyFromAny" fromState="*" toState="*">
        ...
    </s:Transition>
</s:transitions>

<!-- Go to the login view state, transition toLoginFromAny plays. -->
<s:Button click="currentState="login";/>

<!-- Go to the details view state, transition toAnyFromAny plays. -->
<s:Button click="currentState="details";/>

<!-- Go to the login view state, transition toLoginFromDetails plays because you transitioned
from the details to the login view state. -->
<s:Button click="currentState="login";/>

<!-- Go to the default view state, transition toAnyFromAny plays. -->
<s:Button click="currentState='';/>
```

If a state change matches two transitions, the `toState` property takes precedence over the `fromState` property. If more than one transition matches, Flex uses the first matching definition detected in the `transition` Array.

Defining effect targets

The `<s:Transition>` tag shown in the section "Defining transitions" on page 1872 defines the effects that make up a transition. The top-level effect defines the target components of the effects in the transition when the effect does not explicitly define a target. In that example, the transition is performed on all three Panel containers in the application. If you want the transition to play only on the first two panels, you define the Parallel effects as the following example shows:

```
<s:Transition fromState="*" toState="*">
    <!-- Define a Parallel effect as the top most effect.-->
    <s:Parallel id="t1" targets="{[p1,p2]}">
        <s:Move duration="400"/>
        <s:Resize duration="400"/>
    </s:Parallel>
</s:Transition>
```

You removed the third panel from the transition, so it is no longer a target of the Move and Resize effects. Therefore, the third panel appears to jump to its new position and size during the change in view state. The other two panels show a smooth change in size and position for the 400-millisecond (ms) duration of the effects.

You can also use the `target` or `targets` properties of the effects within the transition to explicitly specify the effect target, as the following example shows:

```
<s:Parallel id="t1" targets="{[p1,p2,p3]}">
    <s:Move targets="{[p1,p2]}" duration="400"/>
    <s:Resize duration="400"/>
</s:Parallel>
```

In this example, the Resize effect plays on all three panels, while the Move effect plays only on the first two panels. You could also write this example as the following code shows:

```
<s:Parallel id="t1" targets="{[p1,p2]}">
    <s:Move duration="400"/>
    <s:Resize targets="{[p1,p2,p3]}" duration="400"/>
</s:Parallel>
```

Defining the effect start and end values

Like any effect, an effect within a transition has properties that you use to configure it. For example, most effects have properties that define starting and ending information for the target component, such as the `xFrom`, `yFrom`, `xTo`, and `yTo` properties of the Move effect.

Effects defined in a transition must determine their property values for the effect to execute. Flex uses the following rules to determine the start and end values of effect properties of a transition:

1 If the effect explicitly defines the values of any properties, use them in the transition, as the following example shows:

```
<s:Transition fromState="*" toState="*">
    <s:Sequence id="t1" targets="{[p1,p2,p3]}">
        <mx:Blur duration="100" blurXFrom="0.0" blurXTo="10.0"
            blurYFrom="0.0" blurYTo="10.0"/>
     <s:Parallel>
            <s:Move duration="400"/>
            <s:Resize duration="400"/>
        </s:Parallel>
     <mx:Blur duration="100" blurXFrom="10.0" blurXTo="0.0"
        blurYFrom="10.0" blurYTo="0.0"/>
    </s:Sequence>
</s:Transition>
```

In this example, the two Blur filters explicitly define the properties of the effect.

2 If the effect does not explicitly define the start values of the effect, Flex determines them from the current settings of the target component, as defined by the current view state.

In the example in rule 1, notice that the Move and Resize effects do not define start values. Therefore, Flex determines them from the current size and position of the effect targets in the current view state.

3 If the effect does not explicitly define the end values of the effect, Flex determines them from the settings of the target component in the destination view state.

In the example in rule 1, the Move and Resize effects determine the end values from the size and position of the effect targets in the destination view state. In some cases, the destination view state explicitly defines these values. If the destination view state does not define the values, Flex determines them from the settings of the default view state.

4 If there are no explicit values, and Flex cannot determine values from the current or destination view states, the effect uses its default property values.

The following example modifies the three-panel example shown in “Defining transitions” on page 1872 by adding Blur effects to the transition, where the Blur effect explicitly defines the values of the `blurXFrom`, `blurXTo`, `blurYFrom`, and `blurYTo` properties:

```
<?xml version="1.0" ?>
<!-- transitions\DefiningTransWithBlurs.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark" width="400" >
    <!-- Define the two view states, in addition to the base state.-->
    <s:states>
        <s:State name="default"/>
        <s:State name="One"/>
        <s:State name="Two"/>
    </s:states>

    <!-- Define the single transition for all view state changes.-->
    <s:transitions>
        <s:Transition fromState="*" toState="*">
            <s:Sequence id="t1" targets="{[p1,p2,p3]}">
                <mx:Blur duration="100" blurXFrom="0.0" blurXTo="10.0"
                blurYFrom="0.0" blurYTo="10.0"/>
                <s:Parallel>
                    <mx:Move  duration="400"/>
                    <mx:Resize duration="400"/>
                </s:Parallel>
                <mx:Blur duration="100" blurXFrom="10.0" blurXTo="0.0"
                blurYFrom="10.0" blurYTo="0.0"/>
            </s:Sequence>
        </s:Transition>
    </s:transitions>

    <!-- Define the container holding the three Panel containers.-->
    <s:Group id="pm" width="100%" height="100%">
        <s:Panel id="p1" title="One"
                x="0" y="0"
                x.One="110" y.One="0"
                x.Two="0" y.Two="0"
                width="100" height="100"
                width.One="200" height.One="210"
                width.Two="100" height.Two="100"
                click="currentState='One'">
            <mx:Label fontSize="24" text="One"/>
        </s:Panel>

        <s:Panel id="p2" title="Two"
```

```
                x="0" y="110"
                x.One="0" y.One="0"
                x.Two="110" y.Two="0"
                width="100" height="100"
                width.One="100" height.One="100"
                width.Two="200" height.Two="210"
                click="currentState='Two'">
            <mx:Label fontSize="24" text="Two"/>
        </s:Panel>

        <s:Panel id="p3" title="Three"
                x="110" y="0"
                x.One="0" y.One="110"
                x.Two="0" y.Two="110"
                width="200" height="210"
                width.One="100" height.One="100"
                width.Two="100" height.Two="100"
                click="currentState='default'">
            <mx:Label fontSize="24" text="Three"/>
        </s:Panel>
    </s:Group>
</s:Application>
```

Interrupting and reversing a transition

Flex does not support the playing of multiple transitions simultaneously. If a transition is currently playing when a new transition occurs, by default the currently playing transition stops by calling the `end()` method on all effects in the transition.

For example, a transition is playing between view states A and B. While it is playing, a transition is triggered because of a change from view state B to view state C. The `end()` method causes the current transition, from view state A to B, to snap to the B view state. The new transition, from view state B to C, then starts playing.

Use the `Transition.interruptionBehavior` property of the new transition to control the behavior of the current transition. By default, the `interruptionBehavior` property is set to `end` to specify that the current transition snaps to its end view state. Set the `interruptionBehavior` property of the new transition to `stop` to halt that current transition instead. The new transition then plays from the halt location in the current transition, rather than having the current transition snap to its end view state. The value of `stop` can smooth out the appearance of an interrupted transition. That is because the user does not see the current transition snap to its end state before the new transition begins.

In some cases, the new transition is the reverse of the current transition. For example, a transition is playing between view states A and B. While it is playing, a transition is triggered to change back from view state B to A.

When your application requires a reverse transition, you can either:

- Defines two transitions. Define one transition for the change from view state A to view state B, and one for the change from B to A. Use the `toState` and `fromState` properties of the Transition class to specify the view states for the two transitions, as shown below:

```
<s:transitions>
    <s:Transition id="fromAtoB" fromState="A" toState="B">
        ...
    </s:Transition>

    <s:Transition id="fromBtoA" fromState="B" toState="A">
        ...
    </s:Transition>
</s:transitions>
```

The `interruptionBehavior` property controls the behavior of the current transition when the reverse transition starts playing.

- Define a single transition. Set the `autoReverse` property of the Transition class to `true` to specify that this transition applies to both the forward and reverse view state changes. Therefore, use this transition on a change from view state A to view state B, and on the change from B to A.

```
<s:transitions>
    <s:Transition id="fromAtoBtoA" fromState="A" toState="B" autoReverse="true">
        ...
</s:transitions>
```

***Note:** If a transition uses the `toState` and `fromState` properties to explicitly handle the transition from view state B to A, then Flex ignores the `autoReverse` property.*

While the transition from view state A to view state B is playing, the reverse transition can occur to interrupt the current transition. The reverse transition always halts the current transition at its current location. That is, the reverse transition always plays as if the `interruptionBehavior` property was set to `stop`, regardless of the real value of `interruptionBehavior`.

Handling events when using transitions

You can handle view state events, such as currentStateChange and currentStateChanging, as part of an application that defines transitions. Changes to the view state, dispatching events, and playing transition effects occur in the following order:

1 You set the `currentState` property to the destination view state.

2 Flex dispatches the `currentStateChanging` event.

3 Flex examines the list of transitions to determine the one that matches the change of the view state.

4 Flex examines the components to determine the start values of any effects.

5 Flex applies the destination view state to the application.

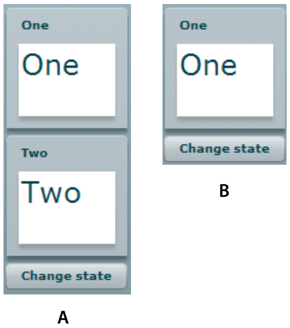
6 Flex dispatches the `currentStateChange` event.

7 Flex plays the effects that you defined in the transition.

If you change state again while a transition plays, Flex jumps to the end of the transition before starting any transition associated with the new change of view state.

Using action effects in a transition

In the following example, you define an application that has two view states:



A. *Default view state* ***B.*** *OneOnly view state*

To move from the default view state to the OneOnly view state, you create the following view state definition:

```
<s:states>
    <s:State name="default"/>
    <s:State name="OneOnly"/>
</s:states>
```

To move from the default view state to the OneOnly view state, you set the value of the `visible` and `includeInLayout` properties to `false` so that Flex makes the second Panel container invisible and ignores it when laying out the application. If the `visible` property is `false`, and the `includeInLayout` property is `true`, the container is invisible, but Flex lays out the application as if the component were visible.

A view state defines how to change states, and the transition defines the order in which the visual changes occur. In the example shown in the previous image, you play an Wipe effect on the second panel when it disappears, and when it reappears on a transition back to the base state.

For the change from the base state to the OneOnly state, you define the toOneOnly transition which uses the Wipe effect to make the second panel disappear, and then sets the panel's `visible` and `includeInLayout` properties to `false`. For a transition back to the base state, you define the toAnyFromAny transition that makes the second panel visible by setting its `visible` and `includeInLayout` properties to `true`, and then uses the Wipe effect to make the panel appear, as the following example shows:

```
<s:transitions>
    <s:Transition id="toOneOnly" fromState="*" toState="OneOnly">
        <s:Sequence id="t1" targets="{[p2]}">
            <s:Wipe direction="left" duration="350"/>
            <s:SetAction property="visible"/>
            <s:SetAction target="{p2}" property="includeInLayout"/>
        </Sequence>
    </s:Transition>

    <s:Transition id="toAnyFromAny" fromState="*" toState="*">
        <s:Sequence id="t2" targets="{[p2]}">
            <s:SetAction target="{p2}" property="includeInLayout"/>
            <s:SetAction property="visible"/>
            <s:Wipe direction="left" duration="350"/>
        </s:Sequence>
    </s:Transition>
</s:transitions>
```

In the toOneOnly transition, if you hide the target by setting its `visible` property to `false`, and then play the Iris effect, you would not see the Iris effect play because the target is already invisible.

To control the order of view state changes during a transition, Flex defines several *actioneffects*. The previous example uses the Spark SetAction action effect to control when to set the `visible` and `includeInLayout` properties in the transition. The following table describes the action effects:

Spark action effect	MX action effect	Corresponding view state class	Use
SetAction	SetPropertyAction	SetProperty	Sets a property value as part of a transition.
SetAction	SetStyleAction	SetStyle	Sets a style to a value as part of a transition.
AddAction	AddChildAction	AddChild	Adds a child as part of a transition.
RemoveAction	RemoveChildAction	RemoveChild	Removes a child as part of a transition.

Adobe recommends that you use the Spark action effects instead of the MX action effects.

To control when a change defined by the view state property occurs in a transition, you use the corresponding action effect. The action effects give you control over the order of the state change.

In the previous example, you used the following statement to define an action effect to occur when the value of the `visible` property of a component changes:

```
<s:SetAction property="visible"/>
```

This action effect plays when the value of the `visible` property changes to either `true` or `false`. You can further control the effect using the `value` property of the `<s:SetAction>` tag, as the following example shows:

```
<s:SetAction property="visible" value="true"/>
```

In this example, you specify to play the effect only when the value of the `visible` property changes to `true`. Adding this type of information to the action effect can be useful if you want to use filters with your transitions. For more information, see “Filtering effects” on page 1882.

The action effects do not support a `duration` property; they only perform the specified action.

Example: Using action effects

The following example shows the complete code for the example in “Using action effects in a transition” on page 1879:

```
<?xml version="1.0" ?>
<!-- transitions\ActionTransitions.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <!-- Define one view state, in addition to the base state.-->
    <s:states>
        <s:State name="default"/>
        <s:State name="OneOnly"/>
    </s:states>
    <!-- Define Transition array with one Transition object.-->
    <s:transitions>
        <s:Transition id="toOneOnly" fromState="*" toState="OneOnly">
            <s:Sequence id="t1" targets="{[p2]}">
                <s:Wipe direction="left" duration="350"/>
                <s:SetAction property="visible"/>
                <s:SetAction property="includeInLayout"/>
            </s:Sequence>
        </s:Transition>

        <s:Transition id="toAnyFromAny" fromState="*" toState="*">
            <s:Sequence id="t2" targets="{[p2]}">
                <s:SetAction property="includeInLayout"/>
                <s:SetAction property="visible"/>
                <s:Wipe direction="right" duration="350"/>
            </s:Sequence>
        </s:Transition>
    </s:transitions>
    <s:Panel id="p1" title="One"
        width="100" height="100">
        <s:Label fontSize="24" text="One"/>
    </s:Panel>

    <s:Panel id="p2" title="Two"
        width="100" height="100"
        visible="true" visible.OneOnly="false"
        includeInLayout="true" includeInLayout.OneOnly="false">
        <s:Label fontSize="24" text="Two"/>
    </s:Panel>

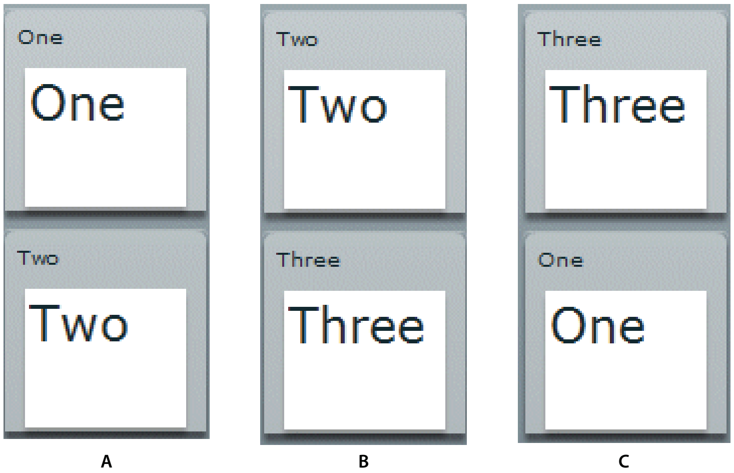
    <s:Button id="b1" label="Change state"
        click="currentState = currentState == 'OneOnly' ? '' : 'OneOnly';"/>
</s:Application>
```

Filtering effects

By default, Flex applies all of the effects defined in a transition to all of the target components of the transition. Therefore, in the following example, Flex applies the Move and Resize effects to all three targets:

```
<s:Transition fromState="*" toState="*">
    <!-- Define a Parallel effect as the top most effect.-->
    <s:Parallel id="t1" targets="{[p1,p2,p3]}">
        <!-- Define a Move and Resize effect.-->
        <s:Move duration="400"/>
        <s:Resize duration="400"/>
    </s:Parallel>
</s:Transition>
```

However, you might want to conditionalize an effect so that it does not apply to all target components, but only to a subset of the components. For example, you define an application with three view states, as the following image shows:



A. *Default view state* ***B.*** *Two view state* ***C.*** *Three view state*

Each change of view state removes the top panel, moves the bottom panel to the top, and adds the next panel to the bottom of the screen. In this example, the third panel is invisible in the default view state.

For this example, you define a single transition that applies a Wipe effect to the top panel as it is removed, applies a Move effect to the bottom panel as it moves to the top position, and applies another Wipe effect to the panel being added to the bottom, as the following example shows:

```
<s:transitions>
    <s:Transition fromState="*" toState="*">
        <s:Sequence targets="{[p1,p2,p3]}">
            <s:Sequence id="sequence1" filter="hide">
                <s:Wipe direction="up"/>
                <s:SetPropertyAction name="visible" value="false"/>
            </s:Sequence>
            <s:Move filter="move"/>
            <s:Sequence id="sequence2" filter="show">
                <s:SetAction property="visible" value="true"/>
                <s:Wipe direction="up"/>
            </s:Sequence>
        </s:Sequence>
    </s:Transition>
</s:transitions>
```

The sequence1 Sequence effect uses the `filter` property to specify the change that a component must go through in order for the effect to play on it. In this example, the sequence1 effect specifies a value of `"hide"` for the `filter` property. Therefore, the Wipe and SetAction effects only play on those components that change from visible to invisible by setting their `visible` property to `false`.

In the sequence2 Sequence effect, you set the `filter` property to `show`. Therefore, the Wipe and SetAction effects only play on those components whose state changes from invisible to visible by setting their `visible` property to `true`.

The Move effect also specifies a `filter` property with a value of `move`. Therefore, it applies to all target components that are changing position.

The following table describes the possible values of the `filter` property:

Value	Description
`add`	Specifies to play the effect on all children added during the change of view state.
`hide`	Specifies to play the effect on all children whose `visible` property changes from `true` to `false` during the change of view state.
`move`	Specifies to play the effect on all children whose `x` or `y` properties change during the change of view state.
`remove`	Specifies to play the effect on all children removed during the change of view state.
`resize`	Specifies to play the effect on all children whose `width` or `height` properties change during the change of view state.
`show`	Specifies to play the effect on all children whose `visible` property changes from `false` to `true` during the change of view state.

Example: Using a filter

The following example shows the complete code for the example in “Filtering effects” on page 1882:

```
<?xml version="1.0" ?>

```

Defining a custom filter

Flex lets you use the EffectTargetFilter class to define a custom filter that is executed by each transition effect on each target of the effect. By defining a custom filter, you can specify your own logic for controlling a transition. The following table describes the properties of the EffectTargetFilter class:

Property	Description
`filterProperties`	An Array of Strings specifying component properties. If any of the properties in the Array have changed on the target component, play the effect on the target.
`filterStyles`	An Array of Strings specifying style properties. If any of the style properties in the Array have changed on the target component, play the effect on the target.
`filterFunction`	A property containing a reference to a callback function that defines custom filter logic. Flex calls this method on every target of the effect. If the function returns `true`, the effect plays on the target; if it returns `false`, the target is skipped by that effect.
`requiredSemantics`	A collection of properties and associated values which must be associated with a target for the effect to be played.

The callback function specified by the `filterFunction` property has the following signature:

```
filterFunc(propChanges:Array, instanceTarget:Object):Boolean {
    // Return true to play the effect on instanceTarget,
    // or false to not play the effect.
}
```

The function takes the following arguments:

propChanges An Array of PropertyChanges objects, one object per target component of the effect. If a property of a target is not modified by the transition, it is not included in this Array.

instanceTarget The specific target component of the effect that you filter.

For an example using a custom filter function, see “Example: Using a custom effect filter” on page 1889.

The following example defines a custom filter that specifies to play the effect only on a target component whose `x` or `width` property is modified as part of the change of view state:

```
<?xml version="1.0" ?>
<!-- transitions\EffectFilterExampleMXML.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    width="700">

    <!-- Define the two view states, in addition to the base state.-->
    <s:states>
        <s:State name="default"/>
        <s:State name="One"/>
        <s:State name="Two"/>
    </s:states>

    <s:transitions>
        <s:Transition fromState="*" toState="*">
            <s:Sequence id="t1" targets="{[p1,p2,p3]}">
                <mx:Blur id="myBlur" duration="100" blurXFrom="0.0"
                    blurXTo="10.0" blurYFrom="0.0" blurYTo="10.0">
                    <!-- Define the custom filter. -->
                    <mx:customFilter>
                        <mx:EffectTargetFilter
                            filterProperties="['width','x']"/>
                    </mx:customFilter>
                </mx:Blur>
                <s:Parallel>
                    <s:Move  duration="400"/>
                    <s:Resize duration="400"/>
                </s:Parallel>
                <mx:Blur id="myUnBlur" duration="100" blurXFrom="10.0"
                    blurXTo="0.0" blurYFrom="10.0" blurYTo="0.0">
                    <!-- Define the custom filter. -->
                    <mx:customFilter>
                        <mx:EffectTargetFilter
                            filterProperties="['width','x']"/>
                    </mx:customFilter>
                </mx:Blur>
            </s:Sequence>
        </s:Transition>
    </s:transitions>

    <!-- Define the container holding the three Panel containers.-->
    <s:Group id="pm" width="100%" height="100%">
        <s:Panel id="p1" title="One"
                x="0" y="0"
                x.One="110" y.One="0"
                x.Two="0" y.Two="0"
                width="100" height="100"
                width.One="200" height.One="210"
                width.Two="100" height.Two="100"
                click="currentState='One'">
            <s:Label fontSize="24" text="One"/>
        </s:Panel>

        <s:Panel id="p2" title="Two"
                x="0" y="110"
                x.One="0" y.One="0"
                x.Two="110" y.Two="0"
                width="100" height="100"
                width.One="100" height.One="100"
                width.Two="200" height.Two="210"
                click="currentState='Two'">
            <s:Label fontSize="24" text="Two"/>
        </s:Panel>

        <s:Panel id="p3" title="Three"
                x="110" y="0"
                x.One="0" y.One="110"
                x.Two="0" y.Two="110"
                width="200" height="210"
                width.One="100" height.One="100"
                width.Two="100" height.Two="100"
                click="currentState='default'">
            <s:Label fontSize="24" text="Three"/>
        </s:Panel>
    </s:Group>
</s:Application>
```

Writing a filter function

To create a filter function, you define an EffectTargetFilter object, and then specify that object as the value of the `Effect.customFilter` property for an effect. The following example uses the `creationComplete` event of an application to initialize an EffectTargetFilter object, and then specify it as the value of the `customFilter` property for two Blur effects:

```
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initFilter(event);" width="700">

    <fx:Script>
        <![CDATA[

            import mx.effects.EffectTargetFilter;
            import flash.events.Event;

            // This function returns true for the Panel moving to x=110.
            public function filterFunc(propChanges:Array,instanceTarget:Object):Boolean
            {
                ...
            }

            // Define the EffectTargetFilter object.
            private var myBlurFilter:EffectTargetFilter;

            // Initialize the EffectTargetFilter object, and set the
            // customFilter property for two Blur effects.
            private function initFilter(event:Event):void {
                myBlurFilter = new EffectTargetFilter();

                myBlurFilter.filterFunction=filterFunc;

                myBlur.customFilter=myBlurFilter;
                myUnBlur.customFilter=myBlurFilter;
            }

        ]]>
    </Script>

    <s:transitions>
        <s:Transition fromState="*" toState="*">
            <s:Sequence id="t1" targets="{[p1,p2,p3]}">
                <mx:Blur id="myBlur"/>
                    <s:Parallel>
                        <s:Move duration="400"/>
                        <s:Resize duration="400"/>
                    </Parallel>
                <mx:Blur id="myUnBlur"/>
            </s:Sequence>
        </s:Transition>
    </s:transitions>

    ...

</s:Application>
```

The `propChanges` argument passed to the filter function contains an Array of PropertyChanges objects, one object per target component of the effect. The following table describes the properties of the PropertyChanges class:

Property	Description
`target`	A target component of the effect. The `end` and `start` properties of the PropertyChanges class define how the target component is modified by the change to the view state.
`start`	An Object that contains the starting properties of the `target` component, as defined by the current view state. For example, for a `target` component that is both moved and resized by a change to the view state, the `start` property contains the starting position and size of the component, as the following example shows: `{x:00, y:00, width:100, height:100}`
`end`	An Object that contains the ending properties of the `target` component, as defined by the destination view state. For example, for a `target` component that is both moved and resized by a change to the view state, the `end` property contains the ending position and size of the component, as the following example shows: `{x:100, y:100, width:200, height:200}`

Within the custom filter function, you first search the `propChanges` Array for the PropertyChanges object that matches the `instanceTarget` argument by comparing the `instanceTarget` argument to the `propChanges.target` property.

The following filter function examines the `propChanges` Array to determine if it should play the effect on the `instanceTarget`. In this example, the filter function returns `true` only for those components being moved to a position where the `translationX` property equals 110, as the following example shows:

```
// This function returns true for a target moving to x=110.
public function filterFunc(propChanges:Array, instanceTarget:Object):Boolean {

    // Determine the length of the propChanges Array.
    for (var i:uint=0; i < propChanges.length; i++)
    {
        // Determine the Array element that matches the effect target.
        if (propChanges[i].target == instanceTarget)
        {
            // Check to see if the end Object contains a value for x.
            if (propChanges[i].end["translationX"] != undefined)
            {
                // Return true of the end value for x is 110.
                return (propChanges[i].end.translationX == 110);
            }
        }
    }
    // Otherwise, return false.
    return false;
}
```

Example: Using a custom effect filter

In the following example, you use a custom filter function to apply Blur effects to one of the three targets of a transition. The other two targets are not modified by the Blur effects.

To determine the target of the Blur effects, the custom filter function examines the `translationX` property of each target. The Blur effects play only on the component moving to x=110, as the following example shows:

```
<?xml version="1.0" ?>
<!-- transitions\EffectFilterExample.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initFilter(event);"
    width="700">

    <fx:Script>
        <![CDATA[
            import mx.effects.EffectTargetFilter;
            import flash.events.Event;
            // This function returns true for the Panel moving to x=110.
            public function filterFunc(propChanges:Array,
                    instanceTarget:Object):Boolean {
                // Determine the length of the propChanges Array.
                for (var i:uint=0; i < propChanges.length; i++)
                {
                    // Determine the Array element
                    // that matches the effect target.
                    if (propChanges[i].target == instanceTarget)
                    {
                        // Check whether the end Object contains
                        // a value for x.
                        if (propChanges[i].end["translationX"] != undefined)
                        {
                            // Return true if the end value for x is 110.
                            return (propChanges[i].end.translationX == 110);
                        }
                    }
                }
                return false;
            }
            // Define the EffectTargetFilter object.
            private var myBlurFilter:EffectTargetFilter;
            // Initialize the EffectTargetFilter object, and set the
            // customFilter property for two Blur effects.
            private function initFilter(event:Event):void {
                myBlurFilter = new EffectTargetFilter();
                myBlurFilter.filterFunction=filterFunc;
                myBlur.customFilter=myBlurFilter;
                myUnBlur.customFilter=myBlurFilter;
            }
          ]]>
    </fx:Script>
    <!-- Define the two view states, in addition to the base state.-->

                width.Two="100" height.Two="100"
                click="currentState='default'">
            <s:Label fontSize="24" text="Three"/>
        </s:Panel>
    </s:Group>
</s:Application>
```

Using the requiredSemantics property

When working with data effects, you can use the `EffectTargetFiler.requiredSemantics` property to filter effects. If you want to play a data effect on all targets of a list control that are not added by the effect, meaning targets that are removed, replaced, moved, or affected in any other way, you can write the effect definition as shown below:

```
<mx:Blur>
    <mx:customFilter>
        <mx:EffectTargetFilter requiredSemantics="{{'added':false}}"/>
    </mx:customFilter>
</mx:Blur>
```

To play a data effect on all targets that are not added or not removed by the effect, you can write the effect definition as shown below:

```
<mx:Blur>
    <mx:customFilter>
        <mx:EffectTargetFilter requiredSemantics="{{'added':false}, {'removed':false}}"/>
    </mx:customFilter>
</mx:Blur>
```

The allowed list of properties that you can specify includes `added`, `removed`, `replaced`, and `replacement`. The allowed values for the properties are `true` and `false`.

For more information on data effects, see “Using MX data effects” on page 1839.

Transition tips and troubleshooting

Tips

Determine the type of transition you are defining:

- With *dynamic* transitions, you know what effects you want to play, but not which targets they will play on.
- With *explicit* transitions, you know exactly what happens to each individual target.

Complex transitions may consist of both dynamic and explicit elements.

Tips for dynamic transitions:

- List all possible targets in the parent composite effect.
- By default, all effects play on all specified targets. Use filtering with dynamic transitions to limit the target set.
- Dynamic transitions can be used with a wide variety of state changes.

Tips for explicit transitions:

- Specify targets on the child effects, or on a composite effect when all child effects of the composite effect have the same targets.
- By default, all effects play on all specified targets. For explicit transitions, make sure the targets are correctly set.
- Explicit transitions typically require a different transition for each change to the view state.

Troubleshooting

Troubleshooting a transition effect that does not play:

- Is the effect target being hidden or removed? If so, make sure you add an `<RemoveChild>` property to the view state definition, or an `<s:SetPropertyAction name="visible">` tag in the transition definition.
- Does the change to the view state define settings that pertain to the transition effect? For example, if you have a Resize effect, you must change the `width` or `height` property of the target when the view state changes to trigger the effect.
- Check that you specified the correct targets to the transition.
- Check that your filter settings on the effect and on any parent effect are not excluding the target.

Troubleshooting an effect playing on too many targets:

- Add a filter for a dynamic transition, or change the targets for an explicit transition.

Troubleshooting wrong effect parameters:

- Did you specify explicit parameters on the effect? Are they correct?
- Ensure that you correctly set the `showTarget` property for mask effects such as the Iris effect, and the wipe effects.

Troubleshooting a flickering or flashing target:

- Ensure that you correctly set the `showTarget` property for mask effects such as the Iris effect, and the wipe effects.
- Is the effect target being hidden or removed? If so, make sure you add an `<RemoveChild>` property to the view state definition to remove the target, or an `<SetPropertyAction name="visible">` tag in the transition definition to hide the target.

Troubleshooting when an application does not look correct after a transition:

- Some effects leave the target with changed properties. For example, a Fade effect leaves the `alpha` property of the target at the `alphaTo` value specified to the effect. If you use the Fade effect on a target that sets `alpha` property to zero, you must set the `alpha` property to a nonzero value before the object appears again.
- Try removing one effect at a time from the transition until it no longer leaves your application with the incorrect appearance.

Drag and drop

The drag-and-drop operation lets you move data from one place in an application to another. It is especially useful in a visual application where you can drag data between two lists, drag controls in a container to reposition them, or drag Flex components between containers.

About drag and drop

Visual development environments typically let you manipulate objects in an application by selecting them with a mouse and moving them around the screen. Drag and drop lets you select an object, such as an item in a List control, or a Flex control such as an Image control, and then drag it over another component to add it to that component.

You can add support for drag and drop to all Flex components. Flex also includes built-in support for the drag-and-drop operation for certain controls such as the MX List, Tree, and DataGrid controls and the Spark List control, that automate much of the processing required to support drag and drop.

About the drag-and-drop operation

The drag-and-drop operation has three main stages: initiation, dragging, and dropping:

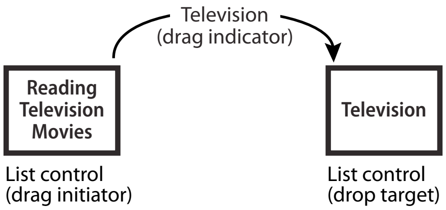
Initiation User initiates a drag-and-drop operation by using the mouse to select a Flex component, or an item in a Flex component, and then moving the component or item while holding down the mouse button. For example, a user selects an item in a List control with the mouse and, while holding down the mouse button, moves the mouse several pixels. The selected component, the List control in this example, is the *drag initiator*.

Dragging While still holding down the mouse button, the user moves the mouse around the application. Flex displays an image during the drag, called the *drag indicator*. A *drag source* object (an object of type DragSource) contains the data being dragged.

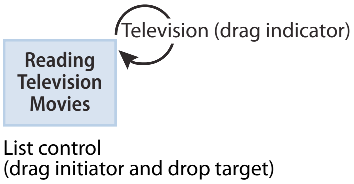
Dropping When the user moves the drag indicator over another Flex component, that component becomes a possible *drop target*. The drop target inspects the drag source object to determine whether the data is in a format that the target accepts and, if so, allows the user to drop the data onto it. If the drop target determines that the data is not in an acceptable format, the drop target disallows the drop.

A drag-and-drop operation either copies or moves data from the drag initiator to the drop target. Upon a successful drop, Flex adds the data to the drop target and, optionally, deletes it from the drag initiator in the case of a move.

The following figure shows one List control functioning as the drag initiator and a second List control functioning as the drop target. In this example, you use drag and drop to move the ’Television’ list item from the drag initiator to the drop target:



A single component can function as both the drag initiator and the drop target. This lets you move the data within the component. The following example shows a List control functioning as both the drag initiator and the drop target:



By specifying the List control as both the drag initiator and the drop target, you can use drag and drop to rearrange the items in the control. For example, if you use a Canvas container as the drag initiator and the drop target, you can then use drag and drop to move controls in the Canvas container to rearrange them.

Performing a drag and drop

Drag and drop is event driven. To configure a component as a drag initiator or as a drop target, you have to write event handlers for specific events, such as the `dragDrop` and `dragEnter` events. For more information, see "Manually adding drag-and-drop support" on page 1902.

For some components that you often use with drag and drop, Flex provides built-in event handlers to automate much of the drag and drop operation. These controls are all subclasses of the MX mx.controls.listClasses.ListBase class and the Spark spark.components.supportClasses.ListBase class, and are referred to as list-based controls. For more information, see "Using drag-and-drop with list-based controls" on page 1894.

For a move or copy operation, the list-based controls can handle all of the events required by a drag-and-drop operation. However, if you want to copy the drag data to the drop target, and the drop target uses a different data format, you have to write an event handler. For more information, see "Moving and copying data" on page 1927.

Using drag-and-drop with list-based controls

The following MX list-based controls include built-in support for the drag-and-drop operation:

- DataGrid
- HorizontalList
- List
- PrintDataGrid
- TileList
- Tree

The Spark List control include built-in support for the drag-and-drop operation.

The built-in support for these controls lets you move and copy items by dragging them from a drag-enabled control to a drop-enabled control.

The following drag-and-drop example lets you move items from one Spark List control to another:

```
<?xml version="1.0"?>
<!-- dragdrop\SimpleListToListMove.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    creationComplete="initApp();">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;
            private function initApp():void {
                srclist.dataProvider =
                    new ArrayCollection(['Reading', 'Television', 'Movies']);
                destlist.dataProvider = new ArrayCollection([]);
            }
        ]]>
    </fx:Script>
    <s:HGroup>
        <s:VGroup>
            <s:Label text="Available Activities"/>
            <s:List id="srclist"
                allowMultipleSelection="true"
                dragEnabled="true"
                dragMoveEnabled="true"/>
        </s:VGroup>
        <s:VGroup>
            <s:Label text="Activities I Like"/>
            <s:List id="destlist"
                dropEnabled="true"/>
        </s:VGroup>
    </s:HGroup>
    <s:Button id="b1"
        label="Reset"
        click="initApp();"/>
</s:Application>
```

By setting the `dragEnabled` property to `true` on the first List and the `dropEnabled` property to `true` on the second List control, you enabled users to drag items from the first list to the second without worrying about any of the underlying event processing.

For all list-based classes except the Tree control, the default value of the `dragMoveEnabled` property is `false`, so you can only copy elements from one control to the other. By setting the `dragMoveEnabled` to `true` in the first List control, you can move and copy data. For the Tree control, the default value of the `dragMoveEnabled` property is `true`.

When the `dragMoveEnabled` property is set to `true`, the default drag-and-drop action is to move the drag data. To perform a copy, hold down the Control key during the drag-and-drop operation.

The only requirement on the drag and drop operation is that the structure of the data providers must match for the two controls. In this example, the data provider for srclist is an Array of Strings, and the data provider for the destination List control is an empty Array. If the data provider for destlist is an Array of some other type of data, destlist might not display the dragged data correctly.

You can modify the dragged data as part of a drag-and-drop operation to make the dragged data compatible with the destination. For an example of dragging data from one control to another when the data formats do not match, see "Example: Copying data from an MX List control to an MX DataGrid control" on page 1928.

You can allow two-way drag and drop by setting the `dragEnabled`, `dropEnabled`, and `dragMoveEnabled` properties to `true` for both list-based controls, as the following example shows for two MX DataGrid controls. In this example, you can drag and drop rows from either MX DataGrid control to the other:

```
<?xml version="1.0"?>
<!-- dragdrop\SimpleDGToDG.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    width="650"
    creationComplete="initApp();">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
      <![CDATA[
          import mx.collections.ArrayCollection;

          private function initApp():void {
            srcgrid.dataProvider = new ArrayCollection([
              {Artist:'Carole King', Album:'Tapestry', Price:11.99},
              {Artist:'Paul Simon', Album:'Graceland', Price:10.99},
              {Artist:'Original Cast', Album:'Camelot', Price:12.99},
              {Artist:'The Beatles', Album:'The White Album', Price:11.99}
            ]);
            destgrid.dataProvider = new ArrayCollection([]);
          }
      ]]>
    </fx:Script>
    <s:HGroup>
        <s:VGroup>
            <s:Label text="Available Albums"/>
            <mx:DataGrid id="srcgrid"
                allowMultipleSelection="true"
                dragEnabled="true"
                dropEnabled="true"
                dragMoveEnabled="true">
                <mx:columns>
                    <mx:DataGridColumn dataField="Artist"/>
                    <mx:DataGridColumn dataField="Album"/>
                    <mx:DataGridColumn dataField="Price"/>
                </mx:columns>
            </mx:DataGrid>
        </s:VGroup>
        <s:VGroup>
            <s:Label text="Buy These Albums"/>
            <mx:DataGrid id="destgrid"
                allowMultipleSelection="true"
                dragEnabled="true"
                dropEnabled="true"
                dragMoveEnabled="true">
                <mx:columns>
                    <mx:DataGridColumn dataField="Artist"/>
                    <mx:DataGridColumn dataField="Album"/>
                    <mx:DataGridColumn dataField="Price"/>
                </mx:columns>
            </mx:DataGrid>
        </s:VGroup>
    </s:HGroup>
    <s:Button id="b1"
        label="Reset"
        click="initApp()"
    />
</s:Application>
```

Dragging and dropping between different list-based controls

You can drag and drop data between different types of list-based controls. For example, you can drag and drop between an MX List and a Spark List control, as the following example shows:

```
<?xml version="1.0"?>
<!-- dragdrop\SimpleListToListMoveSpark.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    creationComplete="initApp();">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayList;
            private function initApp():void {
                srclist.dataProvider =
                    new ArrayList(['Reading', 'Television', 'Movies']);
                destlist.dataProvider = new ArrayList([]);
            }
        ]]>
    </fx:Script>
    <s:HGroup>
        <s:VGroup>
            <s:Label text="Available Activities"/>
            <s:List id="srclist"
                allowMultipleSelection="true"
                dragEnabled="true"
                dragMoveEnabled="true"/>
        </s:VGroup>
        <s:VGroup>
            <s:Label text="Activities I Like"/>
            <mx:List id="destlist"
                dropEnabled="true"/>
        </s:VGroup>
    </s:HGroup>
    <s:Button id="b1"
        label="Reset"
        click="initApp();"/>
</s:Application>
```

Dragging and dropping between two types of List controls is relatively simple because the control use the same data format. However, when you drag and drop between a List and a DataGrid, or a List and a Tree, the data formats might not match. In that case, you have to manipulate the data before dropping it onto the target. see “Example: Copying data from an MX List control to an MX DataGrid control” on page 1928.

Dragging and dropping in the same control

One use of drag and drop is to let you reorganize the items in a list-based control by dragging the items and then dropping them in the same control. In the next example, you define an MX Tree control, and let the user reorganize the nodes of the Tree control by dragging and dropping them. In this example, you set the `dragEnabled` and `dropEnabled` to `true` for the Tree control (the `dragMoveEnabled` property defaults to `true` for the Tree control):

```
<?xml version="1.0"?>
<!-- dragdrop\SimpleTreeSelf.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
            // Initialize the data provider for the Tree.
            private function initApp():void {
                firstList.dataProvider = treeDP;
            }
        ]]>
    </fx:Script>

    <fx:Declarations>
        <fx:XML id="treeDP">
            <node label="Mail">
                <node label="Inbox"/>
                <node label="Personal Folder">
                    <node label="Demo"/>
                    <node label="Personal"/>
                    <node label="Saved Mail"/>
                    <node label="bar"/>
                </node>
                <node label="Calendar"/>
                <node label="Sent"/>
                <node label="Trash"/>
            </node>
        </fx:XML>
    </fx:Declarations>
    <mx:Tree id="firstList"
        showRoot="false"
        labelField="@label"
        dragEnabled="true"
        dropEnabled="true"
        allowMultipleSelection="true"
        creationComplete="initApp();"/>
</s:Application>
```

Drag and drop properties for list-based controls

List-based controls provide properties and methods for managing the drag-and-drop operation. The following table lists these properties and methods:

Property/Method	Description
`dragEnabled`	A Boolean value that specifies whether the control is a drag initiator. The default value is `false`. When `true`, users can drag selected items from the control. When a user drags items from the control, Flex creates a DragSource object that contains the following data objects: • The drag data as a Vector of type Object. Each element of the Vector corresponds to a dragged item from the data provider of the drag initiator. If you drag a single item, the Vector has a length of 1. For all controls except for Tree, the format string of the drag data is `"itemsByIndex"`, and the items implement the IDataProvider interface. • For Tree controls the drag data is an Array. The format string of the drag data is "`treeItems`" and the items implement the ITreeDataProvider API interface. • The index of the item that was clicked by the mouse. The format string of the index is “`caretIndex`”. The index is relative to the items in the drag data. Therefore, if the drag data contains three items, the index is a value between 0 and 2. By default, only the Spark list-based controls working as a drop target use this information to update the selected item on the drop. • A reference to the drag initiator, with a format String of `"source"` .
`dropEnabled`	A Boolean value that specifies whether the control can be a drop target. The default value is `false`, which means that you must write event handlers for the drag events. When the value is `true`, you can drop items onto the control by using the default drop behavior.
`dragMoveEnabled`	If the value is `true`, and the `dragEnabled` property is `true`, specifies that you can move or copy items from the drag initiator to the drop target. When you move an item, the item is deleted from the drag initiator when you add it to the drop target. If the value is `false`, you can only copy an item to the drop target. For a copy, the item in the drag initiator is not affected by the drop. When the `dragMoveEnabled` property is `true`, you must hold down the Control key during the drop operation to perform a copy. The default value is `false` for all list controls except the Tree control, and `true` for the Tree control.

Maintaining type information during a copy

When you use the built-in support of the list-based controls to copy data from one list-based control to another list-based control, you might run into an occasion where you lose the data-type information of the copied data. The loss of data-type information can occur when:

- You perform a copy operation between two list-based controls; it does not occur during a move operation
- The data type of the copied item is not a basic ActionScript data type, such as Date, Number, Object, or String
- The data type of the copied item is not DisplayObject, or a subclass of DisplayObject

For example, you define the following class, Car.as, that you use to populate the data provider of a List control:

```
package
{
    // dragdrop/Car.as

    [RemoteClass]
    public class Car extends Object
    {
        // Constructor.
        public function Car()
        {
            super();
        }

        // Class properties.
        public var numWheels:int;
        public var model:String;
        public var make:String;

        public function get label():String
        {
            return make + " " + model;
        }
    }
}
```

Notice that the Car.as file includes the `[RemoteClass]` metadata tag. This metadata tag is required to register the Car data type with Flex so that its type information is preserved during the copy operation. If you omit the `[RemoteClass]` metadata tag, type information is lost.

You then use that class in your application, as the following example shows:

```
<?xml version="1.0"?>
<!-- dragdrop\DandDRemoteClassListUpdated.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns="*">
    <s:layout>
        <s:BasicLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[

            public function changeit():void
            {
                if (list2.dataProvider != null)
                {
                    msg.text += list2.dataProvider[0]

                    if(list2.dataProvider[0] is Car)
                        msg.text += " Is Car\n";
                    else
                        msg.text += " Is NOT Car\n";
                }
            }
        ]]>
    </fx:Script>
    <s:List id="list1"
        x="10" y="45"
        width="160" height="120"
        dragEnabled="true"
        dragMoveEnabled="true">
        <s:dataProvider>
            <s:ArrayCollection>
                <Car model="Camry" make="Toyota" numWheels="4"/>
                <Car model="Prius" make="Toyota" numWheels="4"/>
            </s:ArrayCollection>
       </s:dataProvider>
    </s:List>
    <s:List  id="list2"
        x="200" y="45"
        width="160" height="120"
        dropEnabled="true"/>

    <s:Button label="Access it as button" click="changeit();"/>

    <s:TextArea id="msg"
        x="10" y="200"
        width="400" height="100"/>
</s:Application>
```

Manually adding drag-and-drop support

The list-based controls have built-in support for drag and drop, but you can use drag and drop with any Flex component. To support drag-and-drop operations with components other than MX list-based controls, or to explicitly control drag and drop with MX list-based controls, you must handle the drag and drop events.

Classes used in drag-and-drop operations

You use the following classes to implement the drag-and-drop operation:

Class	Function
DragManager	Manages the drag-and-drop operations; for example, its `doDrag()` method starts the drag operation.
DragSource	Contains the data being dragged. It also provides additional drag management features, such as the ability to add a handler that is called when data is requested.
DragEvent	Represents the event object for all drag-and-drop events.

Drag-and-drop events for a drag initiator

A component that acts as a drag initiator handles the following events to manage the drag-and-drop operation:

Drag initiator event	**Description**	**Handler required**	**Implemented by list-based controls**
mouseDown and mouseMove	The mouseDown event is dispatched when the user selects a control with the mouse and holds down the mouse button. The mouseMove event is dispatched when the mouse moves. For most controls, you initiate the drag-and-drop operation in response to one of these events. For an example, see "Example: Handling the dragOver and dragExit events for the drop target" on page 1924.	Yes, for nonlist controls	No
dragStart	Dispatched by a list-based component when the user initiates a drag operation. This event is used internally by the list-based controls; you do not handle it when implementing drag and drop. If you want to control the start of a drag-and-drop operation, use the mouseDown or mouseMove event.	Yes, for list controls	Yes
dragComplete	Dispatched when a drag operation completes, either when the drag data drops onto a drop target, or when the drag-and-drop operation ends without performing a drop operation. You can use this event to perform any final cleanup of the drag-and-drop operation. For example, if a user moves data from one component to another, you can use this event to delete the item from the drag initiator. For an example, see "Example: Moving and copying data for a nonlist-based control" on page 1929.	No	Yes

When adding drag-and-drop support to a component, you must implement an event handler for either the mouseDown or mouseMove event, and optionally for the dragComplete event. When you set the dragEnabled property to true for a list-based control, Flex automatically adds event handlers for the dragStart and dragComplete events.

Note: *Do not add an event handler for the* dragStart *event. That is an internal event handled by Flex.*

Drag-and-drop events for a drop target

To use a component as a drop target, you handle the following events:

Drop target event	Description	Handler required	Implemented by list-based controls
`dragEnter`	Dispatched when a drag indicator moves over the drop target from outside the drop target. A component *must* define an event handler for this event to be a drop target. The event handler determines whether the data being dragged is in an accepted format. To accept the drop, the event handler calls the `DragManager.acceptDragDrop()` method. You must call the `DragManager.acceptDragDrop()` method for the drop target to receive the `dragOver`, `dragExit`, and `dragDrop` events. In the handler, you can change the appearance of the drop target to provide visual feedback to the user that the component can accept the drag operation. For example, you can draw a border around the drop target, or give focus to the drop target. For an example, see "Example: Simple drag-and-drop operation for a nonlist-based control" on page 1906.	Yes	Yes
`dragOver`	Dispatched while the user moves the mouse over the target, after the `dragEnter` event. You can handle this event to perform additional logic before allowing the drop operation, such as adding the data to various locations within the drop target, reading keyboard input to determine if the drag-and-drop operation is a move or copy of the drag data, or providing different types of visual feedback based on the type of drag-and-drop operation. For an example, see "Example: Handling the dragOver and dragExit events for the drop target" on page 1924.	No	Yes
`dragDrop`	Dispatched when the user releases the mouse over the drop target. Use this event handler to add the drag data to the drop target. For an example, see "Example: Simple drag-and-drop operation for a nonlist-based control" on page 1906.	Yes	Yes
`dragExit`	Dispatched when the user moves the drag indicator off of the drop target, but does not drop the data onto the target. You can use this event to restore the drop target to its normal appearance if you modified its appearance in response to a `dragEnter` event or other event. For an example, see "Example: Handling the dragOver and dragExit events for the drop target" on page 1924.	No	Yes

When adding drag-and-drop support to a nonlist-based component, you must implement an event handler for the `dragEnter` and `dragDrop` events, and optionally for the other events. When you set the `dropEnabled` property to `true` for a list-based control, Flex automatically adds event handlers for all events.

The drag-and-drop operation

The following steps define the drag-and-drop operation.

1. A component becomes a drag-and-drop initiator in either of the following ways:
   - List-based components with `dragEnabled=true`

     Flex automatically makes the component an initiator when the user clicks and moves the mouse on the component.
   - Nonlist-based components, or list-based components with `dragEnabled=false`

     The component must detect the user's attempt to start a drag operation and explicitly become an initiator. Typically, you use the `mouseMove` or `mouseDown` event to start the drag-and-drop operation.

     The component then creates an instance of the mx.core.DragSource class that contains the data to be dragged, and specifies the format for the data. The drop target can examine the format to determine if it is compatible with the drop target.

     The component then calls the `mx.managers.DragManager.doDrag()` method, to initiate the drag-and-drop operation.
2. While the mouse button is still pressed, the user moves the mouse around the application. Flex displays the drag indicator image in your application.

   ***Note:** Releasing the mouse button when the drag indicator is not over a target ends the drag-and-drop operation. Flex generates a `DragComplete` event on the drag initiator, and the `DragManager.getFeedback()` method returns `DragManager.NONE`.*
3. If the user moves the drag indicator over a Flex component, Flex dispatches a `dragEnter` event for the component.
   - List-based components with `dropEnabled=true`

     Flex checks to see if the component can be a drop target.
   - Nonlist-based components, or list-based components with `dropEnabled=false`

     The component must define an event handler for the `dragEnter` event to be a drop target.

   The `dragEnter` event handler can examine the `DragSource` object to determine whether the data being dragged is in an accepted format. To accept the drop, the event handler calls the `DragManager.acceptDragDrop()` method. You must call the `DragManager.acceptDragDrop()` method for the drop target to receive the `dragOver`, `dragExit`, and `dragDrop` events.
   - If the drop target does not accept the drop, Flex examines all DisplayObject components under the mouse. Flex examines the components in order of depth to determine if any component accepts the drop data.
   - If the drop target accepts the drop, Flex dispatches the `dragOver` event as the user moves the drag indicator over the target.
4. (Optional) The drop target can handle the `dragOver` event. For example, the drop target can use this event handler to set the focus on itself. Or, the target can display a visual indication showing where the drag data is to be inserted.
5. (Optional) If the user decides not to drop the data onto the drop target and moves the drag indicator outside of the drop target without releasing the mouse button, Flex dispatches a `dragExit` event for the drop target. The drop target can optionally handle this event; for example, to undo any actions made in the `dragOver` event handler.
6. If the user releases the mouse while over the drop target, Flex dispatches a `dragDrop` event on the drop target.
   - List-based components with `dropEnabled=true`

     Flex automatically adds the drag data to the drop target.

- Nonlist-based components, or list-based components with `dropEnabled=false`

  The drop target must define an event listener for the `dragDrop` event handler to add the drag data to the drop target.

7 (Optional) When the drop operation completes, Flex dispatches a `dragComplete` event. The drag initiator can handle this event; for example, to delete the drag data from the drag initiator in the case of a move.

- List-based components with `dragEnabled=true`

  If this is a move operation, Flex automatically removes the drag data from the drag initiator.

- Nonlist-based components, or list-based components with `dragEnabled=false`

  The drag initiator completes any final processing required. If this was a move operation, the event handler must remove the drag data from the drag initiator. For an example of writing the event handler for the `dragComplete` event, see "Example: Moving and copying data for a nonlist-based control" on page 1929.

Example: Simple drag-and-drop operation for a nonlist-based control

The following example lets you set the background color of a Canvas container by dropping either of two colors onto it. You are not copying or moving any data; instead, you are using the two drag initiators as a color palette. You then drag the color from one palette onto the drop target to set its background color.

The drag initiators, two Canvas containers, implement an event handler for the `mouseDown` event to initiate the drag and drop operation. This is the only event required to be handled by the drag initiator. The drop target is required to implement event handlers for the `dragEnter` and `dragDrop` events.

```
<?xml version="1.0"?>
<!-- dragdrop\DandDCanvas.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    backgroundColor="white">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
        import mx.core.DragSource;
        import mx.managers.DragManager;
        import mx.events.*;
        import mx.containers.Canvas;
        // Initializes the drag and drop operation.
        private function mouseMoveHandler(event:MouseEvent):void {

            // Get the drag initiator component from the event object.
            var dragInitiator:Canvas=Canvas(event.currentTarget);

            // Get the color of the drag initiator component.
            var dragColor:int = dragInitiator.getStyle('backgroundColor');
            // Create a DragSource object.
            var ds:DragSource = new DragSource();
            // Add the data to the object.
            ds.addData(dragColor, 'color');
            // Call the DragManager doDrag() method to start the drag.
            DragManager.doDrag(dragInitiator, ds, event);
        }
        // Called when the user moves the drag indicator onto the drop target.
        private function dragEnterHandler(event:DragEvent):void {
            // Accept the drag only if the user is dragging data
            // identified by the 'color' format value.
            if (event.dragSource.hasFormat('color')) {
                // Get the drop target component from the event object.
                var dropTarget:Canvas=Canvas(event.currentTarget);
                // Accept the drop.
                DragManager.acceptDragDrop(dropTarget);
            }
        }

        // Called if the target accepts the dragged object and the user
        // releases the mouse button while over the Canvas container.
        private function dragDropHandler(event:DragEvent):void {
            // Get the data identified by the color format
            // from the drag source.
            var data:Object = event.dragSource.dataForFormat('color');
            // Set the canvas color.
            myCanvas.setStyle("backgroundColor", data);
        }
        ]]>
    </fx:Script>
    <!-- A horizontal box with red and green canvases that the user can drag. -->
    <mx:HBox>
        <mx:Canvas
            width="30" height="30"
            backgroundColor="red"

        label="Clear Canvas"
        click="myCanvas.setStyle('backgroundColor', '0xFFFFFF');"/>
</s:Application>
```

The following sections describe the event handlers for the `mouseDown`, `dragEnter`, and `dragDrop` events.

Writing the mouseDown event handler

The event handler that initiates a drag-and-drop operation must do two things.

1 Create a DragSource object and initialize it with the drag data and the data format.

The DragSource object contains the drag data and a description of the drag data, called the data format. The event object for the `dragEnter` and `dragDrop` events contains a reference to this object in their `dragSource` property, which allows the event handlers to access the drag data.

You use the `DragSource.addData()` method to add the drag data and format to the DragSource object, where the `addData()` method has the following signature:

```
addData(data:Object, format:String):void
```

The `format` argument is a text string such as `"color"`, `"list data"`, or `"employee record"`. In the event handler for the `dragEnter` event, the drop target examines this string to determine whether the data format matches the type of data that the drop target accepts. If the format matches, the drop target lets users drop the data on the target; if the format does not match, the target does not enable the drop operation.

One example of using the format string is when you have multiple components in your application that function as drop targets. Each drop target examines the DragSource object during its `dragEnter` event to determine if the drop target supports that format. For more information, see "Handling the dragEnter event" on page 1908.

***Note:** List-based controls have predefined values for the `format` argument. For all list controls other than the Tree control, the format String is `"itemsByIndex"`. For the Tree control, the format String is `"treeItems"`. For previous versions of Flex, list-based controls used a format String of `"items"`. For more information, see "Using drag-and-drop with list-based controls" on page 1894.*

If you drag large or complex data items, consider creating a handler to copy the data, and specify it by calling the `DragSource.addHandler()` method instead of using the `DragSource.addData()` method. If you do this, the data does not get copied until the user drops it, which avoids the processing overhead of copying the data if a user starts dragging data but never drops it. The implementation of the list-based classes use this technique.

2 Call the `DragManager.doDrag()` method to start the drag-and-drop operation.

The `doDrag()` method has the following signature:

```
doDrag(dragInitiator:IUIComponent, dragSource:DragSource, mouseEvent:MouseEvent,
    dragImage:IFlexDisplayObject = null, xOffset:Number = 0, yOffset:Number = 0,
    imageAlpha:Number = 0.5, allowMove:Boolean = true):void
```

The `doDrag()` method requires three arguments: a reference to the component that initiates the drag operation (identified by the `event.currentTarget` object); the DragSource object that you created in step 1, and the event object passed to the event handler.

Optional arguments specify the drag indicator image and the characteristics of the image. For an example that specifies a drag indicator, see "Example: Specifying the drag indicator by using the DragManager" on page 1918.

Handling the dragEnter event

Flex generates a `dragEnter` event when the user moves the drag indicator over any component. A component *must* define a handler for a `dragEnter` event to be a drop target. The event handler typically performs the following actions:

- Use the `format` property in the DragSource object to determine whether the drag data is in a format accepted by the drop target.
- If the drag data is in a compatible format, the handler *must* call the `DragManager.acceptDragDrop()` method to enable the user to drop the data on the drop target.

- If the drag data is not in a compatible format, do not call the `DragManager.acceptDragDrop()` method. If the event handler does not call this method, the user cannot drop the data and the drop target will not receive the `dragOver`, `dragExit`, and `dragDrop` events.
- Optionally, perform any other actions necessary when the user first drags a drag indicator over a drop target.

The value of the `action` property of the event object for the `dragEnter` event is `DragManager.MOVE`, even if you are doing a copy. This is because the `dragEnter` event occurs before the drop target recognizes that the Control key is pressed to signal a copy.

The Flex default event handler for the `dragOver` event for a list-based control automatically sets the `action` property. For nonlist-based controls, or if you explicitly handle the `dragOver` event for a list-based control, use the `DragManager.showFeedback()` method to set the `action` property to a value that signifies the type of drag operation: `DragManager.COPY`, `DragManager.LINK`, `DragManager.MOVE`, or `DragManager.NONE`. For more information on the `dragOver` event, see "Example: Handling the dragOver and dragExit events for the drop target" on page 1924.

Handling the dragDrop event

The `dragDrop` event occurs when the user releases the mouse to drop data on a target, and the `dragEnter` event handler has called the `DragManager.acceptDragDrop()` method to accept the drop. You must define a handler for the event to add the drag data to the drop target.

The event handler uses the `DragSource.dataForFormat()` method to retrieve the drag data. In the previous example, the drag data contains the new background color of the drop target. The event handler then calls `setStyle()` to set the background color of the drop target.

Example: Handling drag and drop events in a list-based control

Flex automatically defines default event handlers for the drag-and-drop events when you set `dragEnabled` or `dropEnabled` property to `true` for an MX list-based control. You can either use these default event handlers, which requires you to do no additional work in your application, or define your own event handlers.

There are three common scenarios for using event handlers with the list-based controls:

Use the default event handlers When you set `dragEnabled` to `true` for a drag initiator, or when you set `dropEnabled` to `true` for a drop target, Flex handles all drag-and-drop events for you. You only have to define your own `dragDrop` event handler when you want to copy data as part of the drag-and-drop operation and the drop target uses a different data format. For more information, see "Moving and copying data" on page 1927.

Define your own event handlers If you want to control the drag-and-drop operation for a list-based control, you can explicitly handle the drag-and-drop events, just as you can for any component. In this scenario, set the `dragEnabled` property to `false` for a drag initiator, or set the `dropEnabled` property to `false` for a drop target. For more information on handling these events, see "Example: Simple drag-and-drop operation for a nonlist-based control" on page 1906.

Define your own event handlers and use the default event handlers You might want to add your own event handler for a drag-and-drop event, and also use the build in drag-and-drop handlers. In this case, your event handler executes first, then the default event handler provided by Flex executes. If, for any reason, you want to explicitly prohibit the execution of the default event handler, call the `Event.preventDefault()` method from within your event handler.

***Note:** If you call `Event.preventDefault()` in the event handler for the `dragComplete` or `dragDrop` event for a Tree control when dragging data from one Tree control to another, it prevents the drop.*

Because of the way data to a Tree control is structured, the Tree control handles drag and drop differently from the other list-based controls. For the Tree control, the event handler for the `dragDrop` event only performs an action when you move or copy data in the same Tree control, or copy data to another Tree control. If you drag data from one Tree control and drop it onto another Tree control to move the data, the event handler for the `dragComplete` event actually performs the work to add the data to the destination Tree control, rather than the event handler for the dragDrop event, and also removes the data from the source Tree control. This is necessary because to reparent the data being moved, Flex must remove it first from the source Tree control.

Therefore, if you call Event.preventDefault() in the event handler for the dragDrop or dragComplete events, you implement the drop behavior yourself. For more information, see "Example: Moving and copying data for a nonlist-based control" on page 1929.

The following example defines an event handler for the dragDrop event that accesses the data dragged from one DataGrid control to another. This event handler is executed before the default event handler for the dragDrop event to display in an Alert control the Artist field of each DataGrid row dragged from the drag initiator to the drop target:

```
<?xml version="1.0"?>
<!-- dragdrop\SimpleDGToDGAlert.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    width="650"
    creationComplete="initApp();">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import mx.events.DragEvent;
            import mx.controls.Alert;
            import mx.collections.ArrayCollection;

            private function initApp():void {
              srcgrid.dataProvider =  new ArrayCollection([
                {Artist:'Carole King', Album:'Tapestry', Price:11.99},
                {Artist:'Paul Simon', Album:'Graceland', Price:10.99},
                {Artist:'Original Cast', Album:'Camelot', Price:12.99},
                {Artist:'The Beatles', Album:'The White Album', Price:11.99}
              ]);

                destgrid.dataProvider = new ArrayCollection([]);
            }
            // Define the event listener.
            public function dragDropHandler(event:DragEvent):void {
                // dataForFormat() always returns an Vector.<Object>
                // for the list-based controls
                // in case multiple items were selected.
                var dragObj:Vector.<Object>=
                    event.dragSource.dataForFormat("itemsByIndex") as Vector.<Object>;
                // Get the Artist for all dragged albums.
                var artistList:String='';
                for (var i:Number = 0; i < dragObj.length; i++) {
                    artistList+='Artist: ' + dragObj[i].Artist + '\n';
                }

                Alert.show(artistList);
            }
        ]]>
    </fx:Script>
    <s:HGroup>
        <s:VGroup>
```

```
            <s:Label text="Available Albums"/>
            <mx:DataGrid id="srcgrid"
                allowMultipleSelection="true"
                dragEnabled="true"
                dropEnabled="true"
                dragMoveEnabled="true">
                <mx:columns>
                    <mx:DataGridColumn dataField="Artist"/>
                    <mx:DataGridColumn dataField="Album"/>
                    <mx:DataGridColumn dataField="Price"/>
                </mx:columns>
            </mx:DataGrid>
        </s:VGroup>
        <s:VGroup>
            <s:Label text="Buy These Albums"/>
            <mx:DataGrid id="destgrid"
                allowMultipleSelection="true"
                dragEnabled="true"
                dropEnabled="true"
                dragMoveEnabled="true"
                dragDrop="dragDropHandler(event);">
                <mx:columns>
                    <mx:DataGridColumn dataField="Artist"/>
                    <mx:DataGridColumn dataField="Album"/>
                    <mx:DataGridColumn dataField="Price"/>
                </mx:columns>
            </mx:DataGrid>
        </s:VGroup>
    </s:HGroup>
    <s:Button id="b1"
        label="Reset"
        click="initApp();"/>
</s:Application>
```

Notice that the `dataForFormat()` method specifies an argument value of "`itemsByIndex`". This is because the list-based controls have predefined values for the data format of drag data. For all list controls other than the Tree control, the format String is "`itemsByIndex`". For the Tree control, the format String is "`treeItems`".

For Spark controls only, the DragSource object also contains the index of the item in the drag initiator that was clicked by the mouse. The format string of the index is “`caretIndex`”. The index is relative to the items in the drag data. Therefore, if the drag data contains three items, the index is a value between 0 and 2.

Notice that the return value of the `dataForFormat()` method is a Vector of type Object. Because list-based controls let you select multiple items, the `dataForFormat()` method always returns a Vector for a list-based control, even if you are only dragging a single item.

Using drag and drop with Flex applications running in AIR

When a Flex application runs in Adobe® AIR™, you can control whether the application uses the Flex drag manager or the AIR drag manager. These drag managers are implemented by the classes mx.managers.DragManager (Flex drag manager) and flash.desktop.NativeDragManager (AIR drag manager).

Internally, the Flex mx.managers.DragManager class uses an implementation class to determine which drag manager to use. It uses either the Flex mx.managers.DragManagerImpl class, or the AIR mx.managers.NativeDragManagerImpl class.

By default, an application defined by the Spark `<s:Application>` or the MX `<mx:Application>` tag uses the Flex drag-and-drop manager, even when the Flex application runs in AIR. If you run your Flex application in AIR, and you want to take advantage of the AIR drag-and-drop manager to drag and drop items from outside of AIR, then you must configure the Flex mx.managers.DragManager class to use the AIR drag-and-drop manager.

There are three scenarios that determine which drag-and-drop manager your Flex application uses when running in AIR:

1 Your main application file uses the Spark `<s:Application>` or the MX `<mx:Application>` tag. In this scenario, you use the Flex drag-and-drop manager, and cannot drag and drop items from outside of AIR.

2 Your main application file uses the Spark `<s:WindowedApplication>` or the MX `<mx:WindowedApplication>` tag. In this scenario, you use the AIR drag-and-drop manager, and can drag and drop items from outside of AIR.

3 Your main application file uses the Spark `<s:Application>` or the MX `<mx:Application>` tag, but loads the AIR drag-and-drop manager as represented by the mx.managers.NativeDragManagerImpl class. In this scenario, you use the AIR drag-and-drop manager, and can drag and drop items from outside of AIR.

For the third scenario, to use the AIR drag-and-drop manager in your Flex application, you must write your application to link to mx.managers.NativeDragManagerImpl class, and to load it at runtime, as the following example shows:

```
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    initialize="initDandD();">

    <fx:Script>
        <![CDATA[
            // Ensure that the NativeDragManagerImpl class is linked in to your application.
            import mx.managers.NativeDragManagerImpl;
            var placeholder:NativeDragManagerImpl;

            // Handle the initialize event to load the DragManager.
            public function initDandD():void
            {
                // Ensure the DragManager is loaded, so that dragging in an AIR works.
                DragManager.isDragging;
            }
        ]]>
    </fx:Script>

    ...
</s:Application>
```

Two drag-and-drop events work differently depending on whether your application runs in Adobe® Flash® Player or AIR, as the following table shows:

Event	Flash Player	AIR
`dragEnter`	Triggers when you move the mouse pointer over any component during a drag and drop operation. The default value of the `DragEvent.action` property is `DragEvent.MOVE`.	Triggers when you move the mouse pointer over any component during a drag and drop operation. The default value of the `DragEvent.action` property is `DragEvent.COPY`.
`dragOver`	Triggers many times when you drag an item over a valid drop target.	Triggers many times when you drag an item over any component, even if the component is not a valid drop target.

There are several other differences between the Flex and AIR drag managers, as described below:

Characteristic	Flash player	AIR
Cursors	Flex draws the drag-and-drop cursors.	The operating system draws the cursors.
Styles	Cursor styles and the `mx.managers.DragManager.defaultDragImageSkin` property are supported.	Cursor styles and the `mx.managers.DragManager.defaultDragImageSkin` property are ignored.
Drag indicator	The drag image of the drag indicator can be an instance of the DisplayObject class, including an animated SWF file, an image, or a Flex component.	By default, the drag image is a bitmap created from the object being dragged. It does not change dynamically as the user drags it. If you pass a drag image to the `doDrag()` method, it must already be loaded by your application when you call `doDrag()`, otherwise it will be blank. For more information on the `doDrag()` method, see “Example: Specifying the drag indicator by using the DragManager” on page 1918.
Drop animation	The DragProxy class animates the drag image based on the results of the drop, such as accepted or rejected.	No custom animations can be used. The operating system handles the behavior of the cursor and the drag image.

Drag and drop differences between Spark and MX

Much of the drag and drop functionality is the same for the Spark and MX list-based controls. However, there are a few differences, as the following table shows:

Topic	Description	Spark	MX
Set the drag indicator	Specifies the appearance of the dragged data during the drag.	Defined by the optional `dragging` view state in the item renderer. You can further customize it by creating a subclass of the spark.components.supportClasses.ListItemDragProxy class.	Override the `mx.controls.listClasses.ListBase.dragImage` property. The default value is ListItemDragProxy.
Set the drop indicator	Specifies the appearance of the drop indicator which shows where the dragged data will be inserted into the drop target.	Define a `dropIndicator` skin part in the skin class of the drop target.	Use the `mx.controls.listClasses.ListBase.dropIndicatorSkin` property to set the skin class. The default value is ListDropIndicator.
Calculate the drop index	Returns the item index in the data provider of the drop target where the item will be dropped. Used by the `dragDrop` event handler to add the items in the correct location. Not available in the MX TileList or HorizontalList controls.	Use the `spark.layouts.supportClasses.LayoutBase.calculateDropLocation()` method. Use the `layout` property of the list class to access this method in the layout class of the component.	Use the `mx.controls.listClasses.ListBase.calculateDropIndex()` method.
Show drop feedback	Specifies to display the focus rectangle around the target control and positions the drop indicator where the drop operation should occur. If the control has active scroll bars, hovering the mouse pointer near the edges of the control scrolls the contents. You typically call this method from within the handler for the `dragOver` event. When you set `dropEnabled` to `true`, Flex automatically shows the drop indicator when necessary.	Use the `spark.layouts.supportClasses.LayoutBase.showDropIndicator()` method. Use the `layout` property to access this method in the layout class of the control. If you override the `dragEnter` event handler, and call `preventDefault()` so that the default handler does not execute, call `List.createDropIndicator()` to create the drop indicator.	Use the `mx.controls.listClasses.ListBase.showDropFeedback()` method.
Hide drop feedback	Hides drop target feedback and removes the focus rectangle from the target. You typically call this method from within the handler for the `dragExit` and `dragDrop` events. When you set `dropEnabled` to `true`, Flex automatically hides the drop indicator when necessary.	Use the `spark.layouts.supportClasses.LayoutBase.hideDropIndicator()` method. Use the `layout` property to access this method in the layout class of the control. Focus not handled by `hideDropIndicator().` If you override the `dragExit` event handler, and call `preventDefault()` so that the default handler does not execute, call `List.destroyDropIndicator()` to delete the drop indicator.	Use the `mx.controls.listClasses.ListBase.hideDropFeedback()` method.

Drag and drop examples

Example: Using a container as a drop target

To use a container as a drop target, you must use the `backgroundColor` property of the container to set a color. Otherwise, the background color of the container is transparent, and the Drag and Drop Manager is unable to detect that the mouse pointer is on a possible drop target.

In the following example, you use the Image control to load a draggable image into a Canvas container. You then add event handlers to let the user drag the Image control within the Canvas container to reposition it:

```
<?xml version="1.0"?>
<!-- dragdrop\DandDImage.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
            //Import classes so you don't have to use full names.
            import mx.managers.DragManager;
            import mx.core.DragSource;
            import mx.events.DragEvent;
            import flash.events.MouseEvent;
            // Embed icon image.
            [Embed(source='assets/globe.jpg')]
            public var globeImage:Class;
            // The mouseMove event handler for the Image control
            // initiates the drag-and-drop operation.
            private function mouseMoveHandler(event:MouseEvent):void
            {
                var dragInitiator:Image=Image(event.currentTarget);
                var ds:DragSource = new DragSource();
                ds.addData(dragInitiator, "img");
                DragManager.doDrag(dragInitiator, ds, event);
            }

            // The dragEnter event handler for the Canvas container
            // enables dropping.
            private function dragEnterHandler(event:DragEvent):void {
                if (event.dragSource.hasFormat("img"))
                {
                    DragManager.acceptDragDrop(Canvas(event.currentTarget));
                }
            }
            // The dragDrop event handler for the Canvas container
            // sets the Image control's position by
            // "dropping" it in its new location.
            private function dragDropHandler(event:DragEvent):void {
                Image(event.dragInitiator).x =
                    Canvas(event.currentTarget).mouseX;
                Image(event.dragInitiator).y =
                    Canvas(event.currentTarget).mouseY;
            }
        ]]>
    </fx:Script>

    <!-- The Canvas is the drag target -->
    <mx:Canvas id="v1"
        width="500" height="500"
        borderStyle="solid"
        backgroundColor="#DDDDDD"
        dragEnter="dragEnterHandler(event);"
        dragDrop="dragDropHandler(event);">

        <!-- The image is the drag initiator. -->
        <s:Image id="myimg"
            source="@Embed(source='assets/globe.jpg')"
            mouseMove="mouseMoveHandler(event);"/>
    </mx:Canvas>
</s:Application>
```

Example: Setting the drag indicator for Spark controls

The drag indicator defines the appearance of the dragged data during drag-and-drop operations. The appearance of the dragged data is determined by the item renderer for the list-based control.

By default, Spark item renderers use the `normal` view state to display the dragged data. For more information on view states in Spark item renderers, see "Defining item renderer view states for a Spark container" on page 488.

Spark item renderers support the optional `dragging` view state that you can use to control the appearance of the drag indicator. The following item renderer add the `dragging` view state to display the dragged data in a bold, blue italic font:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- dragdrop\myComponents\MyListItemRenderer.mxml -->
<s:ItemRenderer focusEnabled="false"
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:states>
        <s:State name="normal" />
        <s:State name="hovered" />
        <s:State name="selected" />
        <s:State name="normalAndShowsCaret"/>
        <s:State name="hoveredAndShowsCaret"/>
        <s:State name="selectedAndShowsCaret"/>
        <s:State name="dragging"/>
    </s:states>

    <s:Rect left="0" right="0" top="0" bottom="0">
        <s:stroke.normalAndShowsCaret>
            <s:SolidColorStroke
                color="{getStyle('selectionColor')}"
                weight="1"/>
        </s:stroke.normalAndShowsCaret>
        <s:stroke.hoveredAndShowsCaret>
            <s:SolidColorStroke
                color="{getStyle('selectionColor')}"
                weight="1"/>
        </s:stroke.hoveredAndShowsCaret>
        <s:stroke.selectedAndShowsCaret>
            <s:SolidColorStroke
                color="{getStyle('selectionColor')}"
                weight="1"/>
        </s:stroke.selectedAndShowsCaret>
        <s:fill>
            <s:SolidColor
                color.normal="0xFFFFFF"
                color.normalAndShowsCaret="0xFFFFFF"
                color.hovered="{getStyle('rollOverColor')}"
                color.hoveredAndShowsCaret="{getStyle('rollOverColor')}"
                color.selected="{getStyle('selectionColor')}"
                color.selectedAndShowsCaret="{getStyle('selectionColor')}"
                color.dragging="0xFFFFFF"/>
        </s:fill>
    </s:Rect>
    <s:Label id="labelDisplay" verticalCenter="0" left="3" right="3" top="6" bottom="4"
        fontStyle.dragging="italic" fontWeight.dragging="bold" color.dragging="blue"/>
</s:ItemRenderer>
```

The following application uses this item renderer:

```
<?xml version="1.0"?>
<!-- dragdrop\SimpleListToListMoveSparkDragIndicator.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    creationComplete="initApp();">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayList;
            private function initApp():void {
                srclist.dataProvider =
                    new ArrayList(['Reading', 'Television', 'Movies']);
                destlist.dataProvider = new ArrayList([]);
            }
        ]]>
    </fx:Script>
    <s:HGroup>
        <s:VGroup>
            <s:Label text="Available Activities"/>
            <s:List id="srclist"
                allowMultipleSelection="true"
                dragEnabled="true"
                dragMoveEnabled="true"
                itemRenderer="myComponents.MyListItemRenderer"/>
        </s:VGroup>
        <s:VGroup>
            <s:Label text="Activities I Like"/>
            <s:List id="destlist"
                dropEnabled="true"/>
        </s:VGroup>
    </s:HGroup>
    <s:Button id="b1"
        label="Reset"
        click="initApp();"/>
</s:Application>
```

Example: Specifying the drag indicator by using the DragManager

In the event handler for the `mouseDown` or `mouseUp` event, you can optionally specify a drag indicator in the `doDrag`() method of the DragManager class. If you do not specify a drag indicator, Flex uses a default drag indicator. The `doDrag()` method takes the following optional arguments to specify the drag indicator and its properties.

Argument	Description
dragIndicator	The image that defines the drag indicator. To specify a symbol, such as a JPEG image of a product that a user wants to order, use a string that specifies the symbol's name, such as myImage.jpg. To specify a component, such as a Flex container or control, create an instance of the control or container, configure and size it, and then pass it as an argument to the `doDrag()` method.
xOffset	Number that specifies the x offset, in pixels, for the `dragImage`. This argument is optional. If omitted, the drag indicator is shown at the upper-left corner of the drag initiator. The offset is expressed in pixels from the left edge of the drag indicator to the left edge of the drag initiator, and is usually a negative number.
yOffset	Number that specifies the y offset, in pixels, for the `dragImage`. This argument is optional. If omitted, the drag indicator is shown at the upper-left corner of the drag initiator. The offset is expressed in pixels from the top edge of the drag indicator to the top edge of the drag initiator, and is usually a negative number.
imageAlpha	A Number that specifies the alpha value used for the drag indicator image. If omitted, Flex uses an alpha value of 0.5. A value of 0 corresponds to transparent and a value of 1.0 corresponds to fully opaque.

You must specify a size for the drag indicator, otherwise it does not appear. The following example modifies the example in "Example: Using a container as a drop target" on page 1915 to use a 15 pixel by 15 pixel Image control as the drag indicator:

```
<?xml version="1.0"?>
<!-- dragdrop\DandDImageProxy.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
            //Import classes so you don't have to use full names.
            import mx.managers.DragManager;
            import mx.core.DragSource;
            import mx.events.DragEvent;
            import flash.events.MouseEvent;
            // Embed icon image.
            [Embed(source='assets/globe.jpg')]
            public var globeImage:Class;
            // The mouseMove event handler for the Image control
            // initiates the drag-and-drop operation.
            private function mouseOverHandler(event:MouseEvent):void
            {
                var dragInitiator:Image=Image(event.currentTarget);
                var ds:DragSource = new DragSource();
                ds.addData(dragInitiator, "img");
                // The drag manager uses the Image control
                // as the drag indicator and sets the alpha to 1.0 (opaque),
                // so it appears to be dragged across the Canvas.
                var imageProxy:Image = new Image();
                imageProxy.source = globeImage;
                imageProxy.height=15;
                imageProxy.width=15;
                DragManager.doDrag(dragInitiator, ds, event,
                    imageProxy, -15, -15, 1.00);
            }
            // The dragEnter event handler for the Canvas container
            // enables dropping.
            private function dragEnterHandler(event:DragEvent):void {
                if (event.dragSource.hasFormat("img"))
                {
                    DragManager.acceptDragDrop(Canvas(event.currentTarget));
                }
            }
            // The dragDrop event handler for the Canvas container
            // sets the Image control's position by
            // "dropping" it in its new location.
            private function dragDropHandler(event:DragEvent):void {
                Image(event.dragInitiator).x =
                    Canvas(event.currentTarget).mouseX;
                Image(event.dragInitiator).y =
                    Canvas(event.currentTarget).mouseY;
            }
        ]]>
    </fx:Script>

    <!-- The Canvas is the drag target -->
    <mx:Canvas id="v1"
        width="500" height="500"
        borderStyle="solid"
        backgroundColor="#DDDDDD"
        dragEnter="dragEnterHandler(event);"
        dragDrop="dragDropHandler(event);">

        <!-- The image is the drag initiator. -->
        <s:Image id="myimg"
            source="@Embed(source='assets/globe.jpg')"
            mouseMove="mouseOverHandler(event);"/>
    </mx:Canvas>
</s:Application>
```

To use a control with specific contents, such as a VBox control with a picture and label, you must create a custom component that contains the control or controls, and use an instance of the component as the *dragIndicator* argument.

Example: Setting the drop indicator for Spark controls

The drop indicator shows where the dragged data will be inserted into the drop target. The appearance of the drop indicator is controlled by the skin class of the drop target. By default, the drop indicator for a Spark control is a solid line that spans the width of the control.

You can create a custom drop indicator by creating a custom skin class for the drop target. In your skin class, create a skin part named `dropIndicator` in the `<fx:Declarations>` area of the skin class, as the following example shows:

```
<fx:Declarations>
    <fx:Component id="dropIndicator">
        <s:Group includeInLayout="false"
            minWidth="4" minHeight="4"
            maxWidth="4" maxHeight="4">
            <s:Line xFrom="0" xTo="10" yFrom="5" yTo="5">
                <s:stroke>
                    <s:SolidColorStroke color="blue" weight="2"/>
                </s:stroke>
            </s:Line>
            <s:Line xFrom="5" xTo="10" yFrom="0" yTo="5">
                <s:stroke>
                    <s:SolidColorStroke color="blue" weight="2"/>
                </s:stroke>
            </s:Line>
            <s:Line xFrom="5" xTo="10" yFrom="10" yTo="5">
                <s:stroke>
                    <s:SolidColorStroke color="blue" weight="2"/>
                </s:stroke>
            </s:Line>
        </s:Group>
    </fx:Component>
</fx:Declarations>
```

This code shows an excerpt from the MyListSkin.mxml file, a custom skin class for the Spark List control. The lines define the drop indicator to be a blue arrow that appears in the drop target to indicate where the dragged data is added.

Note that the bounding Group container specifies the `maxWidth` and `maxHeight` properties. For the drop indicator, only the setting along the major axis of the control is applied. For example, for a List class using vertical layout, the x-axis is the major axis. Therefore, the `maxHeight` property is applied and the `maxWidth` property is ignored.

The Spark layout classes use the following rules to size and position the drop indicator:

1 The drop indicator's size is calculated to be as big as the gap between the neighboring data items in the control.

  Any minimum or maximum setting in the major axis of orientation is honored. Along the minor axis, minimum and maximum settings are ignored. The drop indicator is sized to be as wide as the respective column and as tall as the respective row.

2 After drop indicator is sized, it is centered within the gap between the data items.

The following example uses the MyListSkin.mxml skin class:

```
<?xml version="1.0"?>
<!-- dragdrop\SimpleListToListMoveSparkDropIndicator.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    creationComplete="initApp();">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayList;
            import myComponents.MyListSkin;
            private function initApp():void {
                srclist.dataProvider =
                    new ArrayList(['Reading', 'Television', 'Movies']);
                destlist.dataProvider = new ArrayList([]);
            }
        ]]>
    </fx:Script>
    <s:HGroup>
        <s:VGroup>
            <s:Label text="Available Activities"/>
            <s:List id="srclist"
                allowMultipleSelection="true"
                dragEnabled="true"
                dragMoveEnabled="true"/>
        </s:VGroup>
        <s:VGroup>
            <s:Label text="Activities I Like"/>
            <s:List id="destlist"
                dropEnabled="true"
                skinClass="myComponents.MyListSkin"/>
        </s:VGroup>
    </s:HGroup>
    <s:Button id="b1"
        label="Reset"
        click="initApp();"/>
</s:Application>
```

Example: Setting the cursor styles of the DragManager

The DragManager uses styles to control the display of the different cursors used during the drag and drop operation, such as the move and copy cursors. The cursors are defined as symbols in the Assets.swf file in the *flexInstallDir*\frameworks\projects\framework\assets directory.

By default, Flex defines the cursor styles as if you had used the following type selector in your application:

```
<fx:Style>
    @namespace mx "library://ns.adobe.com/flex/mx";

    mx|DragManager
    {
        copyCursor: Embed(source="Assets.swf",symbol="mx.skins.cursor.DragCopy");
        defaultDragImageSkin: ClassReference("mx.skins.halo.DefaultDragImage");
        linkCursor: Embed(source="Assets.swf",symbol="mx.skins.cursor.DragLink");
        moveCursor: Embed(source="Assets.swf",symbol="mx.skins.cursor.DragMove");
        rejectCursor: Embed(source="Assets.swf",symbol="mx.skins.cursor.DragReject");
    }
</fx:Style>
```

Use the `<fx:Style>` tag to define your own assets to use for the cursors. The following example replaces the copy cursor with a custom cursor:

```
<?xml version="1.0"?>
<!-- dragdrop\SimpleListToListMoveStyles.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    creationComplete="initApp();">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Style>
        @namespace mx "library://ns.adobe.com/flex/mx";
        mx|DragManager
        {
            copyCursor: Embed(source="assets/globe.jpg");
        }
    </fx:Style>

    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;
            private function initApp():void {
                srclist.dataProvider =
                    new ArrayCollection(['Reading', 'Television', 'Movies']);
                destlist.dataProvider = new ArrayCollection([]);
            }
        ]]>
    </fx:Script>
    <s:HGroup>
        <s:VGroup>
            <s:Label text="Available Activities"/>
            <s:List id="srclist"
                allowMultipleSelection="true"
                dragEnabled="true"
                dragMoveEnabled="true"/>
        </s:VGroup>
        <s:VGroup>
            <s:Label text="Activities I Like"/>
            <s:List id="destlist"
                dropEnabled="true"/>
        </s:VGroup>
    </s:HGroup>
    <s:Button id="b1"
        label="Reset"
        click="initApp();"/>
</s:Application>
```

Example: Handling the dragOver and dragExit events for the drop target

The `dragOver` event occurs when the user moves the mouse over a drag-and-drop target whose `dragEnter` event handler has called the `DragManager.acceptDragDrop()` method. This event is dispatched continuously as the user drags the mouse over the target. The `dragOver` event handler is optional; you do not have to define it to perform a drag-and-drop operation.

The `dragOver` event is useful for specifying the visual feedback that the user gets when the mouse is over a drop target. For example, you can use the `DragManager.showFeedback()` method to specify the drag-feedback indicator that appears along with the drag indicator. This method uses four constant values for the argument, as the following table shows:

Argument value	**Icon**
`DragManager.COPY`	A green circle with a white plus sign indicating that you can perform the drop.
`DragManager.LINK`	A grey circle with a white arrow sign indicating that you can perform the drop.
`DragManager.MOVE`	A plain arrow indicating that you can perform the drop.
`DragManager.NONE`	A red circle with a white *x* appears indicating that a drop is prohibited. This is the same image that appears when the user drags over an object that is not a drag target.

You typically show the feedback indicator based on the keys pressed by the user during the drag-and-drop operation. The DragEvent object for the `dragOver` event contains Boolean properties that indicate whether the Control or Shift keys are pressed at the time of the event: `ctrlKey` and `shiftKey`, respectively. No key pressed indicates a move, the Control key indicates a copy, and the Shift key indicates a link. You then call the `showFeedback()` method as appropriate for the key pressed.

Another use of the `showFeedback()` method is that it determines the value of the `action` property of the DragEvent object for the `dragDrop`, `dragExit`, and `dragComplete` events. If you do not call the `showFeedback()` method in the `dragOver` event handler, the `action` property of the DragEvent is always set to `DragManager.MOVE`.

The `dragExit` event is dispatched when the user drags the drag indicator off the drop target, but does not drop the data onto the target. You can use this event to restore any visual changes that you made to the drop target in the `dragOver` event handler.

In the following example, you set the `dropEnabled` property of a List control to `true` to configure it as a drop target and to use the default event handlers. However, you want to provide your own visual feedback, so you also define event handlers for the `dragEnter`, `dragExit`, and `dragDrop` events. The `dragOver` event handler completely overrides the default event handler, so you call the `Event.preventDefault()` method to prohibit the default event handler from execution.

The `dragOver` event handler determines whether the user is pressing a key while dragging the drag indicator over the target, and sets the feedback appearance based on the key that is pressed. The `dragOver` event handler also sets the border color of the drop target to green to indicate that it is a viable drop target, and uses the `dragExit` event handler to restore the original border color.

For the `dragExit` and `dragDrop` handlers, you only want to remove any visual changes that you made in the `dragOver` event handlers, but otherwise you want to rely on the default Flex event handlers. Therefore, these event handlers do not call the `Event.preventDefault()` method:

```
<?xml version="1.0"?>
<!-- dragdrop\DandDListToListShowFeedbackSpark.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    creationComplete="initApp();">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;

Moving and copying data

You implement a move and a copy as part of a drag-and-drop operation.

About moving data

When you move data, you add it to the drop target and delete it from the drag initiator. You use the `dragDrop` event for the drop target to add the data, and the `dragComplete` event for the drag initiator to remove the data.

How much work you have to do to implement the move depends on whether the drag initiator and drop target are list-based controls or nonlist-based controls:

List-based control You do not have to do any additional work; list-based controls handle all of the processing required to move data from one list-based control to another list-based control. For an example, see “Performing a drag and drop” on page 1894.

nonlist-based control If the drag initiator is a nonlist-based control, you have to implement the event handler for the `dragComplete` event to delete the drag data from the drag initiator. If the drop target is a nonlist-based control, you have to implement the event handler for the `dragDrop` event to add the data to the drop target. For an example, see “Example: Moving and copying data for a nonlist-based control” on page 1929.

About copying data

The list-based controls can automate all of the drag-and-drop operation except for when you copy the drag data to the drop target, and the drop target uses a different data format. If the drop target uses a different data format, you must explicitly handle the `dragDrop` event for the drop target.

When using a nonlist-based control as the drop target, you always have to write an event handler for the `dragDrop` event, regardless of whether you are performing a move or copy.

Copying data in an object-oriented environment is not a trivial task. An object may contain pointers to other objects that themselves contain pointers to even more objects. Rather than try to define a universal object copy as part of the drag-and-drop operation, Flex leaves it to you to implement object copying because you will have first-hand knowledge of your data format and requirements.

In some circumstances, you may have objects that implement a clone method that makes it easy to create a byte copy of the object. In other cases, you will have to perform the copy yourself by copying individual fields of the source object to the destination object.

Example: Copying data from an MX List control to an MX DataGrid control

You can use drag and drop to copy data between controls that use different data formats. To handle this situation, you write an event handler for the `dragDrop` event that converts the data from the format of the drag initiator to the format required by the drop target.

In the following example, you can move or copy data from a Spark List control to an MX DataGrid control. The event handler for the `dragDrop` event adds a new field to the dragged data that contains the date:

```
<?xml version="1.0"?>
<!-- dragdrop\DandDListToDGSpark.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    creationComplete="initApp();">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import mx.events.DragEvent;
            import mx.managers.DragManager;
            import mx.core.DragSource;
            import mx.collections.IList;
            import mx.collections.ArrayCollection;

            private function initApp():void {
                srcList.dataProvider = new ArrayCollection([
                    {label:"First", data:"1"},
                    {label:"Second", data:"2"},
                    {label:"Third", data:"3"},
                    {label:"Fourth", data:"4"},
                ]);

                destDG.dataProvider = new ArrayCollection([]);
            }
            private function dragDropHandler(event:DragEvent):void {
                if (event.dragSource.hasFormat("itemsByIndex"))
                {
                    // Explicitly handle the dragDrop event.
                    event.preventDefault();

                    // Since you are explicitly handling the dragDrop event,
                    // call hideDropFeedback(event) to have the drop target
                    // hide the drop indicator.
                    // The drop indicator is created
                    // automatically for the list controls by the built-in
                    // event handler for the dragOver event.
                    event.currentTarget.hideDropFeedback(event);

                    // Get drop target.
                    var dropTarget:DataGrid =
                        DataGrid(event.currentTarget);
                    var itemsVector:Vector.<Object> =
                        event.dragSource.dataForFormat('itemsByIndex') as Vector.<Object>;
                    var tempItem:Object =
                        { label: itemsVector[0].label,
                            data: itemsVector[0].data,
                            date: new Date()
                        };

                    // Get the drop location in the destination.
                    var dropLoc:int = dropTarget.calculateDropIndex(event);

                    IList(dropTarget.dataProvider).addItemAt(tempItem, dropLoc);
                }
            }
        ]]>
    </fx:Script>
    <s:HGroup>
        <s:List  id="srcList"
            dragEnabled="true"
            dragMoveEnabled="true"/>
        <mx:DataGrid  id="destDG"
            dropEnabled="true"
            dragDrop="dragDropHandler(event);">
            <mx:columns>
                <mx:DataGridColumn dataField="label"/>
                <mx:DataGridColumn dataField="data"/>
                <mx:DataGridColumn dataField="date"/>
            </mx:columns>
        </mx:DataGrid>
    </s:HGroup>
    <s:Button id="b1"
        label="Reset"
        click="initApp();"/>
</s:Application>
```

Example: Moving and copying data for a nonlist-based control

The `dragComplete` event occurs on the drag initiator when a drag operation completes, either when the drag data drops onto a drop target, or when the drag-and-drop operation ends without performing a drop operation. The drag initiator can specify a handler to perform cleanup actions when the drag finishes, or when the target does not accept the drop.

One use of the `dragComplete` event handler is to remove from the drag initiator the objects that you move to the drop target. The items that you drag from a control are copies of the original items, not the items themselves. Therefore, when you drop items onto the drop target, you use the `dragComplete` event handler to delete them from the drag initiator.

To determine the type of drag operation (copy or move), you use the `action` property of the event object passed to the event handler. This method returns the drag feedback set by the `dragOver` event handler. For more information, see "Example: Handling the dragOver and dragExit events for the drop target" on page 1924.

In the following example, you drag an Image control from one Canvas container to another. As part of the drag-and-drop operation, you can move the Image control, or copy it by holding down the Control key. If you perform a move, the `dragComplete` event handler removes the Image control from its original parent container:

```
<?xml version="1.0"?>
<!-- dragdrop\DandDImageCopyMove.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx" >
    <s:layout>
        <s:HorizontalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import mx.managers.DragManager;
            import mx.core.DragSource;
            import mx.events.DragEvent;
            import flash.events.MouseEvent;
            // Embed icon image.
            [Embed(source='assets/globe.jpg')]
            public var globeImage:Class;
            // The mouseMove event handler for the Image control
            // functioning as the drag initiator.
            private function mouseOverHandler(event:MouseEvent):void
            {
                var dragInitiator:Image=Image(event.currentTarget);
                var ds:DragSource = new DragSource();
                ds.addData(dragInitiator, "img");
                // The drag manager uses the image as the drag indicator
                // and sets the alpha to 1.0 (opaque),
                // so it appears to be dragged across the canvas.
                var imageProxy:Image = new Image();
                imageProxy.source = globeImage;
                imageProxy.height=10;
                imageProxy.width=10;
                DragManager.doDrag(dragInitiator, ds, event,
                    imageProxy, -15, -15, 1.00);
            }

            // The dragEnter event handler for the Canvas container
            // functioning as the drop target.
            private function dragEnterHandler(event:DragEvent):void {
              if (event.dragSource.hasFormat("img"))
                DragManager.acceptDragDrop(Canvas(event.currentTarget));
            }

            // The dragOver event handler for the Canvas container
            // sets the type of drag-and-drop
            // operation as either copy or move.
            // This information is then used in the
            // dragComplete event handler for the source Canvas container.
            private function dragOverHandler(event:DragEvent):void
            {
                if (event.dragSource.hasFormat("img")) {
                    if (event.ctrlKey) {
                        DragManager.showFeedback(DragManager.COPY);
                        return;
                    }
                    else {
                        DragManager.showFeedback(DragManager.MOVE);
                        return;
                    }
                }
                DragManager.showFeedback(DragManager.NONE);
            }

            // The dragDrop event handler for the Canvas container
            // sets the Image control's position by
            // "dropping" it in its new location.
            private function dragDropHandler(event:DragEvent):void {
              if (event.dragSource.hasFormat("img")) {
                  var draggedImage:Image =
                    event.dragSource.dataForFormat('img') as Image;
                  var dropCanvas:Canvas = event.currentTarget as Canvas;

                  // Since this is a copy, create a new object to
                  // add to the drop target.
                  var newImage:Image=new Image();
                  newImage.source = draggedImage.source;
                  newImage.x = dropCanvas.mouseX;
                  newImage.y = dropCanvas.mouseY;
                  dropCanvas.addChild(newImage);
              }
            }

            // The dragComplete event handler for the source Canvas container
            // determines if this was a copy or move.
            // If a move, remove the dragged image from the Canvas.
            private function dragCompleteHandler(event:DragEvent):void {
                var draggedImage:Image =
                    event.dragInitiator as Image;
                var dragInitCanvas:Canvas =
                    event.dragInitiator.parent as Canvas;
                if (event.action == DragManager.MOVE)
                    dragInitCanvas.removeChild(draggedImage);
            }
        ]]>
    </fx:Script>
    <!-- Canvas holding the Image control that is the drag initiator. -->
    <mx:Canvas
```

```
        width="250" height="500"
        borderStyle="solid"
        backgroundColor="#DDDDDD">

    <!-- The Image control is the drag initiator and the drag indicator. -->
        <s:Image id="myimg"
            source="@Embed(source='assets/globe.jpg')"
            mouseMove="mouseOverHandler(event);"
            dragComplete="dragCompleteHandler(event);"/>
    </mx:Canvas>
    <!-- This Canvas is the drop target. -->
    <mx:Canvas
        width="250" height="500"
        borderStyle="solid"
        backgroundColor="#DDDDDD"
        dragEnter="dragEnterHandler(event);"
        dragOver="dragOverHandler(event);"
        dragDrop="dragDropHandler(event);">
    </mx:Canvas>
</s:Application>
```

Chapter 7: Enhancing usability

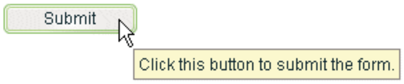
ToolTip controls

Adobe® Flex™ ToolTips are a flexible method of providing helpful information to your users. When a user moves the mouse pointer over graphical components, ToolTips pop up and text appears. You can use ToolTips to guide users through working with your application or customize them to provide additional functionality.

About ToolTip controls

ToolTips are a standard feature of many desktop applications. They make the application easier to use by displaying messages when the user moves the mouse pointer over an onscreen element, such as a Button control.

The following image shows ToolTip text that appears when the user hovers the mouse pointer over a button:



Click this button to submit the form.

When the user moves the mouse pointer away from the component or clicks the mouse button, the ToolTip disappears. If the mouse pointer remains over the component, the ToolTip eventually disappears. The default behavior is to display only one ToolTip at a time.

You can set the time it takes for the ToolTip to appear when a user moves the mouse pointer over the component. You can also set the amount of time it takes for the ToolTip to disappear.

If you define a ToolTip on a container, the ToolTipManager displays the parent's ToolTip for the children if the child does not have one.

Flex ToolTips support style sheets and the dynamic loading of ToolTip text. ToolTip text does not support embedded HTML. For more information on using style sheets and dynamic loading of text, see "Setting styles in ToolTips" on page 1936 and "Using dynamic ToolTip text" on page 1944.

Not all Spark text components support ToolTips. For example, you can add a ToolTip to the RichEditableText component, but not the RichText control.

Some components have their own ToolTip-like "data tips." These components include the List control, most chart controls, and DataGrid control. For more information, see that component's documentation.

ToolTips are the basis for the accessibility implementation within Flex. All controls that support accessibility do so by making their ToolTip text readable by screen readers such as JAWS. For more information on accessibility, see "Accessible applications" on page 2122.

Creating ToolTips

Every visual component that extends the UIComponent, UITextField, or UIFTETextField classes (which implement the IToolTipManagerClient interface) supports a `toolTip` property. This property is inherited from those class that implement IToolTipManagerClient. You set the value of the `toolTip` property to a text string, and when the mouse pointer hovers over that component, the text string appears. The following example sets the `toolTip` property text for a Button control:

```
<?xml version="1.0"?>
<!-- tooltips/BasicToolTip.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Button id="b1" label="Click Me" toolTip="This Button does nothing."/>
</s:Application>
```

To set the value of a ToolTip in ActionScript, use the `toolTip` property of the component. The following example creates a new Button and sets the `toolTip` property of a Button control:

```
<?xml version="1.0"?>
<!-- tooltips/BasicToolTipActionScript.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <fx:Script>
    <![CDATA[
     public function createNewButton(event:MouseEvent):void {
        var myButton:Button = new Button();
        myButton.label = "Create Another Button";
        myButton.toolTip = "Click this new button to create another button.";
        myButton.addEventListener(MouseEvent.CLICK, createNewButton);
        addElement(myButton);
     }
    ]]>
  </fx:Script>

  <s:Button id="b1" label="Create Another Button"
        toolTip="Click this button to create another button."
        click="createNewButton(event);"/>
</s:Application>
```

If you do not define a ToolTip on the child of a container, the ToolTipManager displays the parent's ToolTip. For example, if you add a Button control to a Panel container that has a ToolTip, the user sees the Panel container's ToolTip text when the user moves the mouse pointer over the Panel. When the user moves the mouse pointer over the Button control, the Panel's ToolTip continues to be displayed. You can override the container's ToolTip text by setting the value of the child's `toolTip` property.

The following example shows the inheritance of ToolTip text:

```
<?xml version="1.0"?>
<!-- tooltips/ToolTipInheritance.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:VGroup toolTip="VGroup ToolTip">
        <s:Button id="b1" label="Button 1" toolTip="Button ToolTip"/>
        <s:Button id="b2" label="Button 2"/>
    </s:VGroup>

</s:Application>
```

When the mouse pointer is over button b1, the ToolTip displays “Button ToolTip”. When the mouse pointer is over button b2 or anywhere in the VGroup container except over button b1, the ToolTip displays “VGroup ToolTip”.

The TabNavigator container uses the ToolTips that are on its children. If you add a ToolTip to a child view of a TabNavigator container, the ToolTip appears when the mouse is over the tab for that view, but not when the mouse is over the view itself. If you add a ToolTip to the TabNavigator container, the ToolTip appears when the mouse is over either the tab or the view, unless the ToolTip is overridden by the tab or the view. ToolTips in the following controls also behave this way:

- Accordion
- ButtonBar
- LinkBar
- TabBar
- ToggleButtonBar

There is no limit to the size of the ToolTip text, although long messages can be difficult to read. When the ToolTip text reaches the width of the ToolTip box, the text wraps to the next line. You can add line breaks in ToolTip text. In ActionScript, you use the \n escaped newline character. In MXML tags, you use the &#13; XML entity.

The following examples show using the \n escaped newline character and the &#13; entity:

```
<?xml version="1.0"?>
<!-- tooltips/ToolTipNewlines.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    initialize="doSomething(event)">

    <fx:Script>
        <![CDATA[
            public function doSomething(event:Event):void {
                // Use the \n to force a line break in ActionScript.
                b1.toolTip = "Click this button \nto clear the form.";
            }
        ]]>
    </fx:Script>
    <s:Button id="b1" label="Clear" width="100"/>

    <!-- Use &#13; to force a line break in MXML tags. -->
    <s:Button id="b2" label="Submit" width="100"
        toolTip="Click this button &#13;to submit the form."/>
</s:Application>
```

You also have some flexibility in formatting the text of the ToolTip. You can apply styles and change other settings for all ToolTips in your application by using the ToolTip Cascading Style Sheets (CSS) type selector. The following sections describe how to set styles on the ToolTip text and box.

Setting styles in ToolTips

You can change the appearance of ToolTip text and the ToolTip box by using CSS syntax or the mx.styles.StyleManager class. Changes to ToolTip styles apply to all ToolTips in the current application.

The default styles for ToolTips are defined by the ToolTip type selector in the defaults.css file in the framework.swc file. You can use a type selector in the `<fx:Style>` tag to override the default styles of your ToolTips. The following example sets the styles of the ToolTip type selector using CSS syntax:

```
<?xml version="1.0"?>
<!-- tooltips/ToolTipStyles.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Style>
        @namespace mx "library://ns.adobe.com/flex/mx";
        mx|ToolTip {
            fontFamily: "Arial";
            fontSize: 19;
            fontStyle: "italic";
            color: #FF6699;
            backgroundColor: #33CC99;
        }
    </fx:Style>
    <s:Button id="b1" label="Click Me" toolTip="This Button does nothing."/>
</s:Application>
```

You can also use the StyleManager to apply styles to all ToolTips. You must first get a reference to the top-level StyleManager with the Application object’s `styleManager` property. You then get the ToolTip style declaration with the `getStyleDeclaration()` method. Finally, you apply a style to the ToolTip type selector with the `setStyle()` method, as the following example shows:

```
<?xml version="1.0"?>
<!-- tooltips/ToolTipStyleManager.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="setToolTipStyle()">
    <fx:Script>
        <![CDATA[
            private function setToolTipStyle():void {

styleManager.getStyleDeclaration("mx.controls.ToolTip").setStyle("fontStyle","italic");

styleManager.getStyleDeclaration("mx.controls.ToolTip").setStyle("fontSize","19");

styleManager.getStyleDeclaration("mx.controls.ToolTip").setStyle("fontFamily","Arial");

styleManager.getStyleDeclaration("mx.controls.ToolTip").setStyle("color","#FF6699");

styleManager.getStyleDeclaration("mx.controls.ToolTip").setStyle("backgroundColor","#33CC99"
);
            }
        ]]>
    </fx:Script>
  <s:Button id="b1" label="Click Me" toolTip="This Button does nothing."/>
</s:Application>
```

ToolTips use inheritable styles that you set globally. For example, you can set the `fontWeight` of ToolTips with the StyleManager by setting it on the global selector, as the following example shows:

```
<?xml version="1.0"?>
<!-- tooltips/ToolTipGlobalStyles.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="setToolTipStyle()">
    <fx:Script>
        <![CDATA[
            private function setToolTipStyle():void {
                styleManager.getStyleDeclaration("global").setStyle("fontWeight","bold");
                styleManager.getStyleDeclaration("global").setStyle("color","red");
            }
        ]]>
    </fx:Script>
  <s:Button id="b1" label="Click Me" toolTip="This Button does nothing, but the ToolTip is
styled red and bold."/>
</s:Application>
```

Styles set on the Application object typically apply to all UI objects. However, ToolTips do not inherit styles set on the Application object.

If you set the `fontWeight` property on the global selector, your change affects the text of many controls in addition to ToolTips, so be careful when using the global selector.

For a complete list of styles supported by ToolTips, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*. For more information on using styles, see “Styles and themes” on page 1492.

You can reskin ToolTip controls to give them an entirely new appearance. You can do this by using the ToolTipBorder programmatic skin or reskin them graphically. For an example of programmatically reskinning a ToolTip control, see "Reskinning ToolTips" on page 1958.

Setting the width of ToolTips

You can set the width of the ToolTip box by changing the `maxWidth` property of the ToolTip class. This property is static so when you set it, you are setting it for all ToolTip objects. You cannot set it on an instance of a ToolTip class.

The `maxWidth` property specifies the maximum width in pixels for new ToolTips boxes. For example, the following line changes the maximum width of the ToolTip box to 100 pixels:

```
<?xml version="1.0"?>
<!-- tooltips/SetMaxWidth.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp()">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <fx:Script>
    <![CDATA[
     import mx.controls.ToolTip;
     public function initApp():void {
        ToolTip.maxWidth = 100;
     }
     public function createNewButton(event:MouseEvent):void {
        var myButton:Button = new Button();
        myButton.label = "Create Another Button";
        myButton.toolTip = "Click this new button to create another button.";
        myButton.addEventListener(MouseEvent.CLICK, createNewButton);
        addElement(myButton);
     }
    ]]>
  </fx:Script>

  <s:Button id="b1" label="Create Another Button"
    click="createNewButton(event);"
    toolTip="Click this button to create a new one."/>
</s:Application>
```

Flex wraps the text of a ToolTip onto multiple lines to ensure that the width does not exceed this value. If the text in the ToolTip box is not as wide as the `maxWidth` property, Flex creates a box only wide enough for the text to fit.

The default value of `maxWidth` is `300`. If the value of `maxWidth` exceeds the width of the application, Flex clips the text in the ToolTip box.

Using ToolTip events

ToolTips trigger many events during their life cycle. These events are of type ToolTipEvent.

In addition to the `type` and `target` properties, the ToolTipEvent object references the ToolTip in its `toolTip` property. With a reference to the ToolTip, you can then access the ToolTip text with the `text` property.

To use events of type ToolTipEvent in your `<fx:Script>` blocks, you must import mx.events.ToolTipEvent class.

The following example plays a sound in response to the `TOOL_TIP_SHOW` event:

```
<?xml version="1.0"?>
<!-- tooltips/ToolTipsWithSoundEffects.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    initialize="initApp()">
  <fx:Script>
    <![CDATA[
     import mx.events.ToolTipEvent;
     import flash.media.Sound;
     [Embed(source="../assets/sound1.mp3")]
     private var beepSound:Class;
     private var myClip:Sound;
     public function playSound():void {
        myClip.play();
     }
     private function myListener(event:ToolTipEvent):void {
        playSound();
     }
     private function initApp():void {
        myRichEditableText.addEventListener(ToolTipEvent.TOOL_TIP_SHOW, myListener);
        myClip = new beepSound();
     }
    ]]>
  </fx:Script>
  <s:RichEditableText id="myRichEditableText" toolTip="ToolTip" text="Mouse Over Me"/>
</s:Application>
```

Using ToolTips with MX navigator containers

MX NavBar and TabBar subclasses (such as ButtonBar, LinkBar, and ToggleButtonBar) support ToolTips in their data providers. The data provider array can contain a `toolTip` field that specifies the `toolTip` for the navigation items.

The following example creates ToolTips for each of the navigation items:

```
<?xml version="1.0"?>
<!-- tooltips/NavItemToolTips.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:ButtonBar>
        <s:dataProvider>
            <s:ArrayCollection>
                <fx:Object label="OK" toolTip="OK Button ToolTip"/>
                <fx:Object label="Cancel" toolTip="Cancel Button ToolTip"/>
            </s:ArrayCollection>
        </s:dataProvider>
    </s:ButtonBar>
    <mx:ButtonBar>
        <mx:dataProvider>
                <fx:Object label="OK" toolTip="OK Button ToolTip"/>
                <fx:Object label="Cancel" toolTip="Cancel Button ToolTip"/>
        </mx:dataProvider>
    </mx:ButtonBar>
</s:Application>
```

The Spark ButtonBar component does not by default support the use of a `toolTip` field in its data provider. To add ToolTips to a Spark ButtonBar in this way, you must create a custom item renderer. For more information, see "Custom Spark item renderers" on page 470.

You can use ToolTips on child elements in a navigator container's data provider. The component recognizes those ToolTips and displays them accordingly. In the following example, the ToolTips are propagated up to the LinkBar:

```
<?xml version="1.0"?>
<!-- tooltips/DataProviderToolTips.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
  <mx:VBox>
     <!-- Create a LinkBar control to navigate the ViewStack. -->
     <mx:LinkBar dataProvider="{vs1}" borderStyle="solid"/>

     <!-- Define the ViewStack and the three child containers. -->
     <mx:ViewStack id="vs1" borderStyle="solid" width="100%" height="150">
        <mx:Canvas id="search" label="Search" toolTip="Search Screen">
           <mx:Label text="Search Screen"/>
        </mx:Canvas>
        <mx:Canvas id="custInfo" label="Customer"
           toolTip="Customer Info Screen">
           <mx:Label text="Customer Info"/>
        </mx:Canvas>
        <mx:Canvas id="accountInfo" label="Account"
           toolTip="Account Info Screen">
           <mx:Label text="Account Info"/>
        </mx:Canvas>
     </mx:ViewStack>
  </mx:VBox>
</s:Application>
```

You can also set the value of the NavBar's `toolTipField` property to point to the field in the data provider that provides a ToolTip. The data provider in the following example defines ToolTips in the `myToolTip` field:

```
<?xml version="1.0"?>
<!-- tooltips/ToolTipFieldExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
  <mx:ButtonBar toolTipField="myToolTip">
    <mx:dataProvider>
     <fx:Object label="OK" myToolTip="OK Button TooTip"/>
     <fx:Object label="Cancel" myToolTip="Cancel Button ToolTip"/>
    </mx:dataProvider>
  </mx:ButtonBar>
</s:Application>
```

Using the ToolTip Manager

The ToolTipManager class lets you set basic ToolTip functionality, such as display delay and the disabling of ToolTips. It is located in the mx.managers package. You must import this class when using the ToolTipManager. The ToolTipManager class also contains a reference to the current ToolTip in its `currentToolTip` property.

Enabling and disabling ToolTips

You can enable and disable ToolTips in your applications. When you disable ToolTips, no ToolTip box appears when the user moves the mouse pointer over a visible component, regardless of whether that component's `toolTip` property is set.

You use the enabled property of the ToolTipManager to enable or disable ToolTips. You set this property to true to enable ToolTips or false to disable ToolTips. The default value is true.

The following example toggles ToolTips on and off when the user clicks the Toggle ToolTips button:

```
<?xml version="1.0"?>
<!-- tooltips/ToggleToolTips.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
  <fx:Script>
    <![CDATA[
     import mx.managers.ToolTipManager;
     private function toggleToolTips():void {
        if (ToolTipManager.enabled) {
           ToolTipManager.enabled = false;
        } else {
           ToolTipManager.enabled = true;
        }
     }
    ]]>
  </fx:Script>
  <s:Button id="b1"
    label="Toggle ToolTips"
    width="150"
    click="toggleToolTips();"
    toolTip="Click me to enable/disable tooltips."
  />

</s:Application>
```

Setting delay times

A *delay time* is a measurement of time that passes before something takes place. For example, after the user moves the mouse pointer over a component, there is a brief delay before the ToolTip appears. This gives someone who is not looking for ToolTip text enough time to move the mouse pointer away before seeing the pop-up.

The ToolTipManager lets you set the length of time that passes before the ToolTip box appears, and the length of time that a ToolTip remains on the screen when a mouse pointer hovers over the component. You can also set the delay between ToolTips.

You set the value of the ToolTipManager's showDelay, hideDelay, and scrubDelay properties in ActionScript. The following table describes the time delay properties of the ToolTipManager:

Property	Description
`showDelay`	The length of time, in milliseconds, that Flex waits before displaying the ToolTip box when a user moves the mouse pointer over a component that has a ToolTip. To make the ToolTip appear instantly, set the `showDelay` property to 0. The default value is 500 milliseconds, or half of a second.
`hideDelay`	The length of time, in milliseconds, that Flex waits to hide the ToolTip box after it appears. This amount of time only applies if the mouse pointer is over the target component. Otherwise the ToolTip disappears immediately when you move the mouse pointer away from the target component. After Flex hides a ToolTip box, the user must move the mouse pointer off the component and back onto it to see the ToolTip box again. If you set the `hideDelay` property to 0, Flex does not display the ToolTip. Adobe recommends that you use the default value of 10,000 milliseconds, or 10 seconds. If you set the `hideDelay` property to `Infinity`, Flex does not hide the ToolTip until the user triggers an event (such as moving the mouse pointer off the component). The following example sets the `hideDelay` property to `Infinity`: `ToolTipManager.hideDelay = Infinity;`
`scrubDelay`	The length of time, in milliseconds, that a user can take when moving the mouse between controls before Flex again waits for the duration of `showDelay` to display a ToolTip box. This setting is useful if the user moves quickly from one control to another; after displaying the first ToolTip, Flex displays the others immediately rather than waiting for the duration of the `showDelay` setting. The shorter the setting for `scrubDelay`, the more likely that the user must wait for an amount of time specified by the `showDelay` property in order to see the next ToolTip. A good use of this property is if you have several buttons on a toolbar, and the user will quickly scan across them to see brief descriptions of their functionality. The default value is 100.

The following example uses the Application control's `initialize` event to set the starting values for the ToolTipManager:

```
<?xml version="1.0"?>
<!-- tooltips/ToolTipTiming.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp();">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script><![CDATA[
        import mx.managers.ToolTipManager;
        private function initApp():void {
            ToolTipManager.enabled = true;// Optional. Default value is true.
            ToolTipManager.showDelay = 0;// Display immediately.
            ToolTipManager.hideDelay = 3000; // Hide after 3 seconds of being viewed.
        }
    ]]></fx:Script>
    <s:Button label="Click Me" toolTip="Click this Button to do something."/>
    <s:Button label="Click Me" toolTip="Click this Button to do something else."/>
    <s:Button label="Click Me" toolTip="Click this Button to do a third thing."/>
    <s:Button label="Click Me" toolTip="Click this Button to do the same thing."/>
</s:Application>
```

Using effects with ToolTips

You can use a custom effect or one of the standard Flex effects with ToolTips. You set the `showEffect` or `hideEffect` property of the ToolTipManager to define the effect that is triggered whenever a ToolTip is displayed or is hidden.

The following example uses the Fade effect so that ToolTips fade in when the user moves the mouse pointer over a component with a ToolTip:

```
<?xml version="1.0"?>
<!-- tooltips/FadeInToolTips.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    width="600" height="600"
    initialize="app_init();">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Declarations>
        <s:Fade id="fadeIn" alphaFrom="0" alphaTo="1" duration="1000"/>
    </fx:Declarations>
    <fx:Script>
        <![CDATA[
            import mx.managers.ToolTipManager;
            public function app_init():void {
                ToolTipManager.showEffect = fadeIn;
            }
        ]]>
    </fx:Script>
    <s:Button id="b1" label="Click Me"
        toolTip="This is a ToolTip that fades in."/>
</s:Application>
```

By default, the font used in this example does not fade. You must use an embedded font to achieve the effect. For more information on using embedded fonts, see “Embed fonts” on page 1571.

If you set a fade out effect for the `hideEffect` event, the user must wait with the mouse hovering over the component to trigger that effect; the `hideToolTip` event is not triggered if the user moves the mouse pointer to a different component before the ToolTip object hides on its own.

For more information about using effects and defining custom effects, see “Introduction to effects” on page 1784.

Using dynamic ToolTip text

You can use ToolTips for more than just displaying static help text to the user. You can also bind the ToolTip text to data or component text. This lets you use ToolTips as a part of the user interface, showing drill-down information, query results, or more helpful text that is customized to the user experience.

You bind the value of the ToolTip text to the value of another control’s text using curly braces ({ }) syntax.

The following example inserts the value of the TextInput control into the Button control’s ToolTip text when the user moves the mouse pointer over the Button control:

```
<?xml version="1.0"?>
<!-- tooltips/BoundToolTipText.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:TextInput id="txtTo" width="300"/>
    <s:Button label="Send" toolTip="Send e-mail to {txtTo.text}"/>
</s:Application>
```

In this example, if the user enters **fred@fred.com** in the TextInput box, and then moves the mouse pointer over the button, Flex displays the message “Send e-mail to fred@fred.com” in the ToolTip box.

Another approach to creating dynamic text for ToolTips is to intercept the ToolTip in its `toolTipShow` event handler and change the value of its `text` property. The following example registers the `myToolTipChanger()` method as a listener for the Button control’s `toolTipShow` event. The code in that method changes the value of the `ToolTipManager.currentToolTip.text` property to a value that is not known until run time.

```
<?xml version="1.0"?>
<!-- tooltips/DynamicToolTipText.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    initialize="initApp()">
  <fx:Script>
    <![CDATA[
     import mx.managers.ToolTipManager;
     import mx.controls.ToolTip;
     import mx.events.ToolTipEvent;
     import mx.core.FlexGlobals;
     public function initApp():void {
        b1.addEventListener(ToolTipEvent.TOOL_TIP_SHOW, myToolTipChanger)
     }

     public function myToolTipChanger(event:ToolTipEvent):void {
        /* Pass the value of myName in to your application as a flashVars variable.
           For example, on the query string. */
        ToolTipManager.currentToolTip.text = "Click the button, " +
           FlexGlobals.topLevelApplication.parameters.myName;
     }
    ]]>
  </fx:Script>
  <s:Button id="b1" label="Click Me" toolTip="Click the button."/>
</s:Application>
```

You can only create text for the current ToolTip in the `toolTipShow` event handler if the object had a ToolTip in the first place. For example, if the button in the previous example did not set a value for the `toolTip` property, no ToolTip would appear even after the `myToolTipChanger()` method was called.

For information about using the `FlexGlobals.topLevelApplication.application` object, see “Passing request data with flashVars properties” on page 229.

Creating custom ToolTips

The ToolTipManager has two methods that let you programmatically use ToolTips. These methods are `createToolTip()` and `destroyToolTip()`, which you use to create and destroy new ToolTip objects. When you create a ToolTip object, you can customize it as you would any object, with access to its properties, styles, events, and effects.

The `createToolTip()` method has the following signature:

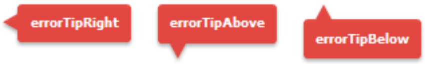
```
createToolTip(text:String, x:Number, y:Number, errorTipBorderStyle:String,
    context:IUIComponent):IToolTip
```

The *`text`* parameter defines the contents of the ToolTip.

The `x` and `y` parameters define the x and y coordinates of the ToolTip, relative to the application container.

The *`errorTipBorderStyle`* parameter sets the location of the pointer on the error tip. This parameter is optional. If you specify the value of the `errorTipBorderStyle` parameter in the `createToolTip()` method, Flex styles the ToolTip as an error tip. Valid values are `"errorTipRight"`, `"errorTipAbove"`, or `"errorTipBelow"`, and indicate the location of the error tip relative to the component. If you set the `errorTipBorderStyle` parameter to `null`, then the ToolTip is a normal ToolTip, not an error tip.

The following example shows the valid values and their resulting locations on the error tip:



The *`context`* parameter determines which StyleManager is used. Typically, you pass the object on which the ToolTip appears, so that the ToolTip's StyleManager is the same one use by that object. This object must be of type IUIComponent, so you might need to cast it in some cases, such as when you want to specify the context as the `event.currentTarget` in an event handler.

For more information about using error tips, see "Using error tips" on page 1954.

The `createToolTip()` method returns a new ToolTip object that implements the IToolTip interface. You typically cast the return value of this method to a ToolTip, although it is more efficient if you do not do this. To cast, you can do one of the following:

- Use the `as` keyword, as the following example shows:

  ```
  myTip = ToolTipManager.createToolTip(s,10,10) as ToolTip;
  ```

- Use the *type*`(`*object*`)` casting syntax, as the following example shows:

  ```
  myTip = ToolTip(ToolTipManager.createToolTip(s,10,10));
  ```

These methods of casting differ only in the way that they behave when a cast fails.

Flex displays the ToolTip until you destroy it. In general, you should not display more than one ToolTip box at a time, because it is confusing to the user.

You can use the `destroyToolTip()` method to destroy the specified ToolTip object. The `destroyToolTip()` method has the following signature:

```
destroyToolTip(toolTip:IToolTip):void
```

The *`toolTip`* parameter is the ToolTip object that you want to destroy. This is the object returned by the `createToolTip()` method.

The following example creates a custom ToolTip when you move the mouse over a Panel container that contains three Button controls. Each Button control has its own ToolTip that appears when you mouse over that particular control. The big ToolTip disappears only when you move the mouse away from the Panel container.

```
<?xml version="1.0"?>
<!-- tooltips/CreatingToolTips.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import mx.managers.ToolTipManager;
            import mx.controls.ToolTip;
            import mx.core.IUIComponent;
            public var myTip:ToolTip;
            private function createBigTip(event:Event):void {
               var s:String = "These buttons let you save, exit, or continue with the current
operation."
                myTip =
ToolTipManager.createToolTip(s,75,75,null,IUIComponent(event.currentTarget)) as ToolTip;
                myTip.setStyle("backgroundColor",0xFFCC00);
                myTip.width = 125;
                myTip.height = 75;
            }
            private function destroyBigTip():void {
                ToolTipManager.destroyToolTip(myTip);
            }
        ]]>
    </fx:Script>

    <fx:Style>
        @namespace s "library://ns.adobe.com/flex/spark";
        s|Panel {
            paddingLeft: 5;
            paddingRight: 5;
            paddingTop: 5;
            paddingBottom: 5;
        }
    </fx:Style>
    <s:Panel title="ToolTips" height="200" width="200" rollOver="createBigTip(event)"
rollOut="destroyBigTip()">
        <s:Button label="OK" y="20" toolTip="Save your changes and exit."/>
        <s:Button label="Apply" y="50" toolTip="Apply changes and continue."/>
        <s:Button label="Cancel" y="80" toolTip="Cancel and exit."/>
    </s:Panel>
</s:Application>
```

Customizing the current ToolTip

Another approach to customizing ToolTip objects is to intercept the current ToolTip and customize it rather than using the ToolTipManager to create a new ToolTip object.

You do this by customizing the ToolTip during one of the ToolTip-related events like `toolTipHide`, `toolTipShow`, and `toolTipShown`.

The following example triggers the customization on the ToolTip's `toolTipShown` event. This lets Flex handle all the logic for displaying and hiding the ToolTip, but lets you modify the current ToolTip's text, position, and other properties.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- tooltips/CustomToolTipInActionScript.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp();">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import spark.components.Button;
            import mx.core.IToolTip;
            import mx.events.ToolTipEvent;
            import mx.managers.ToolTipManager;
            import mx.core.FlexGlobals;

            public var myTip:IToolTip;
            public var b:Button;

            private function initApp():void {
                b = new Button();
                b.addEventListener("toolTipShown", createCustomTip);
                b.label = "Click Me";

                /* You must create a blank ToolTip so that the control
                   can dispatch ToolTip-related events. The new ToolTip
                   will replace this empty ToolTip. */
                b.toolTip = " ";
                addElement(b);
            }

            private function createCustomTip(e:ToolTipEvent):void {
                var s:String = "This is a ToolTip for the button.";
                myTip = ToolTipManager.currentToolTip;

                // Customize the text of the ToolTip.
                myTip.text = s;

                // Customize the alpha of the ToolTip.
                myTip.alpha = .6;

                // Customize the position of the ToolTip.
                myTip.x = FlexGlobals.topLevelApplication.mouseX + 20;
                myTip.y = FlexGlobals.topLevelApplication.mouseY;
            }
        ]]>
    </fx:Script>
</s:Application>
```

Implementing the IToolTip interface

You can also create a custom ToolTip by extending an existing control, such as a Panel or other container, and implementing the IToolTip interface. The following example uses a Panel container as the base for a new implementation of the IToolTip interface:

```
<?xml version="1.0"?>
<!-- tooltips/ToolTipComponents/PanelToolTip.mxml -->
<s:Panel
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    implements="mx.core.IToolTip"
    width="200"
    alpha=".75">
    <fx:Script>
        <![CDATA[
            [Bindable]
            public var bodyText:String = "";
            //  Implement required methods of the IToolTip interface; these
            //  methods are not used in this example, though.
            public var _text:String;
            public function get text():String {
                return _text;
            }
            public function set text(value:String):void {
            }
        ]]>
    </fx:Script>
    <s:RichText text="{bodyText}" percentWidth="100"/>
</s:Panel>
```

In your application, you can create a custom ToolTip by intercepting the `toolTipCreate` event handler of the target component. In the event handler, you instantiate the new ToolTip and set its properties. You then point the `toolTip` property of the ToolTipEvent object to the new ToolTip.

In the following example, the first two buttons in the application use the custom PanelToolTip class in the ToolTipComponents package. The third button uses a default ToolTip to show you how the two are different. To run this example, store the PanelToolTip.mxml file in a subdirectory named ToolTipComponents.

```
<?xml version="1.0"?>
<!-- tooltips/MainCustomApp.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import ToolTipComponents.PanelToolTip;
            import mx.events.ToolTipEvent;
         private function createCustomTip(title:String, body:String, event:ToolTipEvent):void
{
               var ptt:PanelToolTip = new PanelToolTip();
               ptt.title = title;
               ptt.bodyText = body;
               event.toolTip = ptt;
            }
        ]]>
    </fx:Script>

    <s:Button id="b1"
        label="Delete"
        toolTip=" "
        toolTipCreate="createCustomTip('DELETE','Click this button to delete the report.',
event)"
    />
    <s:Button id="b2"
        label="Generate"
        toolTip=" "
       toolTipCreate="createCustomTip('GENERATE','Click this button to generate the report.',
event)"
    />

    <s:Button id="b3"
        label="Stop"
        toolTip="Click this button to stop the creation of the report. This button uses a
standard ToolTip style."
    />
</s:Application>
```

Positioning custom ToolTips

When you use the ToolTipManager to create a custom ToolTip, you specify the coordinates of the ToolTip on the Stage. You do this by specifying the values of the `x` and `y` parameters of the new ToolTip in the `createToolTip()` method. These coordinates are relative to the Stage. For example, a value of 0,0 creates a ToolTip at the top-left corner of the application.

In some cases, you might not know the exact position that you want the ToolTip to be drawn in; instead, you want the location of the ToolTip to be relative to the target component (the component that has a ToolTip on it). In those cases, you can use the location of the target component to calculate the values of these coordinates. For example, if you want the ToolTip to appear to a component's right, you set the ToolTip's x position to be the x position of the component plus the component's width, plus some other value for an offset.

The following image shows the results of this formula:

You also set the value of the ToolTip's y position to be the same as the target component's y position to line the ToolTip and the component up horizontally.

One way to get the values you need to calculate the x position of the ToolTip is to use an event handler. Event objects passed to an event handler can give you the x position and the width of the target component.

The following example gets the value of the current target's `x`, `y`, and `width` properties in the focusIn event handler, and uses them to position the ToolTip. In this case, the current target is the TextInput control, and the ToolTip appears to its right with a 10-pixel offset.

```
<?xml version="1.0"?>
<!-- tooltips/PlacingToolTips.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    height="100" width="300">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
             import mx.controls.ToolTip;
             import mx.managers.ToolTipManager;
             import mx.core.IUIComponent;

             private var tip:ToolTip;
             private var s:String;

             private function showTip(event:Object):void {
                s="My ToolTip";
                // Position the ToolTip to the right of the current target.
                tip = ToolTipManager.createToolTip(s,
                    event.currentTarget.x + event.currentTarget.width + 10,
                    event.currentTarget.y, null,IUIComponent(event.currentTarget))
                    as ToolTip;
            }
            private function destroyTip(event:Object):void {
                 ToolTipManager.destroyToolTip(tip);
            }
        ]]>
    </fx:Script>
    <s:TextInput id="a"
        width="100"
        focusIn="showTip(event)"
        focusOut="destroyTip(event)"/>
    <s:TextInput id="b"
        width="100"
        focusIn="showTip(event)"
        focusOut="destroyTip(event)"/>
</s:Application>
```

The previous example creates a ToolTip on a target component that is not inside any containers. However, in many cases, your components will be inside layout containers such as a VGroup or an HGroup. Under these circumstances, the coordinates you access in the event handler will be relative to the container and not the main application. But the ToolTipManager expects global coordinates when positioning the ToolTip. This will position ToolTips in unexpected locations.

To avoid this, you can use the `contentToGlobal()` method to convert the coordinates in the event handler from local to global. All components that subclass UIComponent have this method. It takes a single Point that is relative to the target's enclosing container as an argument and returns a Point that is relative to the Stage.

The following example calls the TextInput control's `contentToGlobal()` method to convert the control's coordinates from those that are relative to the VGroup container to global coordinates.

```
<?xml version="1.0"?>
<!-- tooltips/PlacingToolTipsInContainers.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    height="400" width="600">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import mx.controls.ToolTip;
            import mx.managers.ToolTipManager;
            import mx.core.IUIComponent;
            private var tip:ToolTip;
            private var s:String;

            private function showTipA(event:Object):void {
                s="My Tip A";
                tip = ToolTipManager.createToolTip(s,
                    event.currentTarget.x + event.currentTarget.width + 10,
                    event.currentTarget.y) as ToolTip;
            }
            private function showTipB(event:Object):void {
                s="My Tip B";
                var pt:Point = new Point(0,0);

                /* Call this method to convert the object's
                   coordinates inside its container to the stage's
                   global coordinates. */
                pt = event.currentTarget.contentToGlobal(pt);

                tip = ToolTipManager.createToolTip(s,
                    pt.x + event.currentTarget.width + 10, pt.y, null,
                    IUIComponent(event.currentTarget)) as ToolTip;
            }
            private function destroyTip(event:Object):void {
                 ToolTipManager.destroyToolTip(tip);
            }
        ]]>
    </fx:Script>
    <!-- A ToolTip at the top level. -->
    <!-- The event handler for this ToolTip does not use any special
    logic to account for whether the ToolTip is inside a container.
    But this ToolTip is not inside a container so it positions itself
    normally. -->
    <s:TextInput id="a"
        text="Good ToolTip placement"
        width="175"
        focusIn="showTipA(event)"
        focusOut="destroyTip(event)"/>
    <s:VGroup>
        <!-- A ToolTip inside a container. -->
        <!-- The event handler for this ToolTip accounts for the control
        being inside a container and positions the ToolTip using the
        contentToGlobal() method. -->
        <s:TextInput id="b"
            text="Good ToolTip placement"
            width="175"
            focusIn="showTipB(event)"
            focusOut="destroyTip(event)"/>
        <!-- A ToolTip inside a container. -->
        <!-- The event handler for this ToolTip does not use any special
        logic to account for whether the ToolTip is inside a container.
        As a result, it positions itself using coordinates that are relative
        to the container, but that are not converted to global coordinates. -->

        <s:TextInput id="c"
            text="Bad ToolTip placement"
            width="175"
            focusIn="showTipA(event)"
            focusOut="destroyTip(event)"/>
    </s:VGroup>
</s:Application>
```

Using error tips

Error tips are instances of the ToolTip class that get their styles from the `errorTip` CSS class selector. They are most often seen when the Flex validation mechanism displays a warning when data is invalid. But you can use the definitions of the `errorTip` style and apply it to ToolTips to create a custom validation warning mechanism.

You can trigger an error tip to appear on any control when you set its `errorString` property to anything other than an empty String (“”).

The styles of an error tip are defined in the defaults.css file, which is in the framework.swc file. It specifies the following default settings for `errorTip` (notice the period preceding `errorTip`, which indicates that it is a class selector):

```
.errorTip {
    color: #FFFFFF;
    fontSize: 9;
    fontWeight: "bold";
    shadowColor: #000000;
    borderColor: #CE2929;
    borderStyle: "errorTipRight";
    paddingBottom: 4;
    paddingLeft: 4;
    paddingRight: 4;
    paddingTop: 4;
}
```

You can customize the appearance of error tips by creating a new theme that overrides these styles, or by overriding the style properties in your application. For more information on creating themes, see “About themes” on page 1561.

You can also set the `errorColor` property of any UIComponent. This defines the color of the “halo” around a component that has an error tip. The ErrorSkin class handles the logic that draws this glow around the target component.

You can create ToolTips that look like validation error tips by applying the `errorTip` style to the ToolTip. The following example does not contain any validation logic, but shows you how to use the `errorTip` style to create ToolTips that look like validation error tips. When you run the example, press the Enter key after entering text into the TextInput controls.

```
<?xml version="1.0"?>
<!-- tooltips/ErrorTipStyle.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <fx:Script>
    <![CDATA[
     import mx.controls.ToolTip;
     import mx.managers.ToolTipManager;
     import mx.core.IUIComponent;

     private var errorTip:ToolTip;
     private var myError:String;

     private function validateEntry(type:String, event:Object):void {
        if (errorTip) {
            resetApp();
        }

        // NOTE: Validation logic would go here.
        switch(type) {
           case "ssn":
            myError="Use SSN format (NNN-NN-NNNN)";
            break;
           case "phone":
            myError="Use phone format (NNN-NNN-NNNN)";
            break;
        }

        // Use the target's x and y positions to set position of error tip.
        trace("event.currentTarget.width" + event.currentTarget.width);
        trace("event.currentTarget.x" + event.currentTarget.x);

        errorTip = ToolTipManager.createToolTip(
          myError, event.currentTarget.x + event.currentTarget.width, event.currentTarget.y,
null, IUIComponent(event.currentTarget)) as ToolTip;

        // Apply the errorTip class selector.
        errorTip.setStyle("styleName", "errorTip");
     }

     private function resetApp():void {
        if (errorTip) {
            ToolTipManager.destroyToolTip(errorTip);
            errorTip = null;
        }
     }
    ]]>
  </fx:Script>
    <s:TextInput id="ssn" enter="validateEntry('ssn',event)"/>
    <s:TextInput id="phone" enter="validateEntry('phone',event)"/>
    <s:Label text="Press the enter key after entering text in each text input."/>
    <s:Button id="b1" label="Reset" click="resetApp()"/>
</s:Application>
```

Another way to use error tips is to set the value of the `errorString` property of the component. This causes the ToolTipManager to create an instance of a ToolTip and apply the `errorTip` style to that ToolTip without requiring any coding on your part.

The following example shows how to set the value of the `errorString` property to create an error tip without performing any validation:

```
<?xml version="1.0"?>
<!-- tooltips/ErrorString.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <fx:Script>
    <![CDATA[
     import mx.controls.ToolTip;
     import mx.managers.ToolTipManager;

     private var errorTip:ToolTip;
     private var myError:String;

     private function validateEntry(type:String, event:Object):void {
        // NOTE: Validation logic would go here.
        switch(type) {
           case "ssn":
            myError="Use SSN format";
            break;
           case "phone":
            myError="Use phone format";
            break;
        }
        event.currentTarget.errorString = myError;
     }
    ]]>
  </fx:Script>
  <s:TextInput id="ssn" enter="validateEntry('ssn',event)"/>
  <s:TextInput id="phone" enter="validateEntry('phone',event)"/>
</s:Application>
```

You can also specify that the ToolTipManager create an error tip when you call the `createToolTip()` method. You do this by specifying the value of the `createToolTip()` method's `errorTipBorderStyle` argument (the fourth argument), as the following example shows:

```
<?xml version="1.0"?>
<!-- tooltips/CreatingErrorTips.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import mx.managers.ToolTipManager;
            import mx.controls.ToolTip;
            import mx.core.IUIComponent;
            public var myTip:ToolTip;
            private function createBigTip(event:Event):void {
                var myError:String = "These buttons let you save, exit, or continue with the 
current operation.";
               // By setting the fourth argument ('errorTipBorderStyle:String') to a non-null 
value,
                // this ToolTip is created as an error tip.
                myTip = ToolTipManager.createToolTip(myError,
                    event.currentTarget.x + event.currentTarget.width,
                    event.currentTarget.y, "errorTipRight",
                    IUIComponent(event.currentTarget)) as ToolTip;
            }
            private function destroyBigTip():void {
                ToolTipManager.destroyToolTip(myTip);
            }
        ]]>
    </fx:Script>
    <fx:Style>
        @namespace s "library://ns.adobe.com/flex/spark";
        s|Panel {
            paddingLeft: 5;
            paddingRight: 5;
            paddingTop: 5;
            paddingBottom: 5;
        }
    </fx:Style>
    <s:Panel id="myPanel" title="ToolTips" rollOver="createBigTip(event)" 
rollOut="destroyBigTip()">
        <s:Button label="OK" y="20" toolTip="Save your changes and exit."/>
        <s:Button label="Apply" y="50" toolTip="Apply changes and continue."/>
        <s:Button label="Cancel" y="80" toolTip="Cancel and exit."/>
    </s:Panel>
</s:Application>
```

Note that if you set the value of the `errorTipBorderStyle` parameter to null, then a regular ToolTip, and not an error tip, is created.

For more information on using validators, see “Validating Data” on page 1964.

Reskinning ToolTips

You can apply a programmatic skin to ToolTip controls. This method of applying skins is consistent with the Halo component architecture. It does not use the rules that apply to the Spark component architecture.

ToolTip skins are defined by the ToolTipBorder programmatic skin. This file is located in the mx.skins.halo package.

To reskin ToolTips, you edit the ToolTipBorder class file, and then apply the new skin to the ToolTip by using CSS. For more information on skinning, see "Skinning MX components" on page 1655.

Reskin ToolTips by using CSS

1 Open the mx.skins.halo.ToolTipBorder.as file. This file is included with the source files, as described in "MX component skin resources" on page 1662.

2 Save the ToolTipBorder.as file under another name, and in a different location. The filename must be the same as the new class name.

3 Change the package from mx.skins.halo to your package name, or to the empty package, as the following example shows:

```
//package mx.skins.halo { // Old package name
package { // New, empty package
```

4 Change the class name in the file, as the following example shows:

```
//public class ToolTipBorder extends RectangularBorder // Old name
public class MyToolTipBorder extends RectangularBorder // New name
```

5 Change the constructor to reflect the new class name, as the following example shows:

```
//public function ToolTipBorder() // Old constructor
public function MyToolTipBorder() // New constructor
```

6 Comment out the versioning line, as the following example shows:

```
//include "../../core/Version.as";
```

7 Edit the class file to change the appearance of the ToolTip. You do this by editing the "toolTip" case in the `updateDisplayList()` method. That is the method that draws the ToolTip's border and sets the default styles. Most commonly, you change the arguments of the `drawRoundRect()` method to change the appearance of the ToolTip.

The following example adds a red tinge to the background of the ToolTip's box by replacing the default `backgroundColor` property with an array of colors:

```
var highlightAlphas:Array = [0.3,0.0];
drawRoundRect(3, 1, w-6, h-4, cornerRadius, [0xFF0000, 0xFFFFBB],
    backgroundAlpha);
```

The values of the `cornerRadius` and `backgroundAlpha` properties that are shown in the previous code snippet are set earlier in the `updateDisplayList()` method.

8 Save the class file.

9 In your application, edit the ToolTip's `borderSkin` style property to point to the new skin. You can do this in an `<fx:Style>` tag inside your application, or by using external CSS file or a custom theme file. The following example sets the `borderSkin` property to the new skin class:

```
<?xml version="1.0"?>
<!-- skins/ApplyCustomToolTipSkin.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

  <fx:Style>
     @namespace mx "library://ns.adobe.com/flex/mx";

     mx|ToolTip {
        borderSkin: ClassReference("MyToolTipBorder");
     }
  </fx:Style>
  <s:Button id="b1" label="Click Me" toolTip="Click this button"/>
</s:Application>
```

You must specify the full package name in the CSS reference. In this example, the file MyToolTipBorder.as is in an empty package and, therefore, has no package designation such as mx.skins.halo.

10 Compile and run the application with the new skin file in the source path. You do this by setting the value of the compiler's `source-path` option.

If the skin class is in the same directory as the application, you do not have to add its location to the source path. The current directory is assumed. For more information, see "Flex compilers" on page 2164.

Cursor Manager

The Cursor Manager in Adobe® Flex® lets you control the cursor image in your Flex application. You can use the Cursor Manager to provide visual feedback to users to indicate when to wait for processing to complete, to indicate allowable actions, or to provide other types of feedback. The cursor image can be a JPEG, GIF, PNG, or SVG image, a Sprite object, or a SWF file.

About the Cursor Manager

By default, Flex uses the system cursor as the application cursor. You control the system cursor by using the settings of your operating system.

The Flex Cursor Manager lets you control the cursor image in your Flex application. For example, if your application performs processing that requires the user to wait until the processing completes, you can change the cursor so that it reflects the waiting period. In this case, you can change the cursor to an hourglass or other image.

You also can change the cursor to provide feedback to the user to indicate the actions that the user can perform. For example, you can use one cursor image to indicate that user input is enabled, and another to indicate that input is disabled.

You can use a JPEG, GIF, PNG, or SVG image, a Sprite object, or a SWF file as the cursor image.

Creating and removing a cursor

To use the Cursor Manager, you import the mx.managers.CursorManager class into your application, and then reference its static properties and methods.

The Cursor Manager controls a prioritized list of cursors, where the cursor with the highest priority is currently visible. If the cursor list contains more than one cursor with the same priority, the Cursor Manager displays the most recently created cursor.

You create a new cursor, and set an optional priority for the cursor, by using the static `setCursor()` method of the CursorManager class. This method adds the new cursor to the cursor list. If the new cursor has the highest priority, it is displayed immediately. If the priority is lower than a cursor already in the list, it is not displayed until the cursor with the higher priority is removed.

To remove a cursor from the list, you use the static `removeCursor()` method. If the cursor is the currently displayed cursor, the Cursor Manager displays the next cursor in the list, if one exists. If the list ever becomes empty, the Cursor Manager displays the default system cursor.

The `setCursor()` method has the following signature:

```
public static setCursor(cursorClass:Class, priority:int = 2, xOffset:Number = 0,
yOffset:Number = 0):int
```

The following table describes the arguments for the `setCursor()` method:

Argument	**Description**	**Req/Opt**
cursorClass	The class name of the cursor to display.	Required
priority	The priority level of the cursor. Valid values are `CursorManagerPriority.HIGH`, `CursorManagerPriority.MEDIUM`, and `CursorManagerPriority.LOW`. The default value is 2, corresponding to `CursorManagerPriority.MEDIUM`.	Optional
xOffset	The x offset of the cursor relative to the mouse pointer. The default value is 0.	Optional
yOffset	The y offset of the cursor relative to the mouse pointer. The default value is 0.	Optional

This method returns the ID of the new cursor. You pass the ID to the `removeCursor()` method to delete the cursor. This method has the following signature:

```
static removeCursor(cursorID:int):void
```

***Note:** In AIR, each instance of the Window class uses its own instance of the CursorManager class. In an AIR application, instead of directly referencing the static methods and properties of the CursorManager class, use the `Window.cursorManager` property to reference the CursorManager instance for the Window instance.*

The following example changes the cursor to a custom *wait* or *busy* cursor while a large image file loads. After the load completes, the application removes the busy cursor and returns the cursor to the system cursor.

***Note:** The Flex framework includes a default busy cursor. For information on using this cursor, see "Using a busy cursor" on page 1962.*

```
<?xml version="1.0"?>
<!-- cursors\CursorManagerApp.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
            import mx.managers.CursorManager;
            import flash.events.*;

            // Define a variable to hold the cursor ID.
            private var cursorID:Number = 0;

            // Embed the cursor symbol.
            [Embed(source="assets/wait.jpg")]
            private var waitCursorSymbol:Class;

            // Define event listener to display the wait cursor
            // and to load the image.
            private function initImage(event:MouseEvent):void {
                // Set busy cursor.
                cursorID = CursorManager.setCursor(waitCursorSymbol);
                // Load large image.
                image1.source = "assets/DSC00034.JPG";
            }
            // Define an event listener to remove the wait cursor.
            private function loadComplete(event:Event):void {
                CursorManager.removeCursor(cursorID);
            }
        ]]>
    </fx:Script>
    <s:VGroup>
        <!-- Image control to load the image. -->
        <s:Image id="image1"
            height="50"
            width="100"
            complete="loadComplete(event);"/>
        <!-- Button triggers the load. -->
        <s:Button id="myButton" label="Show" click="initImage(event);"/>
    </s:VGroup>
</s:Application>
```

This example uses a JPEG image as the cursor image. You can also use a Sprite, or a PNG, GIF, SVG, or SWF file, as the following example shows:

```
[Embed(source="assets/wait.swf")]
var waitCursorSymbol:Class;
```

Or you can reference a symbol from a SWF file, as the following example shows:

```
[Embed(source="assets/cursorList.swf", symbol="wait")]
var waitCursorSymbol:Class;
```

An advantage of using a SWF file is that you can create an animated cursor.

Using a busy cursor

Flex defines a default busy cursor that you can use to indicate that your application is processing, and that users should wait until that processing completes before the application will respond to inputs. The default busy cursor is an animated clock.

You can control a busy cursor in several ways:

- You can use Cursor Manager methods to set and remove the busy cursor.
- You can use the `showBusyCursor` property of the SWFLoader, WebService, HttpService, and RemoteObject classes to automatically display the busy cursor.

Setting a busy cursor

The following static Cursor Manager methods control the busy cursor:

Method	Description
`setBusyCursor()`	Displays the busy cursor.
`removeBusyCursor()`	Removes the busy cursor from the cursor list. If other busy cursor requests are still active in the cursor list, which means that you called the `setBusyCursor()` method more than once, a busy cursor does not disappear until you remove all busy cursors from the list.

You can modify the example in "Creating and removing a cursor" on page 1959 to use the default busy cursor, as the following example shows:

```
<?xml version="1.0"?>
<!-- cursors\DefBusyCursorApp.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
            import mx.managers.CursorManager;
            import flash.events.*;

            private function initImage(event:MouseEvent):void {
                CursorManager.setBusyCursor();
                image1.source = "assets/DSC00034.JPG";
            }

            private function loadComplete(event:Event):void {
                CursorManager.removeBusyCursor();
            }
        ]]>
    </fx:Script>
    <s:VGroup>
        <!-- Image control to load the image. -->
        <s:Image id="image1"
            height="50"
            width="100"
            complete="loadComplete(event);"/>

        <!-- Button triggers the load. -->
        <s:Button id="myButton" label="Show" click="initImage(event);"/>
    </s:VGroup>
</s:Application>
```

Setting the busy cursor does not prevent a user from interacting with your application; a user can still enter text or select buttons. However, all containers support the `enabled` property. By default, this property is set to `true` to enable user interaction with the container and with the container's children. If you set the `enabled` property to `false` when you display a busy cursor, Flex dims the color of the container and of all of its children, and blocks user input to the container and to all of its children.

You can also disable user interaction for the entire application by setting the `FlexGlobals.topLevelApplication.enabled` property to `false`. If you are in a subclass or an ActionScript-only application, you must either explicitly import the mx.core.FlexGlobals class, or specify `mx.core.FlexGlobals.topLevelApplication.enabled` to set the property's value.

The busy cursor has a priority of `CursorManagerPriority.LOW`. Therefore, if the cursor list contains a cursor with a higher priority, the busy cursor does not appear until you remove the higher-priority cursor. To create a default busy cursor at a higher priority level, use the `setCursor()` method, as the following example shows:

```
<?xml version="1.0"?>
<!-- cursors\ShowBusyCursorAppHighP.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
            import mx.managers.CursorManager;
            import mx.managers.CursorManagerPriority;
            import flash.events.*;

            // Define a variable to hold the cursor ID.
            private var cursorID:Number = 0;

            // Define event listener to display the busy cursor
            // and to load the image.
            private function initImage(event:MouseEvent):void {
                // Set busy cursor.
                cursorID = CursorManager.setCursor(
styleManager.getStyleDeclaration("mx.managers.CursorManager").getStyle("busyCursor"),CursorM
anagerPriority.HIGH);
                // Load large image.
                image1.source = "assets/DSC00034.JPG";
            }
            // Define an event listener to remove the wait cursor.
            private function loadComplete(event:Event):void {
                CursorManager.removeCursor(cursorID);
            }
        ]]>
    </fx:Script>
    <s:VGroup>
        <!-- Image control to load the image. -->
        <s:Image id="image1"
            height="50"
            width="100"
            complete="loadComplete(event);"/>
        <!-- Button triggers the load. -->
        <s:Button id="myButton" label="Show" click="initImage(event);"/>
    </s:VGroup>
</s:Application>
```

This statement uses the `getStyleDeclaration()` method of the top-level StyleManager (accessed with the Application object's `styleManager` property) to get the CSSStyleDeclaration object for the Cursor Manager, and uses this object's `getStyle()` method to get the busy cursor, which it sets as a high priority cursor.

When you use this technique, you must also use the cursor ID in the `removeCursor()` method to remove the busy cursor.

Using the showBusyCursor property

The SWFLoader and MX Image controls, and the WebService, HTTPService, and RemoteObject classes, have a `showBusyCursor` property that automatically displays the default busy cursor until the class completes loading data. The default value is `false`.

The Spark Image control does not have a `showBusyCursor` property.

If you set the `showBusyCursor` property to `true`, Flex displays the busy cursor when the first `progress` event of the control is triggered, and hides the busy cursor when the `complete` event is triggered. The following example shows how you can simplify the example in the section "Setting a busy cursor" on page 1962 by using the `showBusyCursor` property of the MX Image control:

```
<?xml version="1.0"?>
<!-- cursors\ShowBusyCursorApp.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:VGroup>
        <!-- MX Image control to load the image. Note that the Spark
            Image control does not support the showBusyCursor property. -->
        <mx:Image id="image1"
            height="50"
            width="100"
            scaleContent="true"
            showBusyCursor="true"/>

        <!-- Button triggers the load. -->
        <s:Button id="myButton" label="Show"
            click="image1.load('../assets/DSC00034.JPG');"/>
    </s:VGroup>
</s:Application>
```

Validating Data

You use the Adobe® Flex™ data validation mechanism to validate the data in an application. Flex provides predefined validators for many common types of user-supplied data, such as date, number, and currency values.

Validating data

The data that a user enters in a user interface might or might not be appropriate to the application. In Flex, you use a *validator* to ensure the values in the fields of an object meet certain criteria. For example, you can use a validator to ensure that a user enters a valid phone number value, to ensure that a String value is longer than a set minimum length, or ensure that a ZIP code field contains the correct number of digits.

In typical client-server environments, data validation occurs on the server after data is submitted to it from the client. One advantage of using Flex validators is that they execute on the client, which lets you validate input data before transmitting it to the server. By using Flex validators, you eliminate the need to transmit data to and receive error messages back from the server, which improves the overall responsiveness of your application.

***Note:** Flex validators do not eliminate the need to perform data validation on the server, but provide a mechanism for improving performance by performing some data validation on the client.*

Flex includes a set of validators for common types of user input data, including the following:

- Validating credit card numbers
- Validating currency
- Validating dates
- Validating e-mail addresses
- Validating numbers
- Validating phone numbers
- Validating using regular expressions
- Validating social security numbers
- Validating strings
- Validating ZIP codes

You often use Flex validators with data models. For more information about data models, see “Storing data” on page 889.

About validators

You define validators by using MXML or ActionScript. In MXML, you declare a validator in an `<fx:Declarations>` tag. You define validators in an `<fx:Declarations>` tag because they are not visual components.

For example, to declare the standard PhoneNumberValidator validator, you use the `<mx:PhoneNumberValidator>` tag, as the following example shows:

```
<?xml version="1.0"?>
<!-- validators\PNValidator.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Declarations>
        <!-- Define the PhoneNumberValidator. -->
        <mx:PhoneNumberValidator id="pnV"
            source="{phoneInput}" property="text"/>
    </fx:Declarations>
    <!-- Define the TextInput control for entering the phone number. -->
    <s:TextInput id="phoneInput"/>
    <s:TextInput id="zipCodeInput"/>
</s:Application>
```

In the previous example, you enter a value into the TextInput control for the phone number. When you remove focus from the TextInput control by selecting the TextInput control for the ZIP code, the validator executes.

You use the source property of the validator to specify an object, and the property property to specify a field of the object to validate. For more information on the `source` and `property` properties, see “About the source and property properties” on page 1967.

In the previous example, the validator ensures that the user enters a valid phone number in the TextInput control. A valid phone number contains at least 10 digits, plus additional formatting characters. For more information, see “Validating phone numbers” on page 2000.

You declare validators in ActionScript either in a script block within an MXML file, or in an ActionScript file, as the following example shows:

```
<?xml version="1.0"?>
<!-- validators\PNValidatorAS.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            // Import PhoneNumberValidator.
            import mx.validators.PhoneNumberValidator;
            // Create the validator.
            private var v:PhoneNumberValidator = new PhoneNumberValidator();
            private function createValidator():void {
                // Configure the validator.
                v.source = phoneInput;
                v.property = "text";
            }
        ]]>
    </fx:Script>
    <!-- Define the TextInput control for entering the phone number. -->
    <s:TextInput id="phoneInput" creationComplete="createValidator();"/>
    <s:TextInput id="zipCodeInput"/>
</s:Application>
```

Spark and MX validators

Flex defines two sets of validators: Spark and MX. The Spark validators rely on the classes in the flash.globalization package. The flash.globalization classes use the locale data provided by the operating system. Therefore, Spark validators provide behavior that is consistent with the operating system and has access to all the locales supported by the operating system.

MX validators use the Flex ResourceManager to access locale-specific data from properties files that are included in the Flex SDK. The MX validators provide the same behavior across operating systems, but are limited to the locales provided by the Flex SDK or by the application developer.

The following table lists the Spark and MX validators. When possible, Adobe recommends that you use the Spark validators in your application:

Spark validator	**MX validator**	**Description**
	CreditCardValidator	Validate a credit card number.
CurrencyValidator	CurrencyValidator	Validate a currency value.
	DateValidator	Validate a date and time value.
	EmailValidator	Validate an email address.
NumberValidator	NumberValidator	Validate a numeric value.
	PhoneNumberValidator	Validate a phone number.
	SocialSecurityValidator	Validate a social security number.
	StringValidator	Validate a String value.
	ZipCodeValidator	Validate a U.S. or Canadian postal code.

Benefits of Spark validators

The Spark validators provides the following functionality:

- Locale-specific parsing of numbers and currency amounts.
- Locale-specific string comparison. For more information, see "Sorting and matching" on page 2062.
- Locale-specific uppercase and lowercase string conversion.
- Support non-European digits in a validation
- Validation of negative and positive formats of all numbers and currencies.
- Consistency with other applications running on the system.
- Operating system updates that include new locales or changes to existing locales are automatically supported.

The Spark validators use of the `locale` style property to select a locale. The `locale` style is an inheritable style that you can set for the entire application or specifically for a particular validator. Once set, the `locale` governs the validation provided by these classes.

If a Spark validator does not explicitly set the `locale` style, then it uses the value specified by the `locale` style of the application container. If you do not set the `locale` style property, the application uses the global default from the defaults.css style sheet, which defaults to `en`. For more information, see "Setting the locale" on page 2056.

You can explicitly configure the validator to use the default locale by setting the `locale` style to the constant value `flash.globalization.LocaleID.DEFAULT`.

About the source and property properties

Validators use the following two properties to specify the item to validate:

source Specifies the object containing the property to validate. Set this to an instance of a component or a data model. You use data binding syntax in MXML to specify the value for the `source` property. This property supports dot-delimited Strings for specifying nested properties.

property A String that specifies the name of the property of `source` that contains the value to validate.

You can set these properties in any of the following ways:

- In MXML when you use a validator tag.
- In ActionScript by assigning values to the properties.
- When you call the `validate()` method to invoke a validator programmatically. For more information, see "Triggering validation programmatically" on page 1973.

You often specify a Flex user-interface control as the value of the `source` property, and a property of the control to validate as the value of the `property` property, as the following example shows:

```
<?xml version="1.0"?>
<!-- validators\ZCValidator.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Declarations>
        <mx:ZipCodeValidator id="zipV"
            source="{myZip}"
            property="text"/>
    </fx:Declarations>

    <s:TextInput id="phoneInput"/>
    <s:TextInput id="myZip"/>
</s:Application>
```

In this example, you use the Flex ZipCodeValidator to validate the data entered in a TextInput control. The TextInput control stores the input data in its `text` property.

About triggering validation

You trigger validation either automatically in response to an event, or programmatically by an explicit call to the `validate()` method of a validator.

When you use events, you can cause the validator to execute automatically in response to a user action. For example, you can use the `click` event of a Button control to trigger validation on the fields of a form, or the `valueCommit` event of a TextInput control to trigger validation after a user enters information in the control. For more information, see "Triggering validation by using events" on page 1969.

You can also trigger a validation programmatically. For example, you might have to inspect multiple, related input fields to perform a single validation. Or you might have to perform conditional validation based on a user input. For example, you may allow a user to select the currency used for payment, such as U.S. dollars or Euros. Therefore, you want to make sure that you invoke a validator configured for the specified currency. In this case, you can make an explicit call to the `validate()` method to trigger the correct validator for the input value. For more information, see "Triggering validation programmatically" on page 1973.

About validating required fields

Flex validators can determine when a user enters an incorrect value into a user-interface control. In addition, all validators support the `required` property, which, if `true`, specifies that a missing or empty value in a user-interface control causes a validation error. The default value is `true`. Therefore, a validation error occurs by default if the user fails to enter any required data in a control associated with a validator. To disable this check, set the `required` property to `false`. For more information, see "Validating required fields" on page 1981.

About validation errors

If a validation error occurs, by default Flex draws a red box around the component associated with the failure. If the user moves the pointer over the component, Flex displays the error message associated with the error.

***Note:** For the Spark Form container, the error message appears in the help area of the Form container without you having to move the pointer over the component.*

You can customize the look of the component and the error message associated with the error. For more information on validation errors, see “Working with validation errors” on page 1986.

About validation events

Validation is event driven. You can use events to trigger validation, programmatically create and configure validators in response to events, and listen for events dispatched by validators.

For example, when a validation operation completes, a validator dispatches a `valid` or `invalid` event, depending on the results of the validation. You can listen for these events, and then perform any additional processing that your application requires.

Alternatively, Flex components dispatch `valid` and `invalid` events, depending on the results of the validation. This lets you listen for the events being dispatched from the component being validated, rather than listening for events dispatched by the validator.

You are not required to listen for validation events. By default, Flex handles a failed validation by drawing a red box around the control that is associated with the source of the data binding. For a successful validation, Flex clears any indicator of a previous failure. For more information, see “Working with validation events” on page 1990.

Using validators

Triggering validation by using events

You can trigger validators automatically by associating them with an event. In the following example, the user enters a ZIP code in a TextInput control, and then triggers validation by clicking the Button control:

```
<?xml version="1.0"?>
<!-- validators\ZCValidatorTriggerEvent.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Declarations>
        <mx:ZipCodeValidator id="zipV"
            source="{myZip}"
            property="text"
            trigger="{mySubmit}"
            triggerEvent="click"/>
    </fx:Declarations>
    <s:TextInput id="myZip"/>
    <s:Button id="mySubmit" label="Submit"/>
</s:Application>
```

This example uses the `trigger` and `triggerEvent` properties of the ZipCodeValidator class to associate an event with the validator. These properties have the following values:

trigger Specifies the component generating the event that triggers the validator. If omitted, by default Flex uses the value of the `source` property.

triggerEvent Specifies the event that triggers the validation. If omitted, Flex uses the `valueCommit` event. Flex dispatches the `valueCommit` event whenever the value of a control changes. Usually this is when the user removes focus from the component, or when a property value is changed programmatically. If you want a validator to ignore all events, set `triggerEvent` to an empty string (`""`).

For information on specific validator classes, see "Using standard validators" on page 1993.

Triggering validation by using the default event

You can rewrite the example from the previous section to use default values for the trigger and triggerEvent properties, as the following example shows:

```
<?xml version="1.0"?>
<!-- validators\ZCValidatorDefEvent.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Declarations>
        <mx:ZipCodeValidator id="zipV"
            source="{myZip}"
            property="text"/>
    </fx:Declarations>
    <s:TextInput id="myZip"/>
    <s:Button id="mySubmit" label="Submit"/>
</s:Application>
```

By omitting the `trigger` and `triggerEvent` properties, Flex triggers the validator when the TextInput control dispatches the `valueCommit` event. Flex controls dispatch the `valueCommit` event when its values changes by user interaction or programmatically.

Triggering validation for data bindings

Data binding provides a syntax for automatically copying the value of a property of one object to a property of another object at run time. With data binding, Flex copies the source value to the destination, typically in response to a modification to the source. The source and destination of data bindings are typically Flex components or data models.

In the next example, you bind data entered in a TextInput control to a data model so that the data in the TextInput control is automatically copied to the data model:

```
<?xml version="1.0"?>
<!-- validators\ValWithDataBinding.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Declarations>
        <!-- Define a data model for storing the phone number. -->
        <fx:Model id="userInfo">
            <phoneInfo>
                <phoneNum>{phoneInput.text}</phoneNum>
            </phoneInfo>
        </fx:Model>
    </fx:Declarations>
    <!-- Define the TextInput control for entering the phone number. -->
    <s:TextInput id="phoneInput"/>
    <s:TextInput id="zipCodeInput"/>
</s:Application>
```

You can use a validator along with a data binding to validate either the source or destination of the data binding, as the following example shows:

```
<?xml version="1.0"?>
<!-- validators\ValTriggerWithDataBinding.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Declarations>
        <!-- Define a data model for storing the phone number. -->
        <fx:Model id="userInfo">
            <phoneInfo>
                <phoneNum>{phoneInput.text}</phoneNum>
            </phoneInfo>
        </fx:Model>
        <!-- Define the PhoneNumberValidator. -->
        <mx:PhoneNumberValidator id="pnV"
            source="{phoneInput}"
            property="text"/>
    </fx:Declarations>
    <!-- Define the TextInput control for entering the phone number. -->
    <s:TextInput id="phoneInput"/>
    <s:TextInput id="zipCodeInput"/>
</s:Application>
```

This example uses a PhoneNumberValidator to validate the data entered in the TextInput control. In this example, the following occurs:

- You assign the validator to the source of the data binding.
- You use the default event, `valueCommit`, on the TextInput control to trigger the validator. This means the validator executes when the user removes focus from the TextInput control by selecting the TextInput control for the ZIP code.

- Flex updates the destination of the data binding on every change to the source. This means that the `userInfo.phoneNum` field updates on every change to the TextInput control, while the validator executes only when the user removes focus from the TextInput control to trigger the `valueCommit` event. You can use the validator's `triggerEvent` property to specify a different event to trigger the validation.

In a model-view-controller (MVC) design pattern, you isolate the model from the view and controller portions of the application. In the previous example, the data model represents the model, and the TextInput control and validator represents the view.

The TextInput control is not aware that its data is bound to the data model, or that there is any binding on it at all. Since the validator is also assigned to the TextInput control, you have kept the model and view portions of your application separate and can modify one without affecting the other.

However, there is nothing in Flex to prohibit you from assigning a validator to the data model, as the following example shows:

```
<?xml version="1.0"?>
<!-- validators\ValTriggerWithDataBindingOnModel.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Declarations>
        <!-- Define a data model for storing the phone number. -->
        <fx:Model id="userInfo">
            <phoneInfo>
                <phoneNum>{phoneInput.text}</phoneNum>
            </phoneInfo>
        </fx:Model>

        <!-- Define the PhoneNumberValidator. -->
        <mx:PhoneNumberValidator id="pnV"
            source="{userInfo}"
            property="phoneNum"
            trigger="{phoneInput}"
            listener="{phoneInput}"/>
    </fx:Declarations>
    <!-- Define the TextInput control for entering the phone number. -->
    <s:TextInput id="phoneInput"/>
    <s:TextInput id="zipCodeInput"/>
</s:Application>
```

In this example, you trigger the data validator by using the `valueCommit` event of the TextInput control, but assign the validator to a field of the data model, rather than to a property of the TextInput control.

This example also uses the `listener` property of the validator. This property configures the validator to display validation error information on the specified object, rather than on the source of the validation. In this example, the source of the validation is a model, so you display the visual information on the TextInput control that provided the data to the model. For more information, see "Specifying a listener for validation" on page 1989.

If the model has a nesting structure of elements, you use dot-delimited Strings with the `source` property to specify the model element to validate, as the following example shows:

```
<?xml version="1.0"?>
<!-- validators\ValTriggerWithDataBindingComplexModel.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Declarations>
        <!-- Define a data model for storing the phone number. -->
        <fx:Model id="userInfo">
            <user>
                <phoneInfo>
                    <homePhoneNum>{homePhoneInput.text}</homePhoneNum>
                    <cellPhoneNum>{cellPhoneInput.text}</cellPhoneNum>
                </phoneInfo>
            </user>
        </fx:Model>

        <!-- Define the PhoneNumberValidator. -->
        <mx:PhoneNumberValidator id="hPNV"
            source="{userInfo.phoneInfo}"
            property="homePhoneNum"
            trigger="{homePhoneInput}"
            listener="{homePhoneInput}"/>

        <!-- Define the PhoneNumberValidator. -->
        <mx:PhoneNumberValidator id="cPNV"
            source="{userInfo.phoneInfo}"
            property="cellPhoneNum"
            trigger="{cellPhoneInput}"
            listener="{cellPhoneInput}"/>
    </fx:Declarations>
    <!-- Define the TextInput controls for entering the phone number. -->
    <s:Label text="Home Phone:"/>
    <s:TextInput id="homePhoneInput"/>
    <s:Label text="Cell Phone:"/>
    <s:TextInput id="cellPhoneInput"/>
</s:Application>
```

Triggering validation programmatically

All validators define a `validate()` method that you can call to invoke a validator directly, rather than triggering the validator automatically by using an event.

The `validate()` method has the following signature:

```
validate(value:Object = null, supressEvents:Boolean = false):ValidationResultEvent
```

The arguments have the following values:

value If *`value`* is `null`, use the `source` and `property` properties to specify the data to validate. If `value` is non-null, it specifies a field of an object relative to the `this` keyword, which means an object in the scope of the document.

You should also set the `Validator.listener` property when you specify the `value` argument. When a validation occurs, Flex applies visual changes to the object specified by the listener property. By default, Flex sets the `listener` property to the value of the `source` property. However, because you do not specify the `source` property when you pass the value argument, you should set it explicitly. For more information, see “Specifying a listener for validation” on page 1989.

supressEvents If false, dispatch either the valid or invalid event on completion. If true, do not dispatch events.

This method returns an event object containing the results of the validation that is an instance of the ValidationResultEvent class. For more information on using the return result, see “Handling the return value of the validate() method” on page 1974.

In the following example, you create and invoke a validator programmatically in when a user clicks a Button control:

```
<?xml version="1.0"?>
<!-- validators\ValTriggerProg.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            // Import ZipCodeValidator.
            import mx.validators.ZipCodeValidator;
            private var v:ZipCodeValidator = new ZipCodeValidator();
            private function performValidation():void {
                v.domain = "US or Canada";
                // Set the listener property to the component
                // used to display validation errors.
                v.listener=myZip;
                v.validate(myZip.text);
            }
        ]]>
    </fx:Script>
    <s:TextInput id="myZip"/>
    <s:Button label="Submit" click="performValidation();"/>
</s:Application>
```

Notice that you are still using an event to trigger the performValidation() function that creates and invokes the validator, but the event itself does not automatically invoke the validator.

Any errors in the validator are shown on the associated component, just as if you had triggered the validation directly by using an event.

Handling the return value of the validate() method

You may want to inspect the return value from the validate() method to perform some action when the validation succeeds or fails. The validate() method returns an event object with a type defined by the ValidationResultEvent class.

The ValidationResultEvent class defines several properties, including the type property. The type property of the event object contains either ValidationResultEvent.VALID or ValidationResultEvent.INVALID, based on the validation results. You can use this property as part of your validation logic, as the following example shows:

```
<?xml version="1.0"?>
<!-- validators\ValTriggerProgProcessReturnResult.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            // Import the ValidationResultEvent class.
            import mx.events.ValidationResultEvent;
            import mx.validators.ZipCodeValidator;
            public var v:ZipCodeValidator = new ZipCodeValidator();
            // Define variable for storing the validation event object.
            public var vResult:ValidationResultEvent;
            public function performValidation():void {
                v.domain = "US or Canada";
                v.listener=myZip;
                vResult = v.validate(myZip.text);

                if (vResult.type==ValidationResultEvent.VALID) {
                    // Validation succeeded.
                    myTA.text='OK';
                }
                else {
                    // Validation failed.
                    myTA.text='Fail';
                }
            }
        ]]>
    </fx:Script>

    <s:TextInput id="myZip"/>
    <s:Button label="Submit" click="performValidation();"/>

    <s:TextArea id="myTA"/>
</s:Application>
```

The ValidationResultEvent class has additional properties that you can use when processing validation events. For more information, see “Working with validation events” on page 1990.

Triggering the DateValidator and CreditCardValidator

The DateValidator and CreditCardValidator can validate multiple fields by using a single validator. A CreditCardValidator examines one field that contains the credit card number and a second field that contains the credit card type. The DateValidator can examine a single field that contains a date, or multiple fields that together make up a date.

When you validate an object that contains multiple properties that are set independently, you often cannot use events to automatically trigger the validator because no single field contains all of the information required to perform the validation.

One way to validate a complex object is to call the `validate()` method of the validator based on some type of user interaction. For example, you might want to validate the multiple fields that make up a date in response to the `click` event of a Button control, as the following example shows:

```
<?xml version="1.0"?>
<!-- validators\DateAndCC.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Declarations>
        <!-- Define the data model. -->
        <fx:Model id="date">
            <dateInfo>
                <month>{monthInput.text}</month>
                <day>{dayInput.text}</day>
                <year>{yearInput.text}</year>
            </dateInfo>
        </fx:Model>

        <!-- Define the validators. -->
        <mx:DateValidator id="dayV"
            triggerEvent=""
            daySource="{dayInput}"
            dayProperty="text"
            monthSource="{monthInput}"
            monthProperty="text"
            yearSource="{yearInput}"
            yearProperty="text"/>
    </fx:Declarations>

    <!-- Define the form to populate the model. -->
    <s:Form>
        <s:TextInput id="monthInput"/>
        <s:TextInput id="dayInput"/>
        <s:TextInput id="yearInput"/>
    </s:Form>
    <!-- Define the button to trigger validation. -->
    <s:Button label="Submit"
        click="dayV.validate();"/>
</s:Application>
```

The validator in this example examines all three input fields. If any field is invalid, validation fails. The validator highlights only the invalid fields that failed. For more information on how validators signal validation errors, see “Working with validation errors” on page 1986. For more information on the DateValidator and CreditCardValidator, see “Using standard validators” on page 1993.

Invoking multiple validators in a function

You can invoke multiple validators programmatically from a single function. In this example, you use the ZipCodeValidator and PhoneNumberValidator validators to validate the ZIP code and phone number input to a data model.

```
<?xml version="1.0"?>
<!-- validators\ValidatorCustomFuncStaticVals.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[

            // Import event class.
            import mx.events.ValidationResultEvent;

            // Define variable for storing the validation event object.
            private var vResult:ValidationResultEvent;

            private function validateZipPhone():void {
                // Validate the ZIP code.
                vResult = zipV.validate();
                // If the ZIP code is invalid,
                // do not move on to the next field.
                if (vResult.type==ValidationResultEvent.INVALID)
                    return;

                // Validate the phone number.
                vResult = pnV.validate();
                // If the phone number is invalid,
                // do not move on to the validation.
                if (vResult.type==ValidationResultEvent.INVALID)
                    return;
            }
        ]]>
    </fx:Script>
    <fx:Declarations>
        <fx:Model id="person">
            <userInfo>
                <zipCode>{zipCodeInput.text}</zipCode>
                <phoneNumber>{phoneNumberInput.text}</phoneNumber>
            </userInfo>
        </fx:Model>
        <!-- Define the validators. -->
        <mx:ZipCodeValidator id="zipV"
            source="{zipCodeInput}"
            property="text"/>
        <mx:PhoneNumberValidator id="pnV"
            source ="{phoneNumberInput}"
            property="text"/>
    </fx:Declarations>

    <s:Form>
        <s:FormItem>
            <s:TextInput id="zipCodeInput"/>
        </s:FormItem>
        <s:FormItem>
            <s:TextInput id="phoneNumberInput"/>
        </s:FormItem>
    </s:Form>

    <s:Button label="Validate"
        click="validateZipPhone();"/>
</s:Application>
```

In this example, you use the predefined ZipCodeValidator and PhoneNumberValidator to validate user information as the user enters it. Then, when the user clicks the Submit button to submit the form, you validate that the ZIP code is actually within the specified area code of the phone number.

You can also use the static `validateAll()` method to invoke all of the validators in an Array. This method returns an Array containing one ValidationResultEvent object for each validator that failed, and an empty Array if all validators succeed. The following example uses this method to invoke two validators in response to the `click` event for the Button control:

```
<?xml version="1.0"?>
<!-- validators\ValidatorMultipleValids.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    creationComplete="initValidatorArray();">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import mx.validators.Validator;

            // Define the validator Array.
            private var myValidators:Array;
            private function initValidatorArray():void {
                myValidators=[zipV, pnV];
            }
        ]]>
    </fx:Script>
    <fx:Declarations>
        <fx:Model id="person">
            <userInfo>
                <zipCode>{zipCodeInput.text}</zipCode>
                <phoneNumber>{phoneNumberInput.text}</phoneNumber>
            </userInfo>
        </fx:Model>
        <!-- Define the validators. -->
        <mx:ZipCodeValidator id="zipV"
            source="{zipCodeInput}"
            property="text"/>
        <mx:PhoneNumberValidator id="pnV"
            source ="{phoneNumberInput}"
            property="text"/>
    </fx:Declarations>
    <s:Form>
        <s:FormItem>
            <s:TextInput id="zipCodeInput"/>
        </s:FormItem>
        <s:FormItem>
            <s:TextInput id="phoneNumberInput"/>
        </s:FormItem>
    </s:Form>
    <s:Button label="Validate"
        click="Validator.validateAll(myValidators);"/>
</s:Application>
```

Creating a reusable validator

You can define a reusable validator so that you can use it to validate multiple fields. To make it reusable, you programmatically set the `source` and `property` properties to specify the field to validate, or pass that information to the `validate()` method, as the following example shows:

```
<?xml version="1.0"?>
<!-- validators\ReusableVals.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import flash.events.Event;

            private function performValidation(eventObj:Event):void {
                zipV.listener=eventObj.currentTarget;
                zipV.validate(eventObj.currentTarget.text);
            }
        ]]>
    </fx:Script>
    <fx:Declarations>
        <mx:ZipCodeValidator id="zipV"
            triggerEvent=""/>
    </fx:Declarations>
    <s:TextInput id="shippingZip"
        focusOut="performValidation(event);"/>
    <s:TextInput id="billingZip"
        focusOut="performValidation(event);"/>
</s:Application>
```

In this example, you have two address areas for a customer: one for a billing address and one for a shipping address. Both addresses have a ZIP code field, so you can reuse a single ZipCodeValidator for both fields. The event listener for the `focusOut` event passes the field to validate to the `validate()` method.

Alternatively, you can write the `performValidation()` function as the following example shows:

```
<?xml version="1.0"?>
<!-- validators\ReusableValsSpecifySource.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import flash.events.Event;

            private function performValidation(eventObj:Event):void {
                zipV.source = eventObj.currentTarget;
                zipV.property = "text";
                zipV.validate();
            }
        ]]>
    </fx:Script>
    <fx:Declarations>
        <mx:ZipCodeValidator id="zipV"
            triggerEvent=""/>
    </fx:Declarations>
    <s:TextInput id="shippingZip"
        focusOut="performValidation(event);"/>
    <s:TextInput id="billingZip"
        focusOut="performValidation(event);"/>
</s:Application>
```

Conditionalizing validator execution

By invoking a validator programmatically, you can use conditional logic in your application to determine which of several validators to invoke, set validator properties, or perform other preprocessing or postprocessing as part of the validation.

In the next example, you use a Button control to invoke a validator, but the application first determines which validator to execute, based on user input:

```
<?xml version="1.0"?>
<!-- validators\ConditionalVal.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import mx.events.ValidationResultEvent;

            private var vEvent:ValidationResultEvent;

            private function validateData():void {
                if (String(country.selectedValue) == "Canada") {
                    vEvent = zipCN.validate(zipInput.text);
                }
                else {
                    vEvent = zipUS.validate(zipInput.text);
                }
            }
        ]]>
    </fx:Script>
    <fx:Declarations>
        <mx:ZipCodeValidator id="zipUS"
            domain="US Only"
            listener="{zipInput}"/>
        <mx:ZipCodeValidator id="zipCN"
            domain="Canada Only"
            listener="{zipInput}"/>

        <s:RadioButtonGroup id="country"/>
    </fx:Declarations>
    <s:RadioButton group="{country}" label="US"/>
    <s:RadioButton group="{country}" label="Canada"/>
    <s:TextInput id="zipInput"/>
    <s:Button label="Submit" click="validateData();"/>
</s:Application>
```

In this example, you use a ZipCodeValidator to validate a ZIP code entered into a TextInput control. However, the `validateData()` function must first determine whether the ZIP code is for the U.S. or for Canada before performing the validation. In this example, the application uses the RadioButton controls to let the user specify the country as part of entering the ZIP code.

Validating required fields

All Flex validators contain a `required` property that, when set to `true`, causes validation to fail when a field is empty. You use this property to configure the validator to fail when a user does not enter data in a required input field.

You typically call the `validate()` method to invoke a validator on a required field. This is often necessary because you cannot guarantee that an event occurs to trigger the validation—an empty input field often means that the user never gave the input control focus.

The following example performs a validation on a required input field:

```
<?xml version="1.0"?>
<!-- validators\RequiredVal.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Declarations>
        <mx:StringValidator id="reqV"
            source="{inputA}"
            property="text"
            required="true"/>
    </fx:Declarations>
    <s:TextInput id="inputA"/>
    <s:Button label="Submit"
        click="reqV.validate();"/>
</s:Application>
```

In this example, the StringValidator executes when the following occurs:

- The TextInput control dispatches the `valueCommit` event. However, to dispatch that event, the user must give the TextInput control focus, and then remove focus. If the user never gives the TextInput control focus, the validator does not trigger, and Flex does not recognize that the control is empty. Therefore, you must call the `validate()` method to ensure that the validator checks for missing data.
- The user clicks the Button control. The validator issues a validation error when the user does not enter any data into the TextInput control. It also issues a validation error if the user enters an invalid String value.

Enabling and disabling a validator

The `enabled` property of a validator lets you enable and disable a validator. When the value of the `enabled` property is `true`, the validator is enabled; when the value is `false`, the validator is disabled. When a validator is disabled, it dispatches no events, and the `validate()` method returns `null`.

For example, you can set the `enabled` property by using data binding, as the following code shows:

```
<?xml version="1.0"?>
<!-- validators\EnableVal.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            protected function enableV_clickHandler(event:MouseEvent):void {
                // If there is an existing error message,
                // remove it when disabling the validator.
                if (enableV.selected == false)
                    inputA.errorString = "";
            }
        ]]>
    </fx:Script>

    <fx:Declarations>
        <mx:ZipCodeValidator id="zcVal"
            source="{inputA}"
            property="text"
            required="true"
            enabled="{enableV.selected}"/>
    </fx:Declarations>
    <s:TextInput id="inputA"/>
    <s:TextInput/>
    <s:CheckBox id="enableV"
        label="Validate input?"
        click="enableV_clickHandler(event)"/>
</s:Application>
```

In this example, you enable the validator only when the user selects the CheckBox control.

Using data binding to configure validators

You configure validators to match your application requirements. For example, the StringValidator lets you specify a minimum and maximum length of a valid string. For a String to be considered valid, it must be at least the minimum number of characters long, and less than or equal to the maximum number of characters.

Often, you set validator properties statically, which means that they do not change as your application executes. For example, the following StringValidator defines that the input string must be at least one character long and no longer than 10 characters:

```
<mx:StringValidator required="true" minlength="1" maxLength="10"/>
```

User input might also define the properties of the validator. In the following example, you let the user set the minimum and maximum values of a NumberValidator:

```
<?xml version="1.0"?>
<!-- validators\ConfigWithBinding.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Declarations>
        <mx:NumberValidator
            source="{inputA}"
            property="text"
            minValue="{Number(inputMin.text)}"
            maxValue="{Number(inputMax.text)}"/>
    </fx:Declarations>
    <s:TextInput id="inputA"/>
    <s:TextInput id="inputMin" text="1"/>
    <s:TextInput id="inputMax" text="10"/>
</s:Application>
```

In this example, you use data binding to configure the properties of the validators.

General guidelines for validation

You should be aware of some guidelines when performing validation on forms. Typically, you associate forms with data models. That lets you trigger validation as part of binding an input user interface control to a field of the data model. You can also perform some of the following actions:

- If possible, assign validators to all the individual user-interface controls of the form. You can use a validator even if all that you want to do is to ensure that the user entered a value.
- Assign validators to multiple fields when necessary. For example, use the CreditCardValidator or the DateValidator with multiple fields.
- If you have any required fields, ensure that you explicitly call the `validate()` method on the validator. For more information, see “Validating required fields” on page 1981.
- Define a Submit button to invoke any validators before submitting data to a server. Typically, you use the `click` event of the Button control to invoke validators programmatically, and then submit the data if all validation succeeds.

The following example uses many of these guidelines to validate a form made up of several TextInput controls:

```
<?xml version="1.0"?>
<!-- validators\FullApp.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import mx.events.ValidationResultEvent;
            private var vResult:ValidationResultEvent;
            // Function to validate data and submit it to the server.
            private function validateAndSubmit():void           {
                // Validate the required fields.
                vResult = fNameV.validate();
                if (vResult.type==ValidationResultEvent.INVALID)
                    return;

                vResult = lNameV.validate();
                if (vResult.type==ValidationResultEvent.INVALID)
                    return;
                // Since the date requires 3 fields, perform the validation
                // when the Submit button is clicked.
                vResult = dayV.validate();
                if (vResult.type==ValidationResultEvent.INVALID)
                    return;

                // Invoke any other validators or validation logic to make
                // an additional check before submitting the data.
                // Submit data to server.
            }
        ]]>
    </fx:Script>
    <fx:Declarations>
        <!-- Define the data model. -->
        <fx:Model id="formInfo">
            <formData>
                <date>
                    <month>{monthInput.text}</month>
                    <day>{dayInput.text}</day>
                    <year>{yearInput.text}</year>
                </date>
                <name>
                    <firstName>{fNameInput.text}</firstName>
                    <lastName>{lNameInput.text}</lastName>
                </name>
                <phoneNum>{phoneInput.text}</phoneNum>
            </formData>
        </fx:Model>

        <!-- Define the validators. -->
        <mx:StringValidator id="fNameV"
            required="true"
            source="{fNameInput}"
            property="text"/>
        <mx:StringValidator id="lNameV"
```

```
            required="true"
            source="{lNameInput}"
            property="text"/>
        <mx:PhoneNumberValidator id="pnV"
            source="{phoneInput}"
            property="text"/>
        <!-- Invoke the DataValidator programmatically. -->
        <mx:DateValidator id="dayV"
            triggerEvent=""
            daySource="{dayInput}" dayProperty="text"
            monthSource="{monthInput}" monthProperty="text"
            yearSource="{yearInput}" yearProperty="text"/>
    </fx:Declarations>
    <!-- Define the form to populate the model. -->
    <s:Form>
        <s:FormItem label="Month">
            <s:TextInput id="monthInput"/>
        </s:FormItem>
        <s:FormItem label="Day">
            <s:TextInput id="dayInput"/>
        </s:FormItem>
        <s:FormItem label="Year">
            <s:TextInput id="yearInput"/>
        </s:FormItem>
        <s:FormItem label="First name">
            <s:TextInput id="fNameInput"/>
        </s:FormItem>
        <s:FormItem label="Last name">
            <s:TextInput id="lNameInput"/>
        </s:FormItem>
        <s:FormItem label="Phone">
            <s:TextInput id="phoneInput"/>
        </s:FormItem>
    </s:Form>
    <!-- Define the button to trigger validation. -->
    <s:Button label="Submit"
        click="validateAndSubmit();"/>
</s:Application>
```

In this example the following actions occur:

- The associated validator executes whenever the TextInput control dispatches a `valueCommit` event.
- The `click` event for the Button control invokes the `validateAndSubmit()` function to perform final validation before submitting data to the server.
- The `validateAndSubmit()` function invokes the validators for all required fields.
- The `validateAndSubmit()` function invokes the DateValidator because it requires three different input fields.
- Upon detecting the first validation error, the `validateAndSubmit()` function returns but does not submit the data.
- When all validations succeed, the `validateAndSubmit()` function submits the data to the server.

Working with validation errors

Subclasses of the UIComponent base class, which include the Flex user-interface components, generally handle validation failures by changing their border color and displaying an error message. When validation succeeds, components hide any existing validation error message and remove any border.

You can configure the content of the error messages and the display characteristics of validation errors.

Configuring error messages

All Flex validators define default error messages. In most cases, you can override these messages with your own.

The default error messages for all validators are defined by using resource bundles so that you can easily change them as part of localizing your application. You can override the default value of an error message for all validator objects created from a validator class by editing the resource bundles associated with that class.

You edit the error message for a specific validator object by writing a String value to a property of the validator. For example, the PhoneNumberValidator defines a default error message to indicate that an input phone number has the wrong number of digits. You can override the default error message for a specific PhoneNumberValidator object by assigning a new message string to the `wrongLengthError` property, as the following example shows:

```
<?xml version="1.0"?>
<!-- validators\PNValidatorErrMessage.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Declarations>
        <!-- Define the PhoneNumberValidator. -->
        <mx:PhoneNumberValidator id="pnV"
            source="{phoneInput}" property="text"
            wrongLengthError="Please enter a 10-digit number."/>
    </fx:Declarations>
    <!-- Define the TextInput control for entering the phone number. -->
    <s:TextInput id="phoneInput"/>
    <s:TextInput id="zipCodeInput"/>
</s:Application>
```

Changing the display of the validation error and error message

By default, the validation error message that appears when you move the mouse pointer over a user-interface control has a red background. You can use the `errorTip` style to change the color, as the following example shows:

```
<?xml version="1.0"?>
<!-- validators\PNValidatorErrMessageStyle.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <!-- Use blue for the error message. -->
    <fx:Style>
        .errorTip { borderColor: #0000FF}
    </fx:Style>
    <fx:Declarations>
        <!-- Define the PhoneNumberValidator. -->
        <mx:PhoneNumberValidator id="pnV"
            source="{phoneInput}" property="text"
            wrongLengthError="Please enter a 10-digit number."/>
    </fx:Declarations>
    <!-- Define the TextInput control for entering the phone number. -->
    <s:TextInput id="phoneInput"/>
    <s:TextInput id="zipCodeInput"/>
</s:Application>
```

In this example, the error message appears in blue.

For Spark components, when a validation error occurs, Flex uses the spark.skins.default.ErrorSkin skin class to draw a red box around the component associated with the failure. You can define a custom skin class to control the display of the validation error. If you define a custom skin class, set the `errorSkin` style of the Spark component that you are validating to the skin class.

Showing a validation error by using errorString

The UIComponent class defines the `errorString` property that you can use to show a validation error for a component, without actually using a validator class. When you write a String value to the `UIComponent.errorString` property, Flex draws a red border around the component to indicate the validation error, and the String appears in a ToolTip as the validation error message when you move the mouse over the component, just as if a validator detected a validation error.

To clear the validation error, write an empty String, " ", to the `UIComponent.errorString` property.

***Note:** Writing a value to the `UIComponent.errorString` property does not trigger the `valid` or `invalid` events; it only changes the border color and displays the validation error message.*

For information on writing custom ToolTip controls, see “ToolTip controls” on page 1933.

Clearing a validation error

The `errorString` property is useful when you want to reset a field that is a source for validation, and prevent a validation error from occurring when you reset the field.

For example, you might provide a form to gather user input. Within your form, you might also provide a button, or other mechanism, that lets the user reset the form. However, clearing form fields that are tied to validators could trigger a validation error. The following example uses the `errorString` property as part of resetting the `text` property of a TextInput control to prevent validation errors when the form resets:

```
<?xml version="1.0"?>
<!-- validators\ResetVal.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import mx.events.ValidationResultEvent;
            private var vResult:ValidationResultEvent;

            // Function to validate data and submit it to the server.
            private function validateAndSubmit():void {
                // Validate the required fields.
                vResult = zipV.validate();
                if (vResult.type==ValidationResultEvent.INVALID)
                    return;

                // Submit data to server.
            }
            // Clear the input controls and the errorString property
            // when resetting the form.
            private function resetForm():void {
                zipInput.text = '';
                zipInput.errorString = '';
            }
        ]]>
    </fx:Script>
    <fx:Declarations>
        <mx:ZipCodeValidator id="zipV"
            source="{zipInput}"
            property="text"/>
    </fx:Declarations>
    <s:Form>
        <s:FormItem label="Enter ZIP code">
            <s:TextInput id="zipInput"/>
        </s:FormItem>
        <s:FormItem label="Enter Country">
            <s:TextInput id="cntryInput"/>
        </s:FormItem>
    </s:Form>
    <!-- Trigger submit. -->
    <s:Button label="Submit" click="validateAndSubmit();"/>

    <!-- Trigger reset. -->
    <s:Button label="Reset" click="resetForm();"/>
</s:Application>
```

In this example, the function that clears the form items also clears the `errorString` property associated with each item, clearing any validation errors.

Specifying a listener for validation

All validators support a listener property. When a validation occurs, Flex applies visual changes to the object specified by the `listener` property.

By default, Flex sets the `listener` property to the value of the source property. That means that all visual changes that occur to reflect a validation event occur on the component being validated. However, you might want to validate one component but have validation results apply to a different component, as the following example shows:

```
<?xml version="1.0"?>
<!-- validators\SetListener.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Declarations>
        <mx:ZipCodeValidator id="zipV"
            source="{zipCodeInput}"
            property="text"
            listener="{errorMsg}"/>
    </fx:Declarations>
    <s:TextInput id="zipCodeInput"/>
    <s:TextArea id="errorMsg"/>
</s:Application>
```

Working with validation events

Flex gives you two ways to listen for validation events:

1 Listen for validation events dispatched by the component being validated.

Flex components dispatch `valid` and `invalid` events, depending on the results of the validation. This lets you listen for the events being dispatched from the component being validated, and perform any additional processing on the component based on its validation result.

The event object passed to the event listener is of type Event. For more information, including an example, see "Explicitly handling component validation events" on page 1990.

2 Listen for validation events dispatched by validators.

All validators dispatch `valid` or `invalid` events, depending on the results of the validation. You can listen for these events, and then perform any additional processing as required by your validator.

The event object passed to the event listener is of type ValidationResultEvent. For more information, including an example, see "Explicitly handing validator validation events" on page 1991.

You are not required to listen for validation events. When these events occur, by default, Flex changes the appropriate border color of the target component, displays an error message for an `invalid` event, or hides any previous error message for a `valid` event.

Explicitly handling component validation events

Sometimes you might want to perform some additional processing for a component if a validation fails or succeeds. In that case, you can handle the `valid` and `invalid` events yourself. The following example defines an event listener for the `invalid` event to perform additional processing when a validation fails:

```
<?xml version="1.0"?>
<!-- validators\ValCustomEventListener -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            // Import event class.
            import flash.events.Event;

            // Define vars for storing text colors.
            private var errorTextColor:Object = "red";
            private var currentTextColor:Object;

            // Initialization event handler for getting default text color.
            private function myCreationComplete(eventObj:Event):void {
                currentTextColor = getStyle('color');
            }

            // For an invalid event, change the text color.
            private function handleInvalidVal(eventObject:Event):void {
                setStyle('color', errorTextColor);
            }
            // For a valid event, restore the text color.
            private function handleValidVal(eventObject:Event):void {
                setStyle('color', currentTextColor);
            }
        ]]>
    </fx:Script>
    <fx:Declarations>
        <mx:PhoneNumberValidator source="{phoneInput}" property="text"/>
    </fx:Declarations>
    <s:TextInput id="phoneInput"
        initialize="myCreationComplete(event);"
        invalid="handleInvalidVal(event);"
        valid="handleValidVal(event);"/>
    <s:TextInput id="zipInput"/>
</s:Application>
```

Explicitly handing validator validation events

To explicitly handle the `valid` and `invalid` events dispatched by validators, define an event listener, as the following example shows:

```
<?xml version="1.0"?>
<!-- validators\ValEventListener.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            // Import event class
            import mx.events.ValidationResultEvent;

            private function handleValid(event:ValidationResultEvent):void {
                if(event.type==ValidationResultEvent.VALID)
                    submitButton.enabled = true;
                else
                    submitButton.enabled = false;
            }
            // Submit form is everything is valid.
            private function submitForm():void {
                // Handle submit.
            }
        ]]>
    </fx:Script>
    <fx:Declarations>
        <mx:ZipCodeValidator
            source="{inputZip}" property="text"
            valid="handleValid(event);"
            invalid="handleValid(event);"/>
    </fx:Declarations>
    <s:TextInput id="inputZip"/>
    <s:TextInput id="inputPn"/>
    <s:Button id="submitButton"
        label="Submit"
        enabled="false"
        click="submitForm();"/>
</s:Application>
```

In this example, the Button control is disabled until the TextInput field contains a valid ZIP code. The `type` property of the event object is either `ValidationResultEvent.VALID` or `ValidationResultEvent.INVALID`, based on the result of the validation.

Within the event listener, you can use all the properties of the ValidationResultEvent class, including the following:

field A String that contains the name of the field that failed validation and triggered the event.

message A String that contains all the validator error messages created by the validation.

results An Array of ValidationResult objects, one for each field examined by the validator. For a successful validation, the `ValidationResultEvent.results` Array property is empty. For a validation failure, the `ValidationResultEvent.results` Array property contains one ValidationResult object for each field checked by the validator, both for fields that failed the validation and for fields that passed. Examine the `ValidationResult.isError` property to determine if the field passed or failed the validation.

Using standard validators

Flex includes the Validator subclasses. You use these validators for common types of data, including credit card numbers, dates, e-mail addresses, numbers, phone numbers, Social Security numbers, strings, and ZIP codes.

Validating credit card numbers

The CreditCardValidator class validates that a credit card number is the correct length, has the correct prefix, and passes the Luhn mod10 algorithm for the specified card type. This validator does not check whether the credit card is an actual active credit card account.

You typically use the `cardNumberSource` and `cardNumberProperty` properties to specify the location of the credit card number, and the `cardTypeSource` and `cardTypeProperty` properties to specify the location of the credit card type to validate.

The CreditCardValidator class validates that a credit card number is the correct length for the specified card type, as follows:

- Visa: 13 or 16 digits
- MasterCard: 16 digits
- Discover: 16 digits
- American Express: 15 digits
- DinersClub: 14 digits, or 16 digits if it also functions as a MasterCard

You specify the type of credit card number to validate by assigning a constant to the `cardTypeProperty` property. In MXML, valid constant values are:

- `"American Express"`
- `"Diners Club"`
- `"Discover"`
- `"MasterCard"`
- `"Visa"`

In ActionScript, you can use the following constants to set the `cardTypeProperty` property:

- `CreditCardValidatorCardType.AMERICAN_EXPRESS`
- `CreditCardValidatorCardType.DINERS_CLUB`
- `CreditCardValidatorCardType.DISCOVER`
- `CreditCardValidatorCardType.MASTER_CARD`
- `CreditCardValidatorCardType.VISA`

The following example validates a credit card number based on the card type that the users specifies. Any validation errors propagate to the Application object and open an Alert window.

```
<?xml version="1.0"?>
<!-- validators\CCExample.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Declarations>
        <mx:CreditCardValidator id="ccV"
            cardTypeSource="{cardTypeCombo.selectedItem}"
            cardTypeProperty="data"
            cardNumberSource="{cardNumberInput}"
            cardNumberProperty="text"/>
    </fx:Declarations>

    <s:Form id="creditCardForm">
        <s:FormItem label="Card Type">
            <s:ComboBox id="cardTypeCombo">
                <s:dataProvider>
                    <s:ArrayList>
                        <fx:Object label="American Express"
                            data="American Express"/>
                        <fx:Object label="Diners Club"
                            data="Diners Club"/>
                        <fx:Object label="Discover"
                            data="Discover"/>
                        <fx:Object label="MasterCard"
                            data="MasterCard"/>
                        <fx:Object label="Visa"
                            data="Visa"/>
                    </s:ArrayList>
                </s:dataProvider>
            </s:ComboBox>
        </s:FormItem>
        <s:FormItem label="Credit Card Number">
            <s:TextInput id="cardNumberInput"/>
        </s:FormItem>
        <s:FormItem>
            <s:Button label="Check Credit" click="ccV.validate();"/>
        </s:FormItem>
    </s:Form>
</s:Application>
```

The following example performs a similar validation, but uses the `source` and `property` properties to specify an object that contains the credit card information. In this example, you use the `listener` property to configure the validator to display validation error information on the TextInput control:

```
<?xml version="1.0"?>
<!-- validators\CCExampleSource.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            [Bindable]
            public var ccObj:Object = {cardType:String, cardNumber:String};

            public function valCC():void
            {
                // Populate ccObj with the data from the form.
                ccObj.cardType = cardTypeCombo.selectedItem.data;
                ccObj.cardNumber = cardNumberInput.text;
                // Validate ccObj.
                ccV.validate();
            }
        ]]>
    </fx:Script>
    <fx:Declarations>
        <mx:CreditCardValidator id="ccV"
            source="{this}"
            property="ccObj"
            listener="{cardNumberInput}"/>
    </fx:Declarations>

    <s:Form id="creditCardForm">
        <s:FormItem label="Card Type">
            <s:ComboBox id="cardTypeCombo">
                <s:dataProvider>
                    <s:ArrayList>
                        <fx:Object label="American Express"
                            data="American Express"/>
                        <fx:Object label="Diners Club"
                            data="Diners Club"/>
                        <fx:Object label="Discover"
                            data="Discover"/>
                        <fx:Object label="MasterCard"
                            data="MasterCard"/>
                        <fx:Object label="Visa"
                            data="Visa"/>
                    </s:ArrayList>
                </s:dataProvider>
            </s:ComboBox>
        </s:FormItem>
        <s:FormItem label="Credit Card Number">
            <s:TextInput id="cardNumberInput"/>
        </s:FormItem>
        <s:FormItem>
            <s:Button label="Check Credit" click="valCC();"/>
        </s:FormItem>
    </s:Form>
</s:Application>
```

Validating currency

The Spark CurrencyValidator class checks that a string is a valid currency expression based on a set of parameters and the current `locale`. The CurrencyValidator class defines the properties that let you specify the format of the currency value, whether to allow negative values, and the precision of the values, and other options.

The digits of the input String can use national digits defined in the flash.globalization.NationalDigitsType class.

The following example uses the CurrencyValidator class to validate a currency value entered in U.S. dollars and in Euros:

```
<?xml version="1.0"?>
<!-- validators\SparkCurrencyExample.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout paddingTop="10" paddingLeft="10"/>
    </s:layout>

    <fx:Declarations>
        <!-- Example for US currency. -->
        <s:CurrencyValidator id="usV"
            locale="en-US"
            source="{priceUS}" property="text"
            trigger="{valButton}"
            triggerEvent="click"/>

        <!-- Example for European currency. -->
        <s:CurrencyValidator id="eurV"
            locale="fr-FR"
            source="{priceEU}" property="text"
            trigger="{valButton}"
            triggerEvent="click"/>
    </fx:Declarations>

    <s:Label text="Enter a US-formatted price:"/>
    <s:TextInput id="priceUS"/>

    <s:Label text="Enter a European-formatted price:"/>
    <s:TextInput id="priceEU"/>

    <s:Button id="valButton" label="Validate Currencies"/>
</s:Application>
```

In this example, you explicitly specify the `locale` for the two validators, rather than relying on the default. Use the first validator to validate currency values for a U.S. locale. Acceptable values include: $23.00, USD 23.00, or 123,456.00. Invalid values include: 2,37 EUR and €2.37.

The second validator specifies the `locale` as fr-FR for French currencies. Valid values include: 2,37, 2,37 EUR, and €2.37. Invalid values include: $23.00 and USD 23.00.

Validating dates

The DateValidator class validates that a String, Date, or Object contains a proper date and matches a specified format. Users can enter a single digit or two digits for month, day, and year. By default, the validator ensures that the following information is provided:

- The month is between 1 and 12 (or 0-11 for Date objects)
- The day is between 1 and 31
- The year is a number

If you specify a single String to validate, the String can contain digits and the formatting characters that the `allowedFormatChars` property specifies, including the slash (/), backslash (\), dash (-), and period (.) characters. By default, the input format of the date in a String is “mm/dd/yyyy” where “mm” is the month, “dd” is the day, and “yyyy” is the year. You can use the `inputFormat` property to specify a different format.

You can also specify to validate a date represented by a single Object, or by multiple fields of different objects. For example, you could use a data model that contains three fields that represent the day, month, and year portions of a date, or three TextInput controls that let a user enter a date as three separate fields. Even if you specify a date format that excludes a day, month, or year element, you must specify all three fields to the validator.

The following table describes how to specify the date to the DateValidator:

Validation source	Required properties	Default listener
String object containing the date	Use the `source` and `property` properties to specify the String.	Flex associates error messages with the field specified by the `property` property.
Date object containing the date	Use the `source` and `property` properties to specify the Date.	Flex associates error messages with the field specified by the `property` property.
Object or multiple fields containing the day, month, and year	Use all of the following properties to specify the day, month, and year inputs: `daySource`, `dayProperty`, `monthSource`, `monthProperty`, `yearSource`, and `yearProperty`.	Flex associates error messages with the field specified by the `daySource`, `monthSource`, and `yearSource` properties, depending on the field that caused the validation error.

The following example validates a date entered into a form:

```
<?xml version="1.0"?>
<!-- validators\DateExample.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Declarations>
        <mx:DateValidator id="dateV"
            daySource="{dayInput}" dayProperty="text"
            monthSource="{monthInput}" monthProperty="text"
            yearSource="{yearInput}" yearProperty="text"/>

        <!-- Alternate method for a single field containing the date. -->
        <fx:Model id="alternateDate">
            <dateInfo>
                <date>{dateInput.text}</date>
            </dateInfo>
        </fx:Model>
        <mx:DateValidator id="stringDateV"
            source="{dateInput}" property="text"
            inputFormat="dd/mm/yyyy"
            allowedFormatChars="*#~/"/>
    </fx:Declarations>
    <s:Form >
        <s:FormItem label="Month">
            <s:TextInput id="monthInput"/>
        </s:FormItem>
        <s:FormItem label="Day">
            <s:TextInput id="dayInput"/>
        </s:FormItem>
        <s:FormItem label="Year">
            <s:TextInput id="yearInput"/>
        </s:FormItem>
        <s:FormItem>
            <s:Button label="Check Date" click="dateV.validate();"/>
        </s:FormItem>
    </s:Form>
    <s:Form>
        <s:FormItem label="Date of Birth (dd/mm/yyyy)">
            <s:TextInput id="dateInput"/>
        </s:FormItem>
        <s:FormItem>
            <s:Button label="Check Date" click="stringDateV.validate();"/>
        </s:FormItem>
    </s:Form>
</s:Application>
```

In the next example, you validate a Date object:

```
<?xml version="1.0"?>
<!-- validators\DateObjectExample.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
            import mx.controls.Alert;
            // myDate is set to the current date and time.
            [Bindable]
            public var myDate:Date = new Date();
        ]]>
    </fx:Script>
    <fx:Declarations>
        <mx:DateValidator id="dateV"
            source="{this}" property="myDate"
            valid="Alert.show('Validation Succeeded!');"/>
    </fx:Declarations>
    <s:Button label="Check Date" click="dateV.validate();"/>
</s:Application>
```

Validating e-mail addresses

The EmailValidator class validates that a string has an at sign character (@) and a period character (.) in the domain. You can use IP domain names if they are enclosed in square brackets; for example, myname@[206.132.22.1]. You can use individual IP numbers from 0 to 255. This validator does not check whether the domain and user name actually exist.

The following example validates an e-mail address to ensure that it is formatted correctly:

```
<?xml version="1.0"?>
<!-- validators\EmailExample.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:Form id="contactForm">
        <s:FormItem id="homePhoneItem" label="Home Phone">
            <s:TextInput id="homePhoneInput"/>
        </s:FormItem>
        <s:FormItem id="cellPhoneItem" label="Cell Phone">
            <s:TextInput id="cellPhoneInput"/>
        </s:FormItem>
        <s:FormItem id="emailItem" label="Email">
            <s:TextInput id="emailInput"/>
        </s:FormItem>
    </s:Form>
    <fx:Declarations>
        <mx:PhoneNumberValidator id="pnVHome"
            source="{homePhoneInput}" property="text"/>
        <mx:PhoneNumberValidator id="pnVCell"
            source="{cellPhoneInput}" property="text"/>
        <mx:EmailValidator id="emV"
            source="{emailInput}" property="text"/>
    </fx:Declarations>
</s:Application>
```

Validating numbers

The Spark NumberValidator class ensures that a string represents a valid number for the current `locale`. This validator can ensure that the input falls within a given range, is an integer, is non-negative, does not exceed a specified precision, and other options. The NumberValidator also correctly validates formatted numbers (for example, "12,345.67").

The digits of the input String can use national digits defined in the flash.globalization.NationalDigitsType class.

The following example uses the NumberValidator class to ensure that an integer is between 1 and 10:

```
<?xml version="1.0"?>
<!-- validators\SparkNumberExample.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    width="700">

    <s:Form >
        <s:FormItem
            label="Number of Widgets (max 10 per customer)">
            <s:TextInput id="quantityInput"/>
        </s:FormItem>
        <s:FormItem >
            <s:Button label="Submit"/>
        </s:FormItem>
    </s:Form>

    <fx:Declarations>
        <s:NumberValidator id="numV"
            source="{quantityInput}" property="text"
            minValue="1" maxValue="10" domain="int"/>
    </fx:Declarations>
</s:Application>
```

Validating phone numbers

The PhoneNumberValidator class validates that a string is a valid phone number. A valid phone number contains at least 10 digits, plus additional formatting characters. This validator does not check if the phone number is an actual active phone number.

The following example uses two PhoneNumberValidator tags to ensure that the home and mobile phone numbers are entered correctly:

```
<?xml version="1.0"?>
<!-- validators\PhoneExample.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:Form id="contactForm">
        <s:FormItem id="homePhoneItem" label="Home Phone">
            <s:TextInput id="homePhoneInput"/>
        </s:FormItem>
        <s:FormItem id="cellPhoneItem" label="Cell Phone">
            <s:TextInput id="cellPhoneInput"/>
        </s:FormItem>
        <s:FormItem id="emailItem" label="Email">
            <s:TextInput id="emailInput"/>
        </s:FormItem>
    </s:Form>
    <fx:Declarations>
        <mx:PhoneNumberValidator id="pnVHome"
            source="{homePhoneInput}" property="text"/>
        <mx:PhoneNumberValidator id="pnVCell"
            source="{cellPhoneInput}" property="text"/>
        <mx:EmailValidator id="emV"
            source="{emailInput}" property="text"/>
    </fx:Declarations>
</s:Application>
```

Validating using regular expressions

The RegExpValidator class lets you use a regular expression to validate a field. You pass a regular expression to the validator by using the `expression` property, and additional flags to control the regular expression pattern matching by using the `flags` property.

The validation is successful if the validator can find a match of the regular expression in the field to validate. A validation error occurs when the validator finds no match.

You use regular expressions with the RegExpValidator. For information on writing regular expressions, see ActionScript 3.0 Developer's Guide.

The RegExpValidator class dispatches the `valid` and `invalid` events. For an `invalid` event, the event object is an instance of the ValidationResultEvent class, and it contains an Array of ValidationResult objects.

However, for a `valid` event, the ValidationResultEvent object contains an Array of RegExpValidationResult objects. The RegExpValidationResult class is a child class of the ValidationResult class, and contains additional properties that you use with regular expressions, including the following:

matchedIndex An integer that contains the starting index in the input String of the match.

matchedString A String that contains the substring of the input String that matches the regular expression.

matchedSubStrings An Array of Strings that contains parenthesized substring matches, if any. If no substring matches are found, this Array is of length 0. Use `matchedSubStrings[0]` to access the first substring match.

The following example uses the regular expression ABC\d to cause the validator to match a pattern consisting of the letters A, B, and C in sequence followed by any digit:

```
<?xml version="1.0"?>
<!-- validators\RegExpExample.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
          import mx.events.ValidationResultEvent;
          import mx.validators.*;

          private function handleResult(event:ValidationResultEvent):void {
              if (event.type == "valid")
              {
                  // For valid events, the results Array contains
                  // RegExpValidationResult objects.
                  var xResult:RegExpValidationResult;
                  myTA.text="";
                  for (var i:uint = 0; i < event.results.length; i++)
                  {
                      xResult = event.results[i];
                      myTA.text=myTA.text + xResult.matchedIndex + " " +
                          xResult.matchedString + "\n";
                  }
              }
              else
              {
                  // Not necessary, but if you needed to access it,
                  // the results array contains ValidationResult objects.
                  var result:ValidationResult;
                  myTA.text="";
              }
          }
        ]]>
    </fx:Script>
    <fx:Declarations>
        <mx:RegExpValidator id="regExpV"
            source="{exp}" property="text"
            flags="g"
            expression="{source.text}"
            valid="handleResult(event);"
            invalid="handleResult(event);"/>
    </fx:Declarations>

    <s:Form>
        <s:FormItem label="Search string">
            <s:TextInput id="exp"/>
        </s:FormItem>
        <s:FormItem label="Regular expression">
            <s:TextInput id="source" text="ABC\d"/>
        </s:FormItem>
        <s:FormItem label="Results">
            <s:TextArea id="myTA"/>
        </s:FormItem>
    </s:Form>
</s:Application>
```

In this example, you specify the regular expression in the TextInput control named source, and bind it to the `expression` property of the validator. You can modify the regular expression by entering a new expression in the TextInput control. A value of `g` for the `flags` property specifies to find multiple matches in the input field.

The event handler for the `valid` event writes to the TextArea control the index in the input String and matching substring of all matches of the regular expression. The `invalid` event handler clears the TextArea control.

Validating social security numbers

The SocialSecurityValidator class validates that a string is a valid United States Social Security Number. This validator does not check if the number is an existing Social Security Number.

The following example validates a Social Security Number:

```
<?xml version="1.0"?>
<!-- validators\SSExample.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:Form id="identityForm">
        <s:FormItem id="ssnItem" label="Social Security Number">
            <s:TextInput id="ssnField"/>
        </s:FormItem>
        <s:FormItem id="licenseItem" label="Driver's License Number">
            <s:TextInput id="licenseInput"/> <!-- Not validated -->
        </s:FormItem>
    </s:Form>
    <fx:Declarations>
        <mx:SocialSecurityValidator id="ssV"
            source="{ssnField}" property="text"/>
    </fx:Declarations>
</s:Application>
```

Validating strings

The StringValidator class validates that a string length is within a specified range. The following example ensures that a string is between 6 and 12 characters long:

```
<?xml version="1.0"?>
<!-- validators\StringExample.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:Form id="membershipForm">
        <s:FormItem id="fullNameItem" label="Full Name">
        <!-- Not validated -->
            <s:TextInput id="fullNameInput"/>
        </s:FormItem>
        <s:FormItem id="userNameItem" label="Username">
            <s:TextInput id="userNameInput"/>
        </s:FormItem>
    </s:Form>
    <fx:Declarations>
        <mx:StringValidator source="{userNameInput}" property="text"
            minLength="6" maxLength="12"/>
    </fx:Declarations>
</s:Application>
```

Validating ZIP codes

The ZipCodeValidator class validates that a string has the correct length for a five-digit ZIP code, a five-digit+four-digit United States ZIP code, or a Canadian postal code.

The following example validates either a United States ZIP code or a Canadian postal code:

```
<?xml version="1.0"?>
<!-- validators\ZCExample.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:Form id="addressForm">
        <s:FormItem id="zipCodeItem" label="Zip Code">
            <s:TextInput id="zipInput"/>
        </s:FormItem>
        <s:FormItem id="submitArea">
            <s:Button label="Submit"/>
        </s:FormItem>
    </s:Form>
    <fx:Declarations>
        <mx:ZipCodeValidator id="zipV"
            source="{zipInput}" property="text"
            domain="US or Canada"/>
    </fx:Declarations>
</s:Application>
```

Formatting Data

Data formatters are user-configurable objects that format raw data into a customized string. You often use formatters with data binding to create a meaningful display of the raw data bound to a component. This can save you time by automating data formatting tasks and by letting you easily change the formatting of fields within your applications.

Using formatters

Formatters in Adobe® Flex® are components that you use to format data into strings. Formatters perform a one-way conversion of raw data to a formatted string. You typically trigger a formatter just before displaying data in a text field. Flex includes standard formatters that let you format currency, dates, numbers, phone numbers, and ZIP codes.

Spark and MX formatters

Flex defines two sets of formatters: Spark and MX. The Spark formatters rely on the classes in the flash.globalization package. The flash.globalization classes use the locale data provided by the operating system. Therefore, Spark formatters provide behavior that is consistent with the operating system and have access to all the locales that are supported by the operating system.

MX formatters use the Flex ResourceManager to access locale-specific data from properties files that are included in the Flex SDK. The MX formatters provide the same behavior across operating systems, but are limited to the locales provided by the Flex SDK or by the application developer.

The following table lists the Spark and MX formatting classes. When possible, Adobe recommends that you use the Spark formatters in your application:

Spark formatter	**MX formatter**	**Description**
CurrencyFormatter	CurrencyFormatter	Format a currency value.
DataTimeFormatter	DateTimeFormatter	Format a date and time value.
NumberFormatter	NumberFormatter	Format a numeric value.
	PhoneFormatter	Format a phone number.
	SwitchSymbolFormatter	Format a String by replacing placeholder characters in one String with numbers from a second String.
	ZipCodeFormatter	Format a U.S. or Canadian postal code.

Formatter example

The following steps describe the general process for using a formatter:

1 Declare a formatter in an `<fx:Declarations>` tag in your MXML code, specifying the appropriate formatting properties. You define formatters in an `<fx:Declarations>` tag because they are not visual components.

You can also create formatters in ActionScript for use in an application.

2 Call the formatter's `format()` method, and specify the value to be formatted as a parameter to the `format()` method. The `format()` method returns a String containing the formatted value.

The following example formats a phone number that a user inputs in an application by using the TextInput control:

```
<?xml version="1.0"?>
<!-- formatters\Formatter2TextFields.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Declarations>
        <!-- Declare a PhoneFormatter and define formatting parameters.-->
        <mx:PhoneFormatter id="phoneDisplay"
            areaCode="415"
            formatString="###-####" />
    </fx:Declarations>
    <!-- Declare the input control.-->
    <s:Label text="Enter 7 digit phone number (########):"/>
    <s:TextInput id="myTI"/>

    <!-- Declare the control to display the formatted data.-->
    <s:TextArea text="{phoneDisplay.format(myTI.text)}"/>
</s:Application>
```

In this example, you use the MX PhoneFormatter class to display the formatted phone number in a TextArea control. The `format()` method is called as part of a data binding expression when the `text` property of the TextInput control changes.

You can call the `format()` method from anywhere in your application, typically in response to an event. The following example declares a Spark DateTimeFormatter. The DateTimeFormatter uses the default locale-specific format for the input String. The application then writes a formatted date to the text property of a TextInput control in response to the `click` event of a Button control:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- formatters\sparkformatters\SparkFormatterDateField.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout paddingTop="10" paddingLeft="5"/>
    </s:layout>

    <fx:Declarations>
        <!-- Declare a Spark DateTimeFormatter and
             define formatting parameters.-->
        <s:DateTimeFormatter id="dateTimeFormatter"/>
    </fx:Declarations>

    <s:Label text="Enter date (mm/dd/yyyy):"/>
    <s:TextInput id="dob" text=""/>

    <s:Label text="Formatted date: "/>
    <s:TextInput id="formattedDate"
        text="" width="300"
        editable="false"/>

    <!-- Format and update the date.-->
    <s:Button label="Format Input"
        click="formattedDate.text=dateTimeFormatter.format(dob.text);"/>
</s:Application>
```

Spark formatters

Flex includes the following Spark classes for formatting dates, numbers and currencies:

- spark.formatters.CurrencyFormatter
- spark.formatters.NumberFormatter
- spark.formatters.DateTimeFormatter

The Spark formatters provide the following functionality:

- Locale-specific formatting of dates, times, number, and currency amounts.
- Locale-specific parsing of numbers and currency amounts.
- Locale-specific string comparison. For more information, see “Sorting and matching” on page 2062.
- Locale-specific uppercase and lowercase string conversion.

The Spark formatters use the `locale` style property to determine how to format data based on the locale. The `locale` style is an inheritable style that you can set for the entire application or specifically for a particular formatter.

If a Spark formatter does not explicitly set the `locale` style, then it uses the value specified by the `locale` style of the application container. If you do not set the `locale` style property, the application uses the global default from the defaults.css style sheet, which defaults to `en`. For more information, see “Setting the locale” on page 2056.

You can explicitly configure the formatter to use the default locale by setting the `locale` style to the constant value `flash.globalization.LocaleID.DEFAULT`.

Adobe Product Evangelist James Ward provides an overview of the Spark formatters in the video Overview of Spark Formatters in Flex.

See a video about Spark formatters from video2brain at New Formatters and Validators.

Error handling in a Spark formatter

You call the `format()` method to format a value. By default, if the `format()` method fails, it returns null. However, you can use the `errorText` property of the formatter to define a String to return, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- formatters\sparkformatters\SparkFormatterError.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout paddingTop="10" paddingLeft="5"/>
    </s:layout>

    <fx:Declarations>
        <!-- Declare a Spark DateTimeFormatter and
        define formatting parameters.-->
        <s:DateTimeFormatter id="dateTimeFormatter"
            dateTimePattern="month: MM, day: DD, year: YYYY"
            errorText="Invalid input value"/>
    </fx:Declarations>

    <s:Label text="Enter date (mm/dd/yyyy):"/>
    <s:TextInput id="dob" text=""/>

    <s:Label text="Formatted date: "/>
    <s:TextInput id="formattedDate"
        text="" width="300"
        editable="false"/>

    <!-- Format and update the date.-->
    <s:Button label="Format Input"
        click="formattedDate.text=dateTimeFormatter.format(dob.text);"/>
</s:Application>
```

Formatting numbers with a Spark formatter

The Spark NumberFormatter class provides basic formatting options for numeric data, including decimal formatting, thousands separator formatting, and negative sign formatting.

The format() method accepts a number or a number formatted as a String value, and returns the formatted string. When a number formatted as a String value is passed to the format() method, the function first uses the Number() function to convert the String to a Number object.

The following example uses the NumberFormatter class in an MXML file:

```
<?xml version="1.0" encoding="utf-8"?>
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx" minWidth="955" minHeight="600">
    <s:layout>
        <s:VerticalLayout paddingTop="10" paddingLeft="5"/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            protected function button2_clickHandler(event:MouseEvent):void {
                displayVal.text = PrepForDisplay.format(bigNumber.text);
            }
        ]]>
    </fx:Script>

    <fx:Declarations>
        <!-- Declare and define parameters for the NumberFormatter.-->
        <s:NumberFormatter id="PrepForDisplay"
            fractionalDigits="3"
            decimalSeparator="."
            groupingSeparator=","
            useGrouping="true"
            negativeNumberFormat="0"
            errorText="'{bigNumber.text}' is an invalid input value"/>
    </fx:Declarations>

    <!-- String to format.-->
    <s:TextInput id="bigNumber" text="Enter number"/>
    <s:Button label="Format Value"
        click="button2_clickHandler(event);"/>

    <!-- Display formatted value.-->
    <s:Label id="displayVal"/>
</s:Application>
```

Formatting currency with a Spark formatter

The Spark CurrencyFormatter class provides the same features as the NumberFormatter class, plus a currency symbol. It also has additional properties to control the formatted result: currencySymbol, negativeCurrencyFormat, and positiveCurrencyFormat.

The format() method accepts a Number value or a number formatted as a String value and formats the resulting string. When a number formatted as a String value is passed to the format() method, the function first uses the Number() function to convert the String to a Number object.

The useCurrencySymbol property determines the currency symbol returned in the formatted String based on the locale style property. When the useCurrencySymbol property is set to true, the formatter returns the value of the currencySymbol property in the formatted String. When the useCurrencySymbol property is set to false, the formatter returns the value of the currencyISOCode property in the formatted String.

The following example uses the CurrencyFormatter class in an MXML file:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- formatters\sparkformatters\SparkCurrencyFormatter.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout paddingTop="10" paddingLeft="5"/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            protected function button1_clickHandler(event:MouseEvent):void {
                displayVal.text = Price.format(currVal.text);
            }
        ]]>
    </fx:Script>

    <fx:Declarations>
        <!-- Declare a CurrencyFormatter and define parameters.-->
        <s:CurrencyFormatter id="Price"
            currencySymbol="$"
            useCurrencySymbol="true"
            negativeCurrencyFormat="0"
            positiveCurrencyFormat="0"
            errorText="'{currVal.text}' is an invalid input value"/>
    </fx:Declarations>

    <!-- Enter currency value, then click the Button to format. -->
    <s:TextInput id="currVal" text="Enter value"/>
    <s:Button label="Format Value"
        click="button1_clickHandler(event);"/>
    <!-- Display formatted value.-->
    <s:Label id="displayVal"/>

</s:Application>
```

Formatting dates with a Spark formatter

The Spark DateTimeFormatter class gives you a wide range of combinations for displaying date and time information. The `format()` method accepts a Date object, which it converts to a String based on a user-defined pattern.

The `format()` method can also accept a String-formatted date. If you pass a String, the formatter first converts it to a Date object by using the Date constructor. The hour value in the String must be between 0 and 23, inclusive. The minutes and seconds value must be between 0 and 59, inclusive. If the `format()` method is unable to parse the String into a Date object, it returns `null`.

The following examples show possible input strings to the `format()` method:

```
"12/31/98" or "12-31-98" or "1998-12-31" or "12/31/1998"
"Friday, December 26, 2005 8:35 am"
"Jan. 23, 1989 11:32:25"
```

Using pattern strings

Use the `dateTimePattern` property of the DateTimeFormatter class to specify the string of pattern letters that determine the appropriate formatting. You compose a pattern string by using specific letter sequences. For example, “yyyy/MM”.

***Note:** By omitting a pattern string, the date is formatted using the default for the current locale. By specifying a pattern string, you override the default formatting. Information, such as month and day names, are still displayed correctly for the locale, but the order of elements in the formatted string is fixed by the specified pattern string.*

You can include text and punctuation in the pattern string. However the characters from “a” to “z” and from “A” to “Z” are reserved as syntax characters. Enclose these characters in single quotes to include them in the formatted output string. To include a single quote, use two single quotes. The two single quotes may appear inside or outside a quoted portion of the pattern string.

When you create a pattern string, you usually repeat pattern letters. The number of repeated letters determines the presentation. For numeric values, the number of pattern letters is the minimum number of digits; shorter numbers are zero-padded to this amount. For example, the four-letter pattern string “yyyy” corresponds to a four-digit year value.

In cases where there is a corresponding mapping of a text description—for example, the name of a month—the full form is used if the number of pattern letters is four or more; otherwise, a short or abbreviated form is used, if available. For example, if you specify the pattern string “MMMM” for month, the formatter requires the full month name, such as “December”, instead of the abbreviated month name, such as “Dec”.

For time values, a single pattern letter is interpreted as one or two digits. Two pattern letters are interpreted as two digits.

The complete list of options to the pattern string is defined by the setDateTimePattern() method of the flash.globalization.DateTimeFormatter class.

The following table shows sample pattern strings and the resulting presentation:

Pattern	Result
`EEEE, MMMM dd, yyyy h:mm:ss a` (default)	Wednesday, December 01, 2010 3:06:43 PM
`yyyy.MM.dd 'at' h:mm:ss`	2010.12.01 at 3:19:44
`EEE, MMM d, yy`	Wed, Dec 1, 10
`kk 'o''clock' a`	15 o'clock PM
`k:mm a`	12:08 PM
`K:mm a`	0:08 PM
`yyyy.MMMM.dd HH:mm:ss`	2005.July.04 12:08:34

Example: Using the Spark DateFormatter class

The following example uses the DateTimeFormatter class in an MXML file for formatting a Date object as a String:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- formatters\spark\SparkDateFormatter.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx" minWidth="955" minHeight="600">
    <s:layout>
        <s:VerticalLayout paddingTop="10" paddingLeft="5"/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            // Define variable to hold the date.
            [Bindable]
            private var today:Date = new Date();
        ]]>
    </fx:Script>

    <fx:Declarations>
        <!-- Declare a DateFormatter and define parameters.-->
        <s:DateTimeFormatter id="DateDisplay1"
            dateTimePattern="MMMM d, yyyy"/>
        <s:DateTimeFormatter id="DateDisplay2"
            dateTimePattern="hh:mm a"/>
        <s:DateTimeFormatter id="DateDisplay3"
            dateTimePattern="hh:mm a, MMMM d, yyyy"/>
        <s:DateTimeFormatter id="DateDisplay4"
            dateTimePattern="yyyy.MMMM.dd HH:mm:ss"/>
</fx:Declarations>

    <!-- Display the date in a Label control.-->
    <s:Label id="myTA1" text="{DateDisplay1.format(today)}"/>
    <!-- Display the date in a Label control.-->
    <s:Label id="myTA2" text="{DateDisplay2.format(today)}"/>
    <!-- Display the date in a Label control.-->
    <s:Label id="myTA3" text="{DateDisplay3.format(today)}"/>
    <!-- Display the date in a Label control.-->
    <s:Label id="myTA4" text="{DateDisplay4.format(today)}"/>
</s:Application>
```

MX formatters

All formatters are subclasses of the mx.formatters.Formatter class. The Formatter class declares a format() method that takes a value and returns a String value.

Writing an error handler function for an MX formatter

For most formatters, when an error occurs, the `format()` method returns an empty string is and a string describing the error is written to the formatter's `error` property. You can check for an empty string in the return value of the `format()` method, and if found, access the `error` property to determine the cause of the error.

Alternatively, you can write an error handler function that returns an error message for a formatting error. The following example shows a simple error handler function:

```
<?xml version="1.0"?>
<!-- formatters\FormatterSimpleErrorForDevApps.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            private function formatWithError(value:Object):String {
                var formatted:String = myFormatter.format(value);
                if (formatted == "") {
                    if (myFormatter.error != null ) {
                        if (myFormatter.error == "Invalid value") {
                            formatted = ": The value is not valid.";
                        }
                        else {
                            formatted = ": The formatString is not valid.";
                        }
                    }
                }
                return formatted;
            }
        ]]>
    </fx:Script>
    <fx:Declarations>
        <!-- Declare a formatter and specify formatting properties.-->
        <mx:DateFormatter id="myFormatter"
            formatString="MXXXMXMXMXMXM"/>
    </fx:Declarations>
    <!-- Trigger the formatter while populating a string with data.-->
    <s:TextInput id="myTI"
        width="75%"
        text="Your order shipped on {formatWithError('May 23, 2005')}"/>
</s:Application>
```

In this example, you define a DateFormatter with an invalid format string. You then use the `formatWithError()` method to invoke the formatter in the TextInput control, rather than calling the Date formatter’s `format()` method directly. In this example, if either the input string or the format string is invalid, the `formatWithError()` method returns an error message instead of a formatted String value.

Formatting currency with an MX formatter

The MX CurrencyFormatter class provides the same features as the NumberFormatter class, plus a currency symbol. It has two additional properties: `currencySymbol` and `alignSymbol`. (For more information about the NumberFormatter class, see “Formatting numbers with an MX formatter” on page 2017.)

The CurrencyFormatter class provides basic formatting options for numeric data, including decimal formatting, thousands separator formatting, and negative sign formatting. The `format()` method accepts a Number value or a number formatted as a String value and formats the resulting string.

When a number formatted as a String is passed to the `format()` method, the function parses the string from left to right and attempts to extract the first sequence of numbers it encounters. The function parses the thousands separators and decimal separators along with their trailing numbers. The parser searches for a comma (,) for the thousands separator unless you set a different character in the `thousandsSeparatorFrom` property. The parser searches for a period (.) for the decimal separator unless you define a different character in the `decimalSeparator` property.

***Note:** When a number is provided to the `format()` method as a String value, a negative sign is recognized if it is a dash (-) immediately preceding the first number in the sequence. A dash, space, and then a first number are not interpreted as a negative sign.*

Example: Using the MX CurrencyFormatter class

The following example uses the CurrencyFormatter class in an MXML file:

```
<?xml version="1.0"?>
<!-- formatters\MainCurrencyFormatter.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            // Define variable to hold the price.
            [Bindable]
            private var todaysPrice:Number=4025;
        ]]>
    </fx:Script>
    <fx:Declarations>
        <!-- Declare a CurrencyFormatter and define parameters.-->
        <mx:CurrencyFormatter id="Price" precision="2"
            rounding="none"
            decimalSeparatorTo="."
            thousandsSeparatorTo=","
            useThousandsSeparator="true"
            useNegativeSign="true"
            currencySymbol="$"
            alignSymbol="left"/>
    </fx:Declarations>
    <!-- Trigger the formatter while populating a string with data.-->
    <s:TextInput text="Today's price is {Price.format(todaysPrice)}."
        width="200"/>
</s:Application>
```

At run time, the following text is displayed:

Today’s price is $4,025.00.

Error handling: MX CurrencyFormatter class

If an error occurs, Flex returns an empty string and saves a description of the error in the error property. An error points to a problem with the value being submitted or the format string containing the user settings, as described in the following table:

Value of error property	When error occurs
`Invalid value`	An invalid numeric value is passed to the `format()` method. The value should be a valid number in the form of a Number or a String.
`Invalid format`	One or more of the parameters contain an unusable setting.

Formatting dates with an MX formatter

The MX DateFormatter class gives you a wide range of combinations for displaying date and time information. The `format()` method accepts a Date object, which it converts to a String based on a user-defined pattern. The `format()` method can also accept a String-formatted date, which it attempts to parse into a valid Date object prior to formatting.

The DateFormatter class has a `parseDateString()` method that accepts a date formatted as a String. The `parseDateString()` method examines sections of numbers and letters in the String to build a Date object. The parser is capable of interpreting long or abbreviated (three-character) month names, time, am and pm, and various representations of the date.

The hour value in the String must be between 0 and 23, inclusive. The minutes and seconds value must be between 0 and 59, inclusive. If the `parseDateString()` method is unable to parse the String into a Date object, it returns `null`.

The following examples show some of the ways strings can be parsed:

```
"12/31/98" or "12-31-98" or "1998-12-31" or "12/31/1998"
"Friday, December 26, 2005 8:35 am"
"Jan. 23, 1989 11:32:25"
```

The DateFormatter class parses strings from left to right. A date value should appear before the time and must be included. The time value is optional. A time signature of 0:0:0 is the Date object’s default for dates that are defined without a time. Time zone offsets are not parsed.

Using Pattern strings

You provide the DateFormatter class with a string of pattern letters, which it parses to determine the appropriate formatting. You must understand how to compose the string of pattern letters to control the formatting options and the format of the string that is returned.

You compose a pattern string by using specific uppercase letters: for example, YYYY/MM. The DateFormatter pattern string can contain other text in addition to pattern letters. To form a valid pattern string, you need only one pattern letter.

When you create a pattern string, you usually repeat pattern letters. The number of repeated letters determines the presentation. For numeric values, the number of pattern letters is the minimum number of digits; shorter numbers are zero-padded to this amount. For example, the four-letter pattern string “YYYY” corresponds to a four-digit year value.

In cases where there is a corresponding mapping of a text description—for instance, the name of a month—the full form is used if the number of pattern letters is four or more; otherwise, a short or abbreviated form is used, if available. For example, if you specify the pattern string “MMMM” for month, the formatter requires the full month name, such as “December”, instead of the abbreviated month name, such as “Dec”.

For time values, a single pattern letter is interpreted as one or two digits. Two pattern letters are interpreted as two digits.

The following table describes each of the available pattern letters:

Pattern letter	**Description**

Y	Year. If the number of pattern letters is two, the year is truncated to two digits; otherwise, it appears as four digits. The year can be zero-padded, as the third example shows in the following set of examples:
	Examples:
	YY = 05
	YYYY = 2005
	YYYYY = 02005

M	Month in year. The format depends on the following criteria: • If the number of pattern letters is one, the format is interpreted as numeric in one or two digits. • If the number of pattern letters is two, the format is interpreted as numeric in two digits. • If the number of pattern letters is three, the format is interpreted as short text. • If the number of pattern letters is four, the format is interpreted as full text. Examples: M = 7 MM= 07 MMM=Jul MMMM= July

D	Day in month. While a single-letter pattern string for day is valid, you typically use a two-letter pattern string.
	Examples:
	D=4
	DD=04
	DD=10

E	Day in week. The format depends on the following criteria: • If the number of pattern letters is one, the format is interpreted as numeric in one or two digits. • If the number of pattern letters is two, the format is interpreted as numeric in two digits. • If the number of pattern letters is three, the format is interpreted as short text. • If the number of pattern letters is four, the format is interpreted as full text. Examples: E = 1 EE = 01 EEE = Mon EEEE = Monday
A	am/pm indicator.
J	Hour in day (0-23).
H	Hour in day (1-24).

Pattern letter	Description
K	Hour in am/pm (0-11).
L	Hour in am/pm (1-12).

N	Minute in hour.
	Examples:
	N = 3
	NN = 03

S	Second in minute. Examples: SS = 30
Q	Millisecond in seconds.Example:s: QQ = 78QQQ = 078
Other text	You can add other text into the pattern string to further format the string. You can use punctuation, numbers, and all lowercase letters. You should avoid uppercase letters because they may be interpreted as pattern letters. Example: EEEE, MMM. D, YYYY at L:NN A = Tuesday, Sept. 8, 2005 at 1:26 PM

The following table shows sample pattern strings and the resulting presentation:

Pattern	Result
`YYYY.MM.DD at HH:NN:SS`	2005.07.04 at 12:08:56
`EEEE, MMM. D, YYYY at L:NN:QQQ A`	Tuesday, Sept. 8, 2005 at 1:26:012 PM
`EEE, MMM D, 'YY`	Wed, Jul 4, '05
`H:NN A`	12:08 PM
`HH o'clock A`	12 o'clock PM
`K:NN A`	0:08 PM
`YYYYY.MMMM.DD. JJ:NN A`	02005.July.04. 12:08 PM
`EEE, D MMM YYYY HH:NN:SS`	Wed, 4 Jul 2005 12:08:56

Example: Using the DateFormatter class

The following example uses the DateFormatter class in an MXML file for formatting a Date object as a String:

```
<?xml version="1.0"?>
<!-- formatters\MainDateFormatter.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            // Define variable to hold the date.
            [Bindable]
            private var today:Date = new Date();
        ]]>
    </fx:Script>
    <fx:Declarations>
        <!-- Declare a DateFormatter and define parameters.-->
        <mx:DateFormatter id="DateDisplay"
            formatString="MMMM D, YYYY"/>
    </fx:Declarations>
    <!-- Display the date in a TextArea control.-->
    <s:TextInput id="myTA" text="{DateDisplay.format(today)}"/>
</s:Application>
```

At run time, the TextInput control displays the current date.

Error handling: DateFormatter class

If an error occurs, Flex returns an empty string and saves a description of the error in the error property. An error points to a problem with the value being submitted or the format string containing the user settings, as described in the following table:

Value of error property	When error occurs
`Invalid value`	A value that is not a Date object is passed to the `format()` method. (An empty argument is allowed.)
`Invalid format`	• The `formatString` property is set to empty (""). • There is less than one pattern letter in the `formatString` property.

Formatting numbers with an MX formatter

The MX NumberFormatter class provides basic formatting options for numeric data, including decimal formatting, thousands separator formatting, and negative sign formatting. The `format()` method accepts a number or a number formatted as a String value, and formats the resulting string.

When a number formatted as a String value is passed to the `format()` method, the function parses the string from left to right and attempts to extract the first sequence of numbers it encounters. The function parses the thousands separators and decimal separators along with their trailing numbers. The parser searches for a comma (,) for the thousands separator unless you set a different character in the `thousandsSeparatorFrom` property. The parser searches for a period (.) for the decimal separator unless you define a different character in the `decimalSeparator` property.

Note: *The `format()` method recognizes a dash (-) immediately preceding the first number in the sequence as a negative number. A dash, space, and then number sequence are not interpreted as a negative number.*

The `rounding` and `precision` properties of the MX NumberFormatter class affect the formatting of the decimal in a number. If you use both `rounding` and `precision` properties, rounding is applied first, and then the decimal length is set by using the specified precision value. This lets you round a number and still have a trailing decimal; for example, 303.99 = 304.00.

Example: Using the MX NumberFormatter class

The following example uses the MX NumberFormatter class in an MXML file:

```
<?xml version="1.0"?>
<!-- formatters\MainNumberFormatter.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            // Define variable to hold the number.
            [Bindable]
            private var bigNumber:Number = 6000000000.65;
        ]]>
    </fx:Script>
    <fx:Declarations>
        <!-- Declare and define parameters for the NumberFormatter.-->
        <mx:NumberFormatter id="PrepForDisplay"
            precision="0"
            rounding="up"
            decimalSeparatorTo="."
            thousandsSeparatorTo=","
            useThousandsSeparator="true"
            useNegativeSign="true"/>
    </fx:Declarations>
    <!-- Trigger the formatter while populating a string with data.-->
    <s:TextInput text="{PrepForDisplay.format(bigNumber)}"/>
</s:Application>
```

At run time, the following text appears:

6,000,000,001

Error handling: MX NumberFormatter class

If an error occurs, Flex returns an empty string and saves a description of the error in the error property. An error refers to a problem with the value being submitted or the format string that contains the user settings, as described in the following table:

Value of error property	When error occurs
`Invalid value`	An invalid numeric value is passed to the `format()` method. The value should be a valid number in the form of a Number or a String.
`Invalid format`	One or more of the parameters contain an unusable setting.

Formatting phone numbers with an MX formatter

The PhoneFormatter class lets you format a phone number by adjusting the format of the area code and the subscriber code. You can also adjust the country code and configuration for international formats. The value passed into the `PhoneFormatter.format()` method must be a Number object or a String object with only digits.

The PhoneFormatter `formatString` property accepts a formatted string as a definition of the format pattern. The following table shows common options for `formatString` values. The `format()` method for the PhoneFormatter accepts a sequence of numbers. The numbers correspond to the number of placeholder (#) symbols in the `formatString` value. The number of placeholder symbols in the `formatString` property and the number of digits in the `format()` method value must match.

formatString value	Input	Output
`###-####`	1234567	(xxx) 456-7890
`(###) ### ####`	1234567890	(123) 456-7890
`###-###-####`	11234567890	123-456-7890
`#(###) ### ####`	11234567890	1(123) 456 7890
`#-###-###-####`	11234567890	1-123-456-7890
`+###-###-###-####`	1231234567890	+123-123-456-7890

In the preceding table, dashes (-) are used as separator elements where applicable. You can substitute period (.) characters or blank spaces for the dashes. You can change the default allowable character set as needed by using the `validPatternChars` property. You can change the default character that represents a numeric placeholder by using the `numberSymbol` property (for example, to change from # to $).

***Note:** A shortcut is provided for the United States seven-digit format. If the `areaCode` property contains a value and you use the seven-digit format string, a seven-digit format entry automatically adds the area code to the string returned. The default format for the area code is (###). You can change this by using the `areaCodeFormat` property. You can format the area code any way you want as long as it contains three number placeholders.*

Example: Using the PhoneFormatter class

The following example uses the PhoneFormatter class in an MXML file:

```
<?xml version="1.0"?>
<!-- formatters\MainPhoneFormatter.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            // Define variable to hold the phone number.
            [Bindable]
            private var newNumber:Number = 1234567;
        ]]>
    </fx:Script>
    <fx:Declarations>
        <!-- Declare a PhoneFormatter and define formatting parameters.-->
        <mx:PhoneFormatter id="PhoneDisplay"
            areaCode="415"
            formatString="###-####"/>
    </fx:Declarations>
    <!-- Trigger the formatter while populating a string with data-->
    <s:TextInput id="myTI"
        initialize="myTI.text=PhoneDisplay.format(newNumber);"/>
</s:Application>
```

At run time, the following text is displayed:

(415) 123-4567

Error handling: PhoneFormatter class

If an error occurs, Flex returns an empty string and saves a description of the error in the error property. An error points to a problem with the value being submitted or the format string containing the user settings, as described in the following table:

Value of error property	**When error occurs**
`Invalid value`	• An invalid numeric value is passed to the `format()` method. The value should be a valid number in the form of a Number or a String. • The value contains a different number of digits than what is specified in the format string.
`Invalid format`	• One or more of the characters in the `formatString` do not match the allowed characters specified in the `validPatternChars` property. • The `areaCodeFormat` property is specified but does not contain exactly three numeric placeholders.

Formatting zip codes with an MX formatter

The ZipCodeFormatter class lets you format five-digit or nine-digit United States ZIP codes and six-character Canadian postal codes. The ZipCodeFormatter class’s `formatString` property accepts a formatted string as a definition of the format pattern. The `formatString` property is optional. If it is omitted, the default value of `#####` is used.

The number of digits in the value to be formatted and the value of the `formatString` property must be five or nine for United States ZIP codes, and six for Canadian postal codes.

The following table shows common `formatString` values, input values, and output values:

formatString value	Input	Output	Format
#####	94117, 941171234	94117, 94117	Five-digit U.S. ZIP code
#####-####	941171234, 94117	94117-1234, 94117-0000	Nine-digit U.S. ZIP code
### ###	A1B2C3	A1B 2C3	Six-character Canadian postal code

For United States ZIP codes, if a nine-digit format is requested and a five-digit value is supplied, `-0000` is appended to the value to make it compliant with the nine-digit format. Inversely, if a nine-digit value is supplied for a five-digit format, the number is truncated to five digits.

For Canadian postal codes, only a six-digit value is allowed for either the `formatString` or the input value.

Note: *For United States ZIP codes, only numeric characters are valid. For Canadian postal codes, alphanumeric characters are allowed. Alphabetic characters must be in uppercase.*

Example: Using the ZipCodeFormatter class

The following example uses the ZipCodeFormatter class in an MXML file:

```
<?xml version="1.0"?>
<!-- formatters\MainZipFormatter.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            // Define variable to hold the ZIP code.
            [Bindable]
            private var storedZipCode:Number=123456789;
        ]]>
    </fx:Script>
    <fx:Declarations>
        <!-- Declare a ZipCodeFormatter and define parameters.-->
        <mx:ZipCodeFormatter id="ZipCodeDisplay"
            formatString="#####-####"/>
    </fx:Declarations>
    <!-- Trigger the formatter while populating a string with data.-->
    <s:TextInput text="{ZipCodeDisplay.format(storedZipCode)}"/>
</s:Application>
```

At run time, the following text is displayed:

12345-6789

Error handling: ZipCodeFormatter class

If an error occurs, Flex returns an empty string and saves a description of the error in the error property. An error refers to a problem with the value being submitted or the format string containing the user settings, as described in the following table:

Value of error property	When error occurs
`Invalid value`	• An invalid numeric value is passed to the `format()` method. The value should be a valid number in the form of a Number or a String, except for Canadian postal codes, which allow alphanumeric values. • The number of digits does not match the allowed digits from the `formatString` property.
`Invalid format`	• One or more of the characters in the `formatString` do not match the allowed characters specified in the `validFormatChars` property. • The number of numeric placeholders does not equal 9, 5, or 6.

Deep linking

About deep linking

One of the benefits of an application built with Flex is that it can smoothly transition from state to state without having to fetch a new page from the server and refresh the browser. By avoiding the constant refreshing of pages, the end-user's experience is more fluid and continuous. In addition, the load on the server is greatly reduced because it need only return the application once, rather than a new page every time the user changes views.

However one of the advantages of a browser's page-oriented model is that an application's navigational state is usually clearly coupled to a URL. Thus, when the state of an application changes, the user can usually do the following:

- Bookmark the URL to get back to that state in the application
- Email the URL to a friend
- Use the Back and Forward buttons to navigate to recently visited application states

Losing the ability to couple a browser-managed URL to a specific state of an application can be a fairly big drawback when creating applications. Deep linking adds URL-mapping or “bookmarking” capabilities to applications. At the high level, deep linking lets you do the following:

- Update the URL when the application state changes. This also generates a new entry in the browser’s history.
- Read in values from the URL to change the state of the application. For example, a bookmark could load the application at a particular state.
- Recognize when the URL in the browser’s address bar has changed. If the user clicks the Forward or Back button, or changes the URL in the address bar, the application is notified and can react to the change.

What states of your application are bookmarkable will vary by application, but possibilities include a login page, a product page, a search result page, or a drill down view into data.

Deep linking only works with certain browsers. The following browsers support deep linking:

- Microsoft Internet Explorer version 6 or later
- FireFox for Windows and Macintosh
- Safari for Macintosh

In addition to requiring these browsers, deep linking requires that the client browser also has JavaScript enabled. Deep linking does not work with the standalone Adobe® Flash® Player or Adobe AIR™.

How deep linking works

Deep linking relies on communication between the browser and the application. The communication is bidirectional: if a change occurs in the application, the browser must be notified, and if a change in the browser occurs, then the application must be notified. This communication is handled by the BrowserManager class. This class uses methods in the HTML wrapper's JavaScript to handle events, update the browser's address bar, and call other methods. Another class, URLUtil, is provided to make it easier to parse the URL as you read it in your application and write it back to the browser.

To use deep linking, you write ActionScript that sets and gets portions of the URL to determine which state the application is in. These portions are called fragments, and occur after the pound sign ("#") in the URL. In the following example, `view=1` is the fragment:

```
http://my.domain.com#view=1
```

If the user navigates to a new view in your application, you update the URL and set `view=2` in the URL fragment. If the user then clicks the browser's Back button, the BrowserManager is notified of the event, and gives you a chance to change the application's state in respond to the URL fragment changing back to `view=1`.

You typically use the methods of the URLUtil class to parse the URL. This class provides methods for detecting the server name, port number, and protocol of a URL. In addition, you can use the `objectToString()` method to convert an ActionScript object to a String that you then append to the end of a URL. Alternatively, you can convert any number of name/value pairs on a query string into an object by using the URLUtil class's `stringToObject()` method. This lets you then manipulate the fragment more easily in your application logic.

Deploying applications that use deep linking

To use deep linking, your HTML wrapper requires that the following files be deployed with your application:

- history.css
- history.js
- historyFrame.html

You must include the history.js and history.css files in your wrapper. The following example imports the JS and CSS files:

```
<!--  BEGIN Browser History required section -->
<link rel="stylesheet" type="text/css" href="history/history.css"/>
<script src="history/history.js" language="javascript"></script>
<!--  END Browser History required section -->
```

You must also deploy the historyFrame.html file with your application. This file must be located in the /history sub-directory; its location is relative to your deployed application SWF file's location.

For Adobe®Flash® Builder™, the history.css, history.js, and historyFrame.html files are located in the *flash_builder_install*/sdks/4.6.0/templates/swfobject/history directory.

For the SDK, the files are located in the *sdk_install*/templates/swfobject/history directory.

Flash Builder generates the history.css, history.js, and historyFrame.html files in your project's output directory if you enable deep linking in your project.

Enable deep linking in Flash Builder

1 Select Project > Properties.

2 Select the Flex Compiler option.

3 Select the "Enable integration with browser navigation" option.

Using the BrowserManager

The BrowserManager is a Singleton class that acts as a proxy between the browser and the application. It provides access to the URL in the browser address bar similar to accessing the `document.location` property in JavaScript. When the URL changes in the browser, the BrowserManager is notified of the event. You can then change the URL, respond to the event, or block the event.

To get a reference to the BrowserManager, you call its `getInstance()` method. This method returns the current instance of the manager, which implements IBrowserManager. You can then call methods on the manager such as `setTitle()` and `setFragment()`.

You can also listen to events on that manager. The events are `browserURLChange`, `urlChange`, and `applicationURLChange`. These events are described in "About BrowserManager events" on page 2029.

You can also access properties of the manager. These properties store the browser's current title, plus the full URL and its sub-parts, `fragment` and `base`. The properties are read-only, but you can use methods of the manager, such as `setTitle()` and `setFragment()`, to set the values of some of them.

You typically call the `getInstance()` method when your application initializes. This returns an instance of the Singleton BrowserManager. You then register an event listener for the `browserURLChange` event. This event is dispatched when the user clicks the Back or Forward button in the browser. Finally, you call the `init()` method to initialize the BrowserManager. The first parameter of the `init()` method defines the default fragment, and the second parameter defines the title for the current page.

The following example instantiates the BrowserManager, registers the `parseURL()` method to listen for `browserURLChange` events, and calls the `init()` method with a blank fragment as the default fragment. It sets the value of the page's title to "Test Deep Linking":

```
private function initApp():void {
    browserManager = BrowserManager.getInstance();
    browserManager.addEventListener(BrowserChangeEvent.BROWSER_URL_CHANGE, parseURL);
    browserManager.init("", "Test Deep Linking");
}
```

Calling the BrowserManager class's `init()` method also gets the current URL as a property in the BrowserManager.

If you set a value for the default fragment in the `init()` method, when the URL changes, the URL with the default fragment will be entered in the browser's history. This way, if the user clicks the Back button or in some other way accesses this page from the browser's history, this fragment will be used. Also, the BrowserManager returns the default fragment if there is nothing after the pound sign ("#") in the URL.

Updating the URL

You use the BrowserManager's `setFragment()` method to update the URL in the browser's address bar. You can only change the fragments in the URL. You cannot change the base of the URL, including the server, protocol, or port numbers.

When you use the `setFragment()` method to change the URL, you trigger an `applicationURLChange` event.

The following example updates the URL in the browser whenever you change the active panel in the TabNavigator container. It also keeps a record of the current URL and previous URL each time an `applicationURLChange` event is triggered.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- deeplinking/UpdateURLExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    creationComplete="init();">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
    <![CDATA[
        import mx.events.BrowserChangeEvent;
        import mx.managers.IBrowserManager;
        import mx.managers.BrowserManager;
        import mx.utils.URLUtil;
        private var browserManager:IBrowserManager;
        private function init():void {
            browserManager = BrowserManager.getInstance();
            browserManager.addEventListener(BrowserChangeEvent.APPLICATION_URL_CHANGE,
                logURLChange);
            browserManager.init("", "Welcome!");
        }
        public function updateTitle(e:Event):void {
            browserManager.setTitle("Welcome " + ti1.text + " from " + ti2.text + "!");
        }
        private function updateURL(event:Event):void {
            var s:String = "panel=" + event.currentTarget.selectedIndex;
            browserManager.setFragment(s);
        }
        private function logURLChange(event:BrowserChangeEvent):void {
            ta1.text += "APPLICATION_URL_CHANGE event:\n";
            ta1.text += " url: " + event.url + "\n"; // Current URL in the browser.
            ta1.text += " prev: " + event.lastURL + "\n"; // Previous URL.
        }
    ]]>
    </fx:Script>
    <mx:TabNavigator id="tn" width="300" change="updateURL(event)">
            <mx:Panel label="Personal Data">
                <mx:Form>
                    <mx:FormItem label="Name:">
                        <mx:TextInput id="ti1"/>
                    </mx:FormItem>
                    <mx:FormItem label="Hometown:">
                        <mx:TextInput id="ti2"/>
                    </mx:FormItem>
                    <mx:Button id="b1" click="updateTitle(event)" label="Submit"/>
                </mx:Form>
            </mx:Panel>
            <mx:Panel label="Credit Card Info">
                <mx:Form>
                    <mx:FormItem label="Type:">
```

```
                        <mx:ComboBox>
                            <mx:dataProvider>
                                <fx:String>Visa</fx:String>
                                <fx:String>MasterCard</fx:String>
                                <fx:String>American Express</fx:String>
                            </mx:dataProvider>
                        </mx:ComboBox>
                    </mx:FormItem>
                    <mx:FormItem label="Number:">
                        <mx:TextInput id="ccnumber"/>
                    </mx:FormItem>
                </mx:Form>
            </mx:Panel>
            <mx:Panel label="Check Out">
              <mx:TextArea id="ta2" text="You must agree to all the following conditions..."/>
                <mx:CheckBox label="Agree"/>
            </mx:Panel>
    </mx:TabNavigator>
    <mx:TextArea id="ta1" width="580" height="400"/>
</s:Application>
```

When you click on the second panel, you trigger a `change` event, which causes Flash Player to call the `updateURL()` method. This method calls the `setFragment()` method that changes the URL in the browser's address bar. If you cycle through the panels, the URL in the browser's address bar will change from this:

```
http://localhost:8100/devapps/code/deeplinking/FragmentExample.html#panel=1
```

To this:

```
http://localhost:8100/devapps/code/deeplinking/FragmentExample.html#panel=2
```

And then, to this:

```
http://localhost:8100/devapps/code/deeplinking/FragmentExample.html#panel=0
```

Each time the application changes the URL in the browser's address bar, Flash Player dispatches an `applicationURLChange` event. This example logs the previous and current URLs, which are properties of this event object.

Parsing the URL

Changing the URL in the browser's address bar does not necessarily provide you with deep linking functionality. For example, loading a bookmarked URL that specifies the panel would not start the application on that panel. You must add code to the application that parses the URL so that the application's state reflects the URL.

In this case, you add a listener for the `browserURLChange` event. In that listener, you parse the URL and set the application state according to the results. For example, if the URL includes a fragment such as `panel=2`, then you write code that sets the current panel with the selected index of 2.

The `browserURLChange` event is not triggered when the application first loads. As a result, you must also check the URL on startup with the application's `creationComplete` event, and trigger the parsing before the application finishes being rendered on the screen.

The following is a simple example that sets the value of the Accordion's `selectedIndex` property to the value of the `index` fragment in the URL. You request this application by setting the value of the `index` fragment on the URL, as the following example shows:

```
http://www.myurl.com/InitFrag.html#index=1
```

When the application starts up, the Accordion is opened to the panel corresponding to the value of the `index` fragment:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- deeplinking/InitFrag.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    creationComplete="init(event);">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import mx.managers.BrowserManager;
            import mx.managers.IBrowserManager;
            import mx.events.BrowserChangeEvent;
            import mx.utils.URLUtil;
            private var bm:IBrowserManager;
            private function init(e:Event):void {
                bm = BrowserManager.getInstance();
                bm.init("", "Welcome!");
                parseURL(e);
            }

            [Bindable]
            private var indexFromURL:int;
            private function parseURL(e:Event):void {
                var o:Object = URLUtil.stringToObject(bm.fragment);
                indexFromURL = o.index;
            }
        ]]>
    </fx:Script>
    <mx:Accordion selectedIndex="{indexFromURL}">
        <mx:VBox label="Panel 1">
            <mx:Label text="Accordion container panel 1"/>
        </mx:VBox>
        <mx:VBox label="Panel 2">
            <mx:Label text="Accordion container panel 2"/>
        </mx:VBox>
        <mx:VBox label="Panel 3">
            <mx:Label text="Accordion container panel 3"/>
        </mx:VBox>
    </mx:Accordion>
</s:Application>
```

The following example expands on the example from “Updating the URL” on page 2024. It reads the URL on startup, and opens the application to the first, second, or third panel, depending on the value of the `panel` fragment. It also sets the title of the HTML page according to which panel is opened.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- deeplinking/TabNavExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    creationComplete="initApp()"
    height="250"
    width="500">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
    <![CDATA[
        import mx.events.BrowserChangeEvent;
        import mx.managers.IBrowserManager;
        import mx.managers.BrowserManager;
        import mx.utils.URLUtil;
        public var browserManager:IBrowserManager;
        private function initApp():void {
            browserManager = BrowserManager.getInstance();
            browserManager.addEventListener(BrowserChangeEvent.BROWSER_URL_CHANGE, parseURL);
            browserManager.init("", "Shipping");
        }
        private var parsing:Boolean = false;
        private function parseURL(event:Event):void {
            parsing = true;
            var o:Object = URLUtil.stringToObject(browserManager.fragment);
            if (o.view == undefined)
                o.view = 0;
            tn.selectedIndex = o.view;
            browserManager.setTitle((tn.selectedIndex == 0) ? "Shipping" : "Receiving");
            tn.validateNow();
            var details:Boolean = o.details == true;
            if (tn.selectedIndex == 0)
                shipDetails.selected = details;
            else
                recvDetails.selected = details;
            parsing = false;
        }
        private function updateURL():void {
            if (!parsing)
                callLater(actuallyUpdateURL);
        }
        private function actuallyUpdateURL():void {
            var o:Object = {};
            var t:String = "";
            if (tn.selectedIndex == 1) {
                t = "Receiving";
                o.view = tn.selectedIndex;
                if (recvDetails.selected)
                    o.details = true;
            } else {
                t = "Shipping";
                o.view = tn.selectedIndex;
                if (shipDetails.selected)
                    o.details = true;
            }
            var s:String = URLUtil.objectToString(o);
            browserManager.setFragment(s);
            browserManager.setTitle(t);
        }
    ]]>
    </fx:Script>
    <mx:TabNavigator id="tn" change="updateURL()" width="300">
            <mx:Panel label="Shipping">
                <mx:CheckBox id="shipDetails" label="Show Details" change="updateURL()" />
            </mx:Panel>
            <mx:Panel label="Receiving">
                <mx:CheckBox id="recvDetails" label="Show Details" change="updateURL()" />
            </mx:Panel>
    </mx:TabNavigator>
</s:Application>
```

This example has one major drawback: it does not “remember” the state of the panel that is not in the current view. If you copy the bookmark and open it in a new browser, the view that you were last looking at, and the state of the CheckBox on that view, are maintained. However, the CheckBox in the other view that was hidden is reset to its original value (unchecked). There are several techniques to solve this issue. For more information, see “Using deep linking with navigator containers” on page 2033.

About BrowserManager events

The BrowserManager triggers the following types of BrowserChangeEvent events:

- `applicationURLChange`
- `browserURLChange`
- `urlChange`

These changes can be triggered by the following actions:

- URL is changed programmatically, such as with the BrowserManager’s `setFragment()` method (`applicationURLChange`)
- User clicks the Forward or Back button (`browserURLChange`)
- User changes the URL and clicks Enter or Go (`browserURLChange`)

The `urlChange` event is triggered whenever either `applicationURLChange` or `browserURLChange` events are triggered.

The following example shows the properties of the change events in a DataGrid control. You can trigger an `applicationURLChange` event by selecting a new value in the ComboBox control. You can trigger a `browserURLChange` event by using the Forward and Back buttons in your browser. In both cases, you also trigger a `urlChange` event.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- deeplinking/URLChangeLogger.mxml -->
<s:Application

    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    creationComplete="init();">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
    <![CDATA[
        import mx.managers.BrowserManager;
        import mx.managers.IBrowserManager;
        import mx.events.BrowserChangeEvent;
        private var bm:IBrowserManager;
        private function init():void {
            bm = BrowserManager.getInstance();
            bm.addEventListener(BrowserChangeEvent.APPLICATION_URL_CHANGE, doEvent);
            bm.addEventListener(BrowserChangeEvent.BROWSER_URL_CHANGE, doEvent);
            bm.addEventListener(BrowserChangeEvent.URL_CHANGE, doEvent);
            bm.init("", "Base title");
        }
        public function doEvent(evt:BrowserChangeEvent):void {
            eventDG.dataProvider.addItem(evt);
        }
    ]]>
    </fx:Script>

    <fx:Declarations>
        <fx:Array id="dp">
            <fx:Object label="one"/>
            <fx:Object label="two"/>
            <fx:Object label="three"/>
        </fx:Array>
    </fx:Declarations>
    <mx:ComboBox id="cb" dataProvider="{dp}"
        change="bm.setFragment('selectedItem=' + cb.selectedItem.label);"/>

    <mx:DataGrid id="eventDG"
        dataProvider="[]"
        width="100%"
        variableRowHeight="true"
        wordWrap="true"
        height="500"/>
</s:Application>
```

Changing the URL fragments in the browser's address bar triggers a `browserURLChange` event but does not trigger a page reload in FireFox or Internet Explorer 7. In Internet Explorer version 6 and earlier, changing the part of the address that is to the right of the pound sign ("#") *does* trigger a page reload.

Setting the title of the HTML wrapper

You can use the BrowserManager's `setTitle()` method to set the title in your HTML wrapper. This shows up as the name of the web page in the title bar of the browser. When you first initialize the BrowserManager, you set the value of the title in the second parameter to the `init()` method.

The following example sets the initial value of the title to "Welcome". It then changes the title depending on the name and hometown that you enter in the TextInput fields.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- deeplinking/TitleManipulationExample.mxml -->

        <mx:FormItem label="Name:">
            <mx:TextInput id="ti1"/>
        </mx:FormItem>
        <mx:FormItem label="Hometown:">
            <mx:TextInput id="ti2"/>
        </mx:FormItem>
        <mx:Button id="b1" click="updateTitle(event)" label="Submit"/>
    </mx:Form>
</s:Application>
```

Passing request data with URL fragments

In applications, there are several ways to pass values to an application with the URL. You can convert query string parameters to `flashVars` variables or you can append them to the SWF file's URL (for example, MyApp.swf?value1=x&value2=y). You do both of these things in the HTML wrapper that embeds the application. To access the values in your application, you then use the `FlexGlobals.topLevelApplication.application` object. For more information on passing `flashVars` variables, see "Passing request data with flashVars properties" on page 229.

The BrowserManager also provides a method of accessing values from a URL inside your application. You do this by accessing the URL fragments that deep linking uses. By default, you can append any Strings after the pound sign ("#") in the URL and be able to access them as semi-colon-separated name/value pairs. For example, with a URL like the following, you can access the `firstName` and `lastName` values once you convert the fragment to an object:

```
http://www.mydomain.com/MyApp.html#firstName=Nick;lastName=Danger
```

To convert these parameters to an object, you get the URL and then use the URLUtil class's `stringToObject()` method. You then access `firstName` and `lastName` as properties on that new object.

To make the URL more "URL-like", you can separate the fragments with an ampersand ("&"). When you convert the fragment to an object with the `stringToObject()` method, you specify the new delimiter.

The following example takes a URL that sets the value of the `firstName` and `lastName` query string parameters in its fragment. It specifies an ampersand as the delimiter.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- deeplinking/PassURLParamsAsFragments.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    creationComplete="init(event);">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
    <![CDATA[
        import mx.managers.BrowserManager;
        import mx.managers.IBrowserManager;
        import mx.utils.URLUtil;
        private var bm:IBrowserManager;
        [Bindable]
        private var fName:String;
        [Bindable]
        private var lName:String;
        private function init(e:Event):void {
            bm = BrowserManager.getInstance();
            bm.init("", "Welcome!");
            /* The following code will parse a URL that passes firstName and lastName as
               query string parameters after the "#" sign; for example:
               http://www.mydomain.com/MyApp.html#firstName=Nick&lastName=Danger */
            var o:Object = URLUtil.stringToObject(bm.fragment, "&");
            fName = o.firstName;
            lName = o.lastName;
        }
    ]]>
    </fx:Script>

    <mx:Form>
        <mx:FormItem label="First name:">
            <mx:Label id="ti1" text="{fName}"/>
        </mx:FormItem>
        <mx:FormItem label="Last name:">
            <mx:Label id="ti2" text="{lName}"/>
        </mx:FormItem>
    </mx:Form>
</s:Application>
```

Using deep linking with navigator containers

A common use case is for a user to start filling out a form, and then either bookmark the form for later use, or send the URL to someone else to take a look at the values. In many cases, forms are implemented as navigator containers such as TabNavigator and Accordion containers.

This can be a problem for deep linking because you might try to read properties on controls that are in views that have not yet been viewed (and therefore, the controls have not yet been instantiated). One possible solution is to disable deferred instantiation, and set the value of the container's `creationPolicy` property to `all`. This instructs Flex to instantiate all controls in all views at application startup, regardless of whether they can be viewed initially or not. This is not a recommended solution because it creates additional overhead when the application starts, and can end up using unnecessary amounts of processor time and memory. Depending on the complexity of the user interface, setting the value of the `creationPolicy` property to `all` can seriously degrade performance of your application and detract from a positive user experience. For more information about creation policies, see "About the creationPolicy property" on page 2336.

A technique that does not rely on deferred instantiation is to bind the values of the properties you want to maintain state on to the values in the URL. Controls that have not yet been created apply these values when they are created. This has the benefit of keeping the URL and the application's state in sync with each other, without requiring that a view's controls are first created.

You do this by setting up variables that are mapped to the URL's values at start up and then kept in sync with the application as the user interacts with it. When the application starts up, you set the value of the bound property to the value taken from the URL (if there is one). Then, whenever the application's state changes (such as when the user navigates to a new panel or clicks on a check box), you update the bound property to the new value. You also update the value of the property's fragment in the URL.

By doing this, though, you must wrap your variable assignments with try/catch blocks because you will attempt to set the values of variables with properties of components that might not yet have been instantiated. This ensures that assignment errors are caught rather than thrown as run-time errors.

The following example uses a TabNavigator container to help the user through a payment process. Whenever the user navigates to a new panel, changes the value in a TextInput control, or checks the CheckBox control, the URL and the bound properties are updated. At any time, you can bookmark the URL, close your browser, and then come back to the application at a later time. The values of all the properties are maintained in the bookmarked URL.

```

                        enter="updateURL()"/>
                </mx:FormItem>
                <mx:Button id="b1" click="updateTitle(event)" label="Submit"/>
            </mx:Form>
        </mx:Panel>
        <mx:Panel label="Credit Card Info">
            <mx:Form>
                <mx:FormItem label="Type:">
                    <mx:ComboBox id="cctype"
                        change="updateURL()"
                        selectedIndex="{cctypeFromURL}">
                        <mx:dataProvider>
                            <fx:String>Visa</fx:String>
                            <fx:String>MasterCard</fx:String>
                            <fx:String>American Express</fx:String>
                        </mx:dataProvider>
                    </mx:ComboBox>
                </mx:FormItem>
                <mx:FormItem label="Number:">
                    <mx:TextInput id="ccnumber"
                        text="{ccnumberFromURL}"
                        focusOut="updateURL()"
                        enter="updateURL()"/>
                </mx:FormItem>
            </mx:Form>
        </mx:Panel>
        <mx:Panel label="Check Out">
            <mx:TextArea id="ta2" text="You must agree to all the following conditions..."/>
            <mx:CheckBox id="agreeBox"
                label="Agree"
                selected="{agreeBoxFromURL}"
                click="updateURL()"/>
        </mx:Panel>
    </mx:TabNavigator>
    <mx:TextArea id="l1" height="400" width="300"/>
</s:Application>
```

Rather than update the values of the bindable variables in the `updateURL()` method, you can also set their values in the event handlers. For example, when the user changes the value of the TextInput control, you can use the `focusOut` and `enter` event handlers to set the value of the `hometownFromURL` property:

```
<mx:TextInput id="hometown"
    text="{hometownFromURL}"
    focusOut="hometownFromURL=hometown.text;updateURL()"
    enter="hometownFromURL=hometown.text;updateURL()"/>
```

In this example, the controls in the view update the model when the controls' properties change. This helps enforce a cleaner separation between the model and the view.

Accessing information about the current URL

In some cases, it is important to get information about the current URL, such as the server name or the protocol that was used to return the SWF's wrapper. You do this by using the BrowserManager and the URLUtil class.

You use the BrowserManager to get the URL, using either the `url`, `fragment`, or `base` properties. You can then use convenience methods of the URLUtil class to parse the URL. You can use these methods to extract the port, protocol, and server name from the URL. You can also use the URLUtil class to check if the protocol is secure or not.

The following example uses the URLUtil and BrowserManager classes to get information about the URL that was used to return the application.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- deeplinking/UseURLUtil.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"

        </mx:FormItem>
        <mx:FormItem label="Is secure?:">
            <mx:Label text="{isSecure}"/>
        </mx:FormItem>
        <mx:FormItem label="Previous URL:">
            <mx:Label text="{previousURL}"/>
        </mx:FormItem>
    </mx:Form>
</s:Application>
```

Printing

Many applications built in Adobe® Flex® let users print from within the application. For example, you might have an application that returns confirmation information after a user completes a purchase. Your application can allow users to print the information on the page to keep for their records.

***Note:** You can also print by using the context menu in Adobe® Flash® Player, or the Flash ActionScript PrintJob class, which is documented in the ActionScript 3.0 Reference for the Adobe Flash Platform.*

About printing by using Flex classes

The Flex mx.printing package contains classes that facilitate the creation of printing output from Flex applications:

FlexPrintJob A class that prints one or more objects. Automatically splits large objects for printing on multiple pages and scales the output to fit the page size.

PrintDataGrid A subclass of the DataGrid control with a default appearance that is customized for printing. The class includes properties and a method that provide additional sizing and printing features.

PrintAdvancedDataGrid A subclass of the AdvancedDataGrid control with a default appearance that is customized for printing. The class includes properties and a method that provide additional sizing and printing features.

PrintOLAPDataGrid A subclass of the OLAPDataGrid control with a default appearance that is customized for printing. The class includes properties and a method that provide additional sizing and printing features.

FlexPrintJobScaleType Defines constants used in the FlexPrintJob `addObject()` method.

Together, these classes give you control over how the user prints information from the application. For example, your application can print only a selected subset of the information on the screen, or it can print information that is not being displayed. Also, your application can reformat the information and optimize its layout and appearance for printing.

Users can print to PostScript and non-PostScript printers, including the Adobe® PDF® and Adobe® FlashPaper™ from Adobe® printer drivers.

Using the FlexPrintJob class

You use the FlexPrintJob class to print one or more Flex objects, such as a Form or VBox container. For each object that you specify, Flex prints the object and all objects that it contains. The objects can be all or part of the displayed interface, or they can be components that format data specifically for printing. The FlexPrintJob class lets you scale the output to fit the page, and automatically uses multiple pages to print an object that does not fit on a single page.

You use the FlexPrintJob class to print a dynamically rendered document that you format specifically for printing. This capability is especially useful for rendering and printing such information as receipts, itineraries, and other displays that contain external dynamic content, such as database content and dynamic text.

You often use the FlexPrintJob class within an event listener. For example, you can use a Button control with an event listener that prints some or all of the application.

***Note:** The FlexPrintJob class causes the operating system to display a Print dialog box. You cannot print without some user action.*

Build and send a print job

You print output by building and sending a print job.

1 Create an instance of the FlexPrintJob class:

```
var printJob:FlexPrintJob = new FlexPrintJob();
```

2 Start the print job:

```
printJob.start();
```

This causes the operating system to display a Print dialog box.

3 Add one or more objects to the print job and specify how to scale them:

```
printJob.addObject(myObject, FlexPrintJobScaleType.MATCH_WIDTH);
```

Each object starts on a new page.

4 Send the print job to the printer:

```
printJob.send();
```

5 Free up any unneeded objects.

***Note:** Because you are spooling a print job to the user's operating system between your calls to the `start()` and `send()` methods, you should limit the code between these calls to print-specific activities. For example, the content should not interact with the user between the `start()` and `send()` methods.*

The following sections detail the procedures to use in these steps.

Starting a print job

To start a print job, you create an instance of the FlexPrintJob class and call its `start()` method. This method prompts Flash Player or Adobe® AIR™ to spool the print job to the user's operating system, which causes the user's operating system to display a Print dialog box.

If the user selects an option to begin printing from the Print dialog box, the `start`() method returns a value of `true`. If the user cancels the print job, the return value is `false`. After the user exits the operating system Print dialog box, the `start()` method uses the printer information to set values for the FlexPrintJob object's `pageHeight` and `pageWidth` properties, which represent the dimensions of the printed page area.

***Note:** Depending on the user's operating system, an additional dialog box might appear until spooling is complete and the application calls the `send()` method.*

Only one print job can be active at a time. You cannot start a second print job until one of the following has happened with the previous print job:

- The `start()` method returns a value of `false` (the job failed).
- The `send()` method completes execution following a successful call to the `addObject()` method. Because the `send()` method is synchronous, code that follows it can assume that the call completed successfully.

Adding objects to the print job

You use the `addObject()` method of the FlexPrintJob class to add objects to the print job. Each object starts on a new page; therefore, the following code prints a DataGrid control and a Button control on separate pages:

```
printJob.addObject(myDataGrid);
printJob.addObject(myButton);
```

Scaling a print job

The *scaleType* parameter of the `addObject()` method determines how to scale the output. Use the following FlexPrintJobScaleType class constants to specify the scaling method:

Constant	Action
MATCH_WIDTH	(Default) Scales the object to fill the available page width. If the resulting object height exceeds the page height, the output spans multiple pages.
MATCH_HEIGHT	Scales the object to fill the available page height. If the resulting object width exceeds the page width, the output spans multiple pages.
SHOW_ALL	Scales the object to fit on a single page, filling one dimension; that is, it selects the smaller of the MATCH_WIDTH or MATCH_HEIGHT scale types.
FILL_PAGE	Scales the object to fill at least one page completely; that is, it selects the larger of the MATCH_WIDTH or MATCH_HEIGHT scale types.
NONE	Does not scale the output. The printed page has the same dimensions as the object on the screen. If the object height, width, or both dimensions exceed the page width or height, the output spans multiple pages.

If an object requires multiple pages, the output splits at the page boundaries. This can result in unreadable text or inappropriately split graphics. For information on how to format your print job to avoid these problems, see “Printing multipage output” on page 2045.

The FlexPrintJob class includes two properties that can help your application determine how to scale the print job. These properties are read-only and are initially 0. When the application calls the `start()` method and the user selects the Print option in the operating system Print dialog box, Flash Player or AIR retrieves the print settings from the operating system. The `start()` method populates the following properties:

Property	Type	Unit	Description
`pageHeight`	Number	Points	Height of the printable area on the page; does not include any user-set margins.
`pageWidth`	Number	Points	Width of the printable area on the page; does not include any user-set margins.

***Note:** A point is a print unit of measurement that is 1/72 of an inch. Flex automatically maps 72 pixels to one inch (72 points) of printed output, based on the printer settings.*

Completing the print operation

To send the print job to a printer after using the FlexPrintJob `addObject()` method, use the `send()` method, which causes Flash Player or AIR to stop spooling the print job so that the printer starts printing.

After sending the print job to a printer, if you use print-only components to format output for printing, call `removeChild()` to remove the print-specific component. For more information, see “Using a print-specific output format” on page 2042.

Example: A simple print job

The following example prints a DataGrid object exactly as it appears on the screen, without scaling:

```
<?xml version="1.0"?>
<!-- printing\DGPrint.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
            import mx.printing.*;
            // Create a PrintJob instance.
            private function doPrint():void {
                // Create an instance of the FlexPrintJob class.
                var printJob:FlexPrintJob = new FlexPrintJob();
                // Start the print job.
                if (printJob.start() != true) return;
                // Add the object to print. Do not scale it.
                printJob.addObject(myDataGrid, FlexPrintJobScaleType.NONE);
                // Send the job to the printer.
                printJob.send();
            }
        ]]>
    </fx:Script>
    <mx:VBox id="myVBox">
        <mx:DataGrid id="myDataGrid" width="300">
            <mx:dataProvider>
                <fx:Object Product="Flash" Code="1000"/>
                <fx:Object Product="Flex" Code="2000"/>
                <fx:Object Product="ColdFusion" Code="3000"/>
                <fx:Object Product="JRun" Code="4000"/>
            </mx:dataProvider>
        </mx:DataGrid>
        <mx:Button id="myButton"
            label="Print"
            click="doPrint();"/>
    </mx:VBox>
</s:Application>
```

In this example, selecting the Button control invokes the `doPrint()` event listener. The event listener creates an instance of the FlexPrintJob class to print the DataGrid control, adds the DataGrid control to the print job using the `addObject()` method, and then uses the `send()` method to print the page.

To print the DataGrid and Button controls on your page, specify myVBox, the ID of the object that contains both controls, in the `addObject()` method's *object* parameter. If want to print the DataGrid and Button controls on separate pages, specify each object in a separate `addObject()` method.

To print the DataGrid control so that it spans the page width, omit the second `addObject()` method parameter, or specify `FlexPrintJobScaleType.MATCH_WIDTH`. To print the DataGrid control with the largest size that fits on a single page, specify `FlexPrintJobScaleType.SHOW_ALL`. In the previous example, `FlexPrintJobScaleType.SHOW_ALL` has the same result as `FlexPrintJobScaleType.MATCH_WIDTH` because the DataGrid is short.

Print containers with a transparent background

Many Flex containers, such as the Spark Group and MX Box containers, are transparent by default. If you print a transparent container, the background color of anything behind the transparent container prints.

As an alternative to the Spark Group container, use a Spark BorderContainer or a SkinnableContainer with the `backgroundColor` property set. You can also define another container behind the Group with the appropriate background color. Or, set the `backgroundColor` property of the Application container.

For the MX Box and other containers, make sure to set the `backgroundColor` property.

Using a print-specific output format

In most cases, you do not want your printed output to look like the screen display. The screen might use a horizontally oriented layout that is not appropriate for paper printing. You might have display elements on the screen that would be distracting in a printout. You might also have other reasons for wanting the printed and displayed content to differ; for example, you might want to omit a password field.

To print your output with print-specific contents and appearance, use separate objects for the screen layout and the print layout, and share the data used in the screen layout with the print layout. You then use the print layout in your call or calls to the FlexPrintJob `addObject()` method.

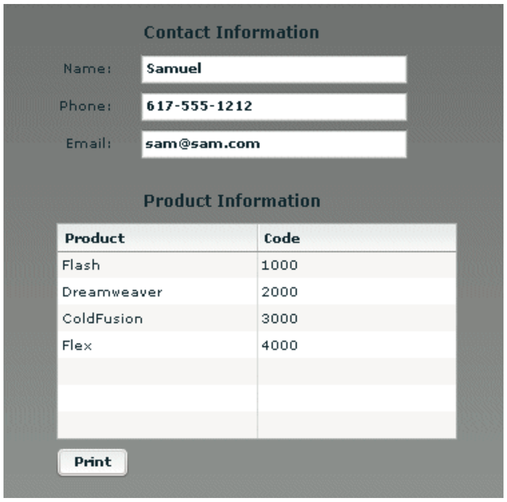
If your form includes a DataGrid, AdvancedDataGrid, or OLAPDataGrid control, use the PrintDataGrid, PrintAdvancedDataGrid, PrintOLAPDataGrid or control in your print layout. The print version of these controls have two advantages over the normal controls for printed output:

- It has a default appearance that is designed specifically for printing.
- It has properties and methods that support printing grids that contain multiple pages of data.

The code in the next section uses a short PrintDataGrid control. For more information on using the PrintDataGrid control, see “Using the PrintDataGrid control for multipage grids” on page 2045. For more information on using the PrintAdvancedDataGrid and PrintOLAPDataGrid control, see “Using the PrintAdvancedDataGrid control” on page 2053.

Example: A simple print-specific output format

This example creates a Flex form with three text boxes for entering contact information, and a data grid that displays several lines of product information. The following image shows how the output of this application looks on the screen:



Contact Information

Name: Samuel

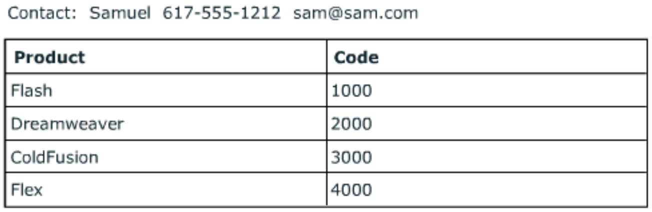
Phone: 617-555-1212

Email: sam@sam.com

Product Information

Product	Code
Flash	1000
Dreamweaver	2000
ColdFusion	3000
Flex	4000

The following image shows how the output looks when the user clicks the Print button to print the data:



Contact: Samuel 617-555-1212 sam@sam.com

Product	Code
Flash	1000
Dreamweaver	2000
ColdFusion	3000
Flex	4000

In this example, the MXML application file displays the screen and controls the printing. A separate custom MXML component defines the appearance of the printed output.

When the user clicks the Print button, the application's `doPrint()` method does the following things:

1 Creates and starts the print job to display the operating system's Print dialog box.

2 After the user starts the print operation in the Print dialog box, creates a child control using the myPrintView component.

3 Sets the MyPrintView control's data from the form data.

4 Sends the print job to the printer.

5 Cleans up memory by removing the print-specific child component.

The printed output does not include the labels from the screen, and the application combines the text from the screen's three input boxes into a single string for printing in a Label control.

The following code shows the contents of the application file:

```
<?xml version="1.0"?>
<!-- printing\DGPrintCustomComp.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    height="450" width="600">
    <fx:Script>
        <![CDATA[
            import mx.printing.FlexPrintJob;
            import myComponents.MyPrintView;
            public function doPrint():void {
                // Create a FlexPrintJob instance.
                var printJob:FlexPrintJob = new FlexPrintJob();

                // Start the print job.
                if(printJob.start()) {
                    // Create a MyPrintView control as a child
                    // of the current view.
                    var formPrintView:MyPrintView = new MyPrintView();
                    addElement(formPrintView);

                    // Populate the print control's contact label
                    // with the text from the form's name,
                    // phone, and e-mail controls.
                    formPrintView.contact.text =
                        "Contact: " + custName.text + "  " +
                        custPhone.text + "  " + custEmail.text;
                    // Set the print control's data grid data provider to be
                    // the displayed data grid's data provider.
                    formPrintView.myDataGrid.dataProvider =
                        myDataGrid.dataProvider;

                    // Add the SimplePrintview control to the print job.
                    // For comparison, try setting the
                    // second parameter to "none".
                    printJob.addObject(formPrintView);

                    // Send the job to the printer.
                    printJob.send();

                    // Remove the print-specific control to free memory.
                    removeElement(formPrintView);
                }
            }
        ]]>
    </fx:Script>
    <!-- The form to display-->
    <mx:Form id="myForm">
        <mx:FormHeading label="Contact Information"/>
        <mx:FormItem label="Name: ">
            <mx:TextInput id="custName"
                width="200"
                text="Samuel Smith"
                fontWeight="bold"/>
        </mx:FormItem>
        <mx:FormItem label="Phone: ">
            <mx:TextInput id="custPhone"
                width="200"
                text="617-555-1212"
                fontWeight="bold"/>
        </mx:FormItem>
        <mx:FormItem label="Email: ">
            <mx:TextInput id="custEmail"
                width="200"
                text="sam@sam.com"
                fontWeight="bold"/>
        </mx:FormItem>
        <mx:FormHeading label="Product Information"/>
        <mx:DataGrid id="myDataGrid" width="300">
            <mx:dataProvider>
                <fx:Object Product="Flash" Code="1000"/>
                <fx:Object Product="Flex" Code="2000"/>
                <fx:Object Product="ColdFusion" Code="3000"/>
                <fx:Object Product="JRun" Code="4000"/>
            </mx:dataProvider>
        </mx:DataGrid>
        <mx:Button id="myButton"
            label="Print"
            click="doPrint();"/>
    </mx:Form>
</s:Application>
```

The following MyPrintView.mxml file defines the component used by the application's `doPrint()` method. The component is a VBox container; it contains a Label control, into which the application writes the contact information from the first three fields of the form, and a PrintDataGrid control, which displays the data from the data source of the screen view's DataGrid control. For more information on the PrintDataGrid control and its advantages for printing, see "Using the PrintDataGrid control for multipage grids" on page 2045.

```
<?xml version="1.0"?>
<!-- printing\myComponents\MyPrintView.mxml -->
<mx:VBox xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    backgroundColor="#FFFFFF"
    height="300" width="500"
    paddingTop="50" paddingLeft="50" paddingRight="50">
    <!-- The controls to print, a label and a PrintDataGrid control. -->
    <mx:Label id="contact"/>
    <mx:PrintDataGrid id="myDataGrid" width="100%">
        <mx:columns>
            <mx:DataGridColumn dataField="Product"/>
            <mx:DataGridColumn dataField="Code"/>
        </mx:columns>
    </mx:PrintDataGrid>
</mx:VBox>
```

Printing multipage output

You can print well-formatted multipage output under the following conditions:

- When each control fits on a print page or less. You often encounter such jobs when printing a form with fixed-length fields.
- When the printed output includes one or more PrintDataGrid controls that are too long to print on a single page, particularly if the control height might vary, depending on the data. A good example of this type of output is a customer order receipt, which starts with the customer information, has an indeterminate number of order line items, and ends with total information.

Printing known-length multipage output

If you know the length of each component in a multipage document, you can create a separate print layout component for each page you print, and specify each layout page in a separate `addObject()` method, as follows:

```
printJob.addObject(introPrintView, "ShowAll");
printJob.addObject(finDetailPrintView, "ShowAll");
printJob.addObject(hrDetailPrintView, "ShowAll");
printJob.addObject(summaryPrintView, "ShowAll");
```

Using the PrintDataGrid control for multipage grids

When a DataGrid control with many rows does not fit on a single screen in your application, you typically have scroll bars that let users view all the data. When you print the DataGrid control, the output is the same as the screen display. Therefore, if your DataGrid control has rows or columns that are not immediately visible, they do not print. If you replace the DataGrid control with a PrintDataGrid control that does not have a height specified (or has a large height), you print all the rows, but some rows could be partially printed on the bottom of one page and partially printed at the top of another, as you often see with HTML printout.

You can solve these problems by using the following features of the PrintDataGrid control. These features let you correctly print grids that contain multiple pages of data without splitting rows across pages:

sizeToPage property Makes the printed data grid contain only full rows.

nextPage() method Gets the next printable page of data.

validNextPage property Is `true` if printing the data requires an additional page.

Using the sizeToPage attribute to format pages

A PrintDataGrid page consists of the rows that are visible in the control's current view. Suppose, for example, that a PrintDataGrid control has a height of 130 pixels. The total height of each row and header is 30 pixels, and the control's data provider has 10 rows. In this situation, the printed PrintDataGrid page contains only three complete data rows, plus the header. The `sizeToPage` property specifies whether to include a fourth and partial data row.

The `sizeToPage` property, which is `true` by default, causes the PrintDataGrid control to remove any partially visible or empty rows and to resize itself to include only complete rows in the current view. For the data grid described in the preceding paragraph, when this property is `true`, the DataGrid shrinks to show three complete data rows, and no incomplete rows; if the attribute is `false`, the grid includes a partial row at the bottom.

The following properties provide information on page sizing that are affected by the `sizeToPage` property:

Property	Description
`currentPageHeight`	Contains the height of the grid, in pixels, that results if the `sizeToPage` property is `true`. If the `sizeToPage` property is `true`, the `currentPageHeight` property equals the `height` property.
`originalHeight`	Contains the grid height that results if the `sizeToPage` property is `false`. If the `sizeToPage` property is `false`, the `originalHeight` property equals the `height` property.

In most applications, you leave the `sizeToPage` attribute at its default value (`true`), and use the `height` property to determine the grid height.

The `sizeToPage` property does *not* affect the way the page breaks when a single PrintDataGrid control page is longer than a print page. To print multipage data grids without splitting rows, you must divide the grid items into multiple views by using the `nextPage()` method, as described in the following section.

Using the nextPage() method and validNextPage property to print multiple pages

The `validNextPage` property is `true` if the PrintDataGrid control has data beyond the rows that fit on the current print page. You use it to determine whether you need to format and print an additional page.

The `nextPage()` method lets you page through the data provider contents by setting the first row of the PrintDataGrid control to be the data provider row that follows the last row of the previous PrintDataGrid page. In other words, the `nextPage()` method increases the grid's `verticalScrollPosition` property by the value of the grid's `rowCount` property.

The following code shows a loop that prints a grid using multiple pages, without having rows that span pages:

```
// Queue the first page.
printJob.addObject(thePrintView);
// While there are more pages, print them.
while (thePrintView.myDataGrid.validNextPage) {
    //Put the next page of data in the view.
    thePrintView.myDataGrid.nextPage();
    //Queue the additional page.
    printJob.addObject(thePrintView);
}
```

The section "Example: Printing with multipage PrintDataGrid controls" on page 2047 shows how to use the `nextPage()` method to print a report with a multipage data grid.

Updating the PrintDataGrid layout

When you use a PrintDataGrid control to print a single data grid across multiple pages, you queue each page of the grid individually. If your application customizes each page beyond simply using the `nextPage()` method to page through the PrintDataGrid, you must call the `validateNow()` method to update the page layout before you print each page, as shown in "Print output component" on page 2050.

Example: Printing with multipage PrintDataGrid controls

The following example prints a data grid in which you can specify the number of items in the data provider. You can, therefore, set the DataGrid control contents to print on one, two, or more pages, so that you can see the effects of different-sized data sets on the printed result.

The example also shows how you can put header information before the grid and footer information after the grid, as in a shipping list or receipt. It uses the technique of selectively showing and hiding the header and footer, depending on the page being printed. To keep the code as short as possible, the example uses simple placeholder information only.

The application consists of the following files:

- The application file displays the form to the user, including TextArea and Button controls to set the number of lines and a Print button. The file includes the code to initialize the view, get the data, and handle the user's print request. It uses the FormPrintView MXML component as a template for the printed output.
- The FormPrintView.mxml file formats the printed output. It has two major elements:
  - The print output template includes the PrintDataGrid control and uses two MXML components to format the header and footer contents.
  - The `showPage()` function determines which sections of the template to include in a particular page of the output, based on the page type: first, middle, last, or single. On the first page of multipage output, the `showPage()` function hides the footer; on the middle and last pages, it hides the header. On a single page, it shows both header and footer.
- The FormPrintHeader.mxml and formPrintFooter.mxml files specify the contents of the start and the end of the output. To keep the application simple, the header has a single, static Label control. The footer displays a total of the numbers in the Quantity column. In a more complete application, the header page could have, for example, a shipping address, and the footer page could show more detail about the shipment totals.

The files include detailed comments explaining the purpose of the code.

Multipage print application file

The following code shows the multipage print application file:

```
<?xml version="1.0"?>
<!-- printing\MultiPagePrint.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    initialize="initData();">
    <fx:Script>
    <![CDATA[
        import mx.printing.*;
        import mx.collections.ArrayCollection;
        // Import the MXML custom print view control.
        import myComponents.FormPrintView;
        // Declare variables and initialize simple variables.
        // The dgProvider ArrayCollection is the DataGrid data provider.
        // It must be bindable because you change its contents dynamically.
        [Bindable]

Using the PrintAdvancedDataGrid control

The PrintAdvancedDataGrid and PrintOLAPDataGrid controls provide the same functionality for the AdvancedDataGrid and OLAPDataGrid controls as the PrintDataGrid control does for the DataGrid control. For more information, see “Using the PrintDataGrid control for multipage grids” on page 2045.

The following example uses the PrintAdvancedDataGrid control to print an instance of the AdvancedDataGrid control.

```
<?xml version="1.0"?>
<!-- printing\ADGPrint.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Script>
        <![CDATA[
            import mx.printing.*;
            import mx.collections.ArrayCollection;
            import mx.printing.PrintAdvancedDataGrid;

            include "SimpleHierarchicalData.as";
            // Create a PrintJob instance.
            private function doPrint():void {
                // Create an instance of the FlexPrintJob class.
                var printJob:FlexPrintJob = new FlexPrintJob();

                // Initialize the PrintAdvancedDataGrid control.
                var printADG:PrintAdvancedDataGrid =
                    new PrintAdvancedDataGrid();
                // Exclude the PrintAdvancedDataGrid control from layout.
                printADG.includeInLayout = false;
                printADG.source = adg;
                // Add the print-specific control to the application.
                addElement(printADG);

                // Start the print job.
                if (printJob.start() == false) {
                    // User cancelled print job.
                    // Remove the print-specific control to free memory.
                    removeElement(printADG);
                    return;
                }
                // Add the object to print. Do not scale it.
                printJob.addObject(printADG, FlexPrintJobScaleType.NONE);
                // Send the job to the printer.
                printJob.send();
                // Remove the print-specific control to free memory.
                removeElement(printADG);
            }
        ]]>
    </fx:Script>
    <mx:VBox id="myVBox"
        width="100%" height="100%">
        <mx:AdvancedDataGrid id="adg"
            width="100%" height="100%">
            <mx:dataProvider>
                <mx:HierarchicalData source="{dpHierarchy}"/>
            </mx:dataProvider>
            <mx:columns>
                <mx:AdvancedDataGridColumn dataField="Region"/>
                <mx:AdvancedDataGridColumn dataField="Territory_Rep"
                    headerText="Territory Rep"/>
                <mx:AdvancedDataGridColumn dataField="Actual"/>
                <mx:AdvancedDataGridColumn dataField="Estimate"/>
            </mx:columns>
        </mx:AdvancedDataGrid>
        <mx:Button id="myButton"
            label="Print"
            click="doPrint();"/>
    </mx:VBox>
</s:Application>
```

The contents of the included SimpleHierarchicalData.as file are as follows:

```
[Bindable]
private var dpHierarchy:ArrayCollection = new ArrayCollection([
  {Region:"Southwest", children: [
     {Region:"Arizona", children: [
        {Territory_Rep:"Barbara Jennings", Actual:38865, Estimate:40000},
        {Territory_Rep:"Dana Binn", Actual:29885, Estimate:30000}]},
     {Region:"Central California", children: [
        {Territory_Rep:"Joe Smith", Actual:29134, Estimate:30000}]},
     {Region:"Nevada", children: [
        {Territory_Rep:"Bethany Pittman", Actual:52888, Estimate:45000}]},
     {Region:"Northern California", children: [
        {Territory_Rep:"Lauren Ipsum", Actual:38805, Estimate:40000},
        {Territory_Rep:"T.R. Smith", Actual:55498, Estimate:40000}]},
     {Region:"Southern California", children: [
        {Territory_Rep:"Alice Treu", Actual:44985, Estimate:45000},
        {Territory_Rep:"Jane Grove", Actual:44913, Estimate:45000}]}
  ]}
]);
```

This example uses the `PrintAdvancedDataGrid.source` property to initialize the PrintAdvancedDataGrid control from the AdvancedDataGrid control.

To support the AdvancedDataGrid control, the PrintAdvancedDataGrid control adds the following properties not available in the PrintDataGrid control:

Property	**Description**
`allowInteractions`	If `true`, allow some interactions with the control, such as column resizing, column reordering, and expanding or collapsing nodes. The default value is `false`.

Property	**Description**
`displayIcons`	If `true`, display the folder and leaf icons in the navigation tree. The default value is `true`.
`source`	Initialize the PrintAdvancedDataGrid control and all of its properties from the specified AdvancedDataGrid control.
`validPreviousPage`	Indicates that the data provider contains data rows that precede the rows that the PrintAdvancedDataGrid control currently displays.

Localization

Flex includes robust support for localizing your applications.

Introduction to localization

Localization is the process of including assets and formatting an application to support a locale. A *locale* is the combination of a language and a country code; for example, en_US refers to the English language as spoken in the United States, and fr_FR refers to the French language as spoken in France. To localize an application for the US and France, you would provide two sets of assets, one for the en_US locale and one for the fr_FR locale.

Locales can share languages. For example, en_US and en_GB (Great Britain) are different locales and therefore use different sets of assets. In this case, both locales use the English language, but the country code indicates that they are different locales, and might therefor use different assets. For example, an application in the en_US locale might spell the word “color”, whereas the word would be “colour” in the en_GB locale. Also, units of currency would be represented in dollars or pounds, depending on the locale, and the format of dates and times would also be different.

Localization goes beyond formatting numbers and translating strings that are used in your application. It can also include any type of asset such as audio files, images, styles, SWF files, and video files.

There are two ways to localize an application:

- Using built-in localization support. Flex includes localization-aware classes for the following:
  - Currency formatters
  - Number formatters
  - Date and time formatters
  - Layout mirroring
  - Bidirectional text
  - Sorters and collators
- Using resource bundles. Resource bundles let you define assets such as strings and images for various locales and use those assets at run time.

You can use a combination of these approaches, depending on how much of your application needs to be localized.

Library containing utility classes for sorting application locales

Setting the locale

When an application starts up, you should generally determine which locale the user wants and then set the application's `locale` style property to that locale. This ensures that the localization-aware classes such as formatters and sorters behave as the user expects. If you use resource bundles, then you should use some method to determine the user's preferred locale, and load the appropriate resource bundle.

To determine which locale your users want to use, you can use one or more of the following methods:

- User prompt — You can start the application in a default locale, and then ask the user to choose their preferred locale from a list of pre-determined locales.
- `Capabilities.language` — The `Capabilities.language` property in ActionScript provides the language code for Adobe® Flash® Player and Adobe AIR™. On English systems, this property returns only the language code, not the country code. This property returns the user interface language, which refers to the language used for all menus, dialog boxes, error messages, and help files in Flash Player and AIR.
- `Accept-Language` header — When a browser makes an HTTP request, it sends a list of languages to the server in the `Accept-Language` header. You can parse this header in your HTML wrapper and pass it as a `flashVars` variable into your Flex application. If you use URLLoader to load an application, you will not have access to this header.
- Browser preferences — You can access the browser's language settings in the HTML wrapper by using JavaScript. You can then pass the values as `flashVars` variables to your application. You can also use the ExternalInterface API to access the values from within your Flex application. The language is typically accessible via the Navigator object's `language` property. Depending on the browser, you also access the `userLanguage` or `systemLanguage` properties. For more information on using the ExternalInterface API, see "Using the ExternalInterface API to access JavaScript" on page 235.

Built-in localization support

Typically, you set the `locale` style property of the application or the component to the value of the `LocaleID.DEFAULT` property. This instructs Flex to use the client's operating system for locale information (such as the currency symbol, date/time format, or preferred sorting rules).

You can set the `locale` style property on an individual component or on the entire application. The style is inheritable, which means if you set it on the application, then all components in that application inherit that style, unless they specifically override it. If you do not set the `locale` style property, the compiler uses the global defaults that are defined in the defaults.css style sheet. In this case, the default value is "en".

The following example sets the value of the application's `locale` style property to the `LocaleID.DEFAULT` constant. When you run this example, the value of the DateTimeFormatter's `actualLocaleIDName` property will be whatever language preference you have set in your operating system.

```
<?xml version="1.0"?>
<!-- l10n/LocaleApp.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp()">
    <fx:Declarations>
        <s:DateTimeFormatter id="dateTimeFormatter"/>
    </fx:Declarations>
    <fx:Script>
        <![CDATA[
        import flash.globalization.LocaleID;

        public function initApp():void {
            this.setStyle("locale", LocaleID.DEFAULT);
        }

        public function doSomething():void {
            l1.text = dateTimeFormatter.actualLocaleIDName;
        }
        ]]>
    </fx:Script>
    <s:VGroup>
        <s:Label id="l1"/>
        <s:Button id="b1" label="Click Me" click="doSomething()"/>
    </s:VGroup>

</s:Application>
```

You can create a LocaleID object to retrieve data about the locale. You can use methods such as `getKeysAndValues()`, `getLanguage()`, `getRegion()`, `getScript()`, `getVariant()`, and `isRightToLeft()` to set properties and create other objects in your application.

Resource bundles

For applications that use resource bundles, you must explicitly compile assets for the supported locales into the application. You can then let your users choose from a list of the compiled-in locales. After determining the user's preferred locale, you set the value of the ResourceManager's `localeChain` property so that that locale's assets are used in your application.

Formatting dates, numbers, and currencies

Flex includes the following Spark classes for formatting dates, numbers and currencies:

- spark.formatters.CurrencyFormatter
- spark.formatters.NumberFormatter
- spark.formatters.DateTimeFormatter

Each of these classes is based on a similar class in the flash.globalization.* package. Flex lets you instantiate these formatters in MXML as well as ActionScript.

The formatters' output might differ depending on the runtime environment of the client. The formatters call the underlying operating system which can return different results, depending on the device.

The Spark formatters inherit the `locale` style property, have bindable properties and methods, and generate events.

As with other non-visual classes, you declare formatters in the `<fx:Declarations>` block of your applications.

The following example uses a CurrencyFormatter and a NumberFormatter to display formatted values in the client's default locale. The currency symbol and grouping separator (sometimes called the thousands separator) are defined by whatever the client machine's locale is. The client's preferred locale is obtained by using the `LocaleID.DEFAULT` property.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- l10n/CurrencyFormatterApp.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
               xmlns:s="library://ns.adobe.com/flex/spark"
               xmlns:mx="library://ns.adobe.com/flex/mx"
               minWidth="955" minHeight="600">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Declarations>
        <!-- Get the client's default locale from the OS
            by using the LocaleID.DEFAULT constant. -->
        <s:CurrencyFormatter id="curFormatter"
            useCurrencySymbol="true"
            locale="{LocaleID.DEFAULT}"/>
        <s:NumberFormatter id="numFormatter"
            locale="{LocaleID.DEFAULT}"/>
    </fx:Declarations>

    <fx:Script>
        <![CDATA[
            import flash.globalization.LocaleID;
        ]]>
    </fx:Script>

    <s:Label id="la1" text="{curFormatter.format(4500000)}"/>
    <s:Label id="la2" text="{numFormatter.format(4500000)}"/>

</s:Application>
```

You can explicitly let a user select their locale, and bind your formatters to the selected locale. You can also create a new LocaleID object based on the selected locale so that you can get other details about the locale.

The following example lets a user select from a list of locales, and then returns various information about that locale, including the script, language, and currency symbol:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- l10n/CurrencyFormatterSelector.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
               xmlns:s="library://ns.adobe.com/flex/spark"
               xmlns:mx="library://ns.adobe.com/flex/mx"
               minWidth="955" minHeight="600">
    <fx:Declarations>
        <s:CurrencyFormatter id="curFormatter"
            useCurrencySymbol="true"
            locale="{myDDL.selectedItem}"/>
    </fx:Declarations>

    <fx:Script>
        import flash.globalization.LocaleID;

        private function updateLocaleDetails():void {
            var locale:LocaleID = new LocaleID(myDDL.selectedItem);
            l6.text = "Locale Script: " + locale.getScript();
            l7.text = "Locale Region: " + locale.getRegion();
            l8.text = "Locale Language: " + locale.getLanguage();
        }
    </fx:Script>

    <s:VGroup>
        <s:HGroup>
            <s:Label text="Select Locale ID: "/>
            <s:DropDownList id="myDDL"
                change="updateLocaleDetails()"
                width="200"
                prompt="Select One"
                labelField="product">
                <mx:ArrayCollection>
                    <fx:String>ar-SA</fx:String>
                    <fx:String>da-DK</fx:String>
                    <fx:String>de-DE</fx:String>
                    <fx:String>en-GB</fx:String>
                    <fx:String>en-US</fx:String>
                    <fx:String>es-ES</fx:String>
                    <fx:String>fi-FI</fx:String>
                    <fx:String>fr-FR</fx:String>
                    <fx:String>it-IT</fx:String>
                    <fx:String>ja-JP</fx:String>
                    <fx:String>ko-KR</fx:String>
                    <fx:String>nb-NO</fx:String>
                    <fx:String>nl-NL</fx:String>
                    <fx:String>pt-BR</fx:String>
                    <fx:String>ru-RU</fx:String>
                    <fx:String>sv-SE</fx:String>
                    <fx:String>zh-CN</fx:String>
                    <fx:String>zh-TW</fx:String>
                </mx:ArrayCollection>
            </s:DropDownList>
        </s:HGroup>
        <s:Label id="currencyLabel"
            fontWeight="bold"
            fontSize="16"
            text="{curFormatter.format(4500000)}"/>
        <s:Label id="l2" text="Actual Locale ID Name: {curFormatter.actualLocaleIDName}"/>
        <s:Label id="l4" text="Currency Symbol: {curFormatter.currencySymbol}"/>
        <s:Label id="l5" text="Currency ISO Code: {curFormatter.currencyISOCode}"/>
        <s:Label id="l6" text="Locale Script: "/>
        <s:Label id="l7" text="Locale Region: "/>
        <s:Label id="l8" text="Locale Language: "/>
        <s:Label text="All Available Locale ID Names: "/>
        <s:TextArea id="ta1"
            text="{String(CurrencyFormatter.getAvailableLocaleIDNames())}"
            width="300" height="400"/>
    </s:VGroup>
</s:Application>
```

In addition, this example shows a list of all available locales. These are the locales that are supported by the client's operating system.

In some cases, you do not necessarily want your application to support all possible locales, or you want your application to use only one locale. In these cases, you can set the locale(s) programmatically. To do this, you can use the `locale` style property to apply a particular locale to individual components or to an entire application; for example:

```
<fx:Style>
    @namespace s "library://ns.adobe.com/flex/spark";
    s|Application {
        locale: 'fr-FR';
    }
</fx:Style>
```

You can also use resource bundles to configure the formatters. For more information, see "Custom formatting with resource bundles" on page 2119.

For more information on using the Spark formatter classes, see "Formatting Data" on page 2004.

Mirroring and bidirectional text

One aspect of localizing applications is the direction of the text. Some languages are read from left to right, such as English, and other languages are read from right to left, such as Hebrew.

The layout of the controls and the direction of text inputs should match the direction of the language. For example, an application that uses an RTL language should layout on the right side of the application's stage.

There are two primary ways to control the appearance of an application that supports both left-to-right (LTR) and right-to-left (RTL) languages:

- Layout mirroring — Layout mirroring is the process of flipping the appearance of the layout controls. For example, in an RTL application, vertical scroll bars should appear on the left instead of the right. For horizontal scrollbars, the thumb should appear on the right side of the control instead of the left. Layout mirroring is commonly used to make a UI match the direction of an RTL language.

- Text direction — Text direction defines the direction that text flows in the text controls. For RTL languages such as Hebrew and Arabic, the characters should render from the right side to the left. This also includes bidirectional text support, where a control might need to render some of the text RTL, and some of the text LTR in the same control. The Spark text controls handle directionality of the text internally. They do not use mirroring to render text.

To change an application's layout from LTR to RTL, set the `layoutDirection` property of the application object to `"rtl"`. The direction of text is automatically set based on the characters used, but you should also set the `direction` style property to `"rtl"` if the majority of your text is RTL. This property instructs the text control to apply RTL rules to the text.

For more information, see "Mirroring and bidirectional text" on page 2067.

Transforming text

The spark.globalization.StringTools class provides methods to convert letters to minuscules (lowercase letters) or majuscules (uppercase letters) for languages based on writing systems that incorporate the concept of capitalization (essentially, the Armenian, Latin, Cyrillic, and Greek alphabets). Using the StringTools class enables your application to use language-specific rules to perform those transformations.

The Spark StringTools class is based on the flash.globalization.StringTools class. This lets you use this class in MXML as well as ActionScript, and also lets it inherit the value of the `locale` style property. In addition, the Spark StringTools class has bindable properties and methods and generates events.

As with formatters, you declare an instance of the StringTools class in the `<fx:Declarations>` block of your application.

The following example uses the StringTools class to convert a string to all lower case:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- l10n/TransformingText.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx" minWidth="955" minHeight="600">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Declarations>
        <s:StringTools id="st1" locale="{LocaleID.DEFAULT}"/>
    </fx:Declarations>

    <fx:Script>
        <![CDATA[
            import flash.globalization.LocaleID;
        ]]>
    </fx:Script>
    <s:Label id="l1" text="{st1.toLowerCase('THIS LABEL WAS IN ALL CAPS.')}"/>
</s:Application>
```

Note that some characters for some languages do not have the same character length before and after case conversion. For example, the lower case sharp-s ("ß") is represented with two characters, "SS", when converted to upper case in the German language.

Sorting and matching

When ordering a list that is presented visually to the user, it is essential to follow the user's expectations. It is not just a question of aesthetics: expecting it at the end of the list, a Swedish user might fail to find an element that begins with "ö" if placed next to the plain "o". Fortunately, avoiding that problem is easy: sort the list with a Sort or SortingCollator class that is configured for the user's locale.

The sorting and matching classes' output might differ depending on the runtime environment of the client. The collators call the underlying operating system which can return different results, depending on the device.

As with formatters, the Spark Sort and SortField classes inherit the value of the `locale` style property on the application, or you can set the locale style on the component.

The following example creates a Spark Sort with two Spark SortFields. Select a locale from the the drop-down list to change the sort order to match the preferences of the selected locale.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- l10n/SortLocale2.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
               xmlns:s="library://ns.adobe.com/flex/spark"
               xmlns:mx="library://ns.adobe.com/flex/mx"
               minWidth="955" minHeight="600">
    <fx:Declarations>
        <s:Sort id="sortbyLastName_FirstName">
            <s:fields>
                <s:SortField name="last"/>
                <s:SortField name="first"/>
            </s:fields>
        </s:Sort>
        <mx:ArrayCollection id="collection" sort="{sortbyLastName_FirstName}">
            <mx:source>
                <fx:Object first="Anders" last="Öhlund"/>
                <fx:Object first="Eileen" last="Oehland"/>
                <fx:Object first="Aiden" last="Zorn"/>
                <fx:Object first="Steve" last="Ohlin"/>
            </mx:source>
        </mx:ArrayCollection>
    </fx:Declarations>

    <fx:Script>
        /* Sets the locale style on the document UI component.
            The SortField and Sort objects defined in the
            fx:Declarations section will inherit this style. */
        private function updateSort(e:Event):void {
            setStyle('locale', myDDL.selectedItem);
            collection.refresh();
        }
    </fx:Script>

    <s:VGroup>
        <s:HGroup>
            <s:Label text="Select Locale ID Name: "/>
            <s:DropDownList id="myDDL" prompt="Select One"
                width="200"
                labelField="product"
                change="updateSort(event)">
                <mx:ArrayCollection>
                    <fx:String>en-US</fx:String>
                    <fx:String>sv-SE</fx:String>
                    <fx:String>zh-CN</fx:String>
                </mx:ArrayCollection>
            </s:DropDownList>
        </s:HGroup>
        <s:DataGrid
            dataProvider="{collection}"
            creationComplete="{collection.refresh()}">
            <s:columns>
                <s:ArrayList>
                    <s:GridColumn dataField="last"/>
                    <s:GridColumn dataField="first"/>
                </s:ArrayList>
            </s:columns>
        </s:DataGrid>
    </s:VGroup>
</s:Application>
```

The following example uses the Spark Sort and SortField classes in ActionScript to create a locale-dependent sort:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- l10n/SweeterSwedishSort.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    width="500"
    creationComplete="initApp()">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            import mx.collections.ISort;
            import mx.collections.ISortField;
            import mx.collections.ArrayCollection;
            import spark.collections.Sort;
            import spark.collections.SortField;

            private var defaultSort:ISort = new Sort();
            private var swedishSort:ISort = new Sort();
            private var a:Array = new Array('Öhlund','Oehland','Zorn','Ohlin');
            private var names:ArrayCollection = new ArrayCollection(a);
            private var sortField:SortField = new SortField(null);
            private function initApp():void {
                originalOrder.text = "Original Order: " + names.toString();
                /* Add a style client, so sortField can pick up the locale style. */
                addStyleClient(sortField as spark.collections.SortField);
                /* Add the sortField to the fields array of the sorts. */
                defaultSort.fields = [sortField];
                swedishSort.fields = [sortField];
            }
            private function changeSortOrder(s:String):void {
                if (s=="en-US") {
                    /* Set the locale for the SortField. */
                    sortField.setStyle("locale","en-US");
                    names.sort = defaultSort;
                    /* Refresh the ArrayCollection after changing the sort property. */
                    names.refresh();
                    ta1.text = "Default Order: " + names.toString();
                } else {
                    /* Set the locale for the SortField. */
                    sortField.setStyle("locale","sv-SE");
                    names.sort = swedishSort;
                    /* Refresh the ArrayCollection after changing the sort property. */
                    names.refresh();
                    ta1.text = "Swedish Order: " + names.toString();
                }
            }
        ]]>
    </fx:Script>

    <s:Label id="originalOrder" paddingTop="10" fontWeight="bold"/>
    <s:TextArea id="ta1" height="200" width="400"/>
    <s:HGroup>
        <s:Button label="Show Default Sort Order" click="changeSortOrder('en-US')"/>
        <s:Button label="Show Swedish Sort Order" click="changeSortOrder('sv-SE')"/>
    </s:HGroup>
</s:Application>
```

The following example shows a custom sort that also depends on locale. This example uses the SortingCollator class and defines the logic for the sort. As with formatters and StringTools, you declare collators in the `<fx:Declarations>` block your application.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- l10n/SwedishSort.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
               xmlns:s="library://ns.adobe.com/flex/spark"
               xmlns:mx="library://ns.adobe.com/flex/mx" minWidth="955" minHeight="600"
               creationComplete="initApp()">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Declarations>
        <s:SortingCollator id="defaultSorter" locale="{LocaleID.DEFAULT}"/>
        <s:SortingCollator id="swedishSorter" locale="sv-SE"/>
    </fx:Declarations>

    <fx:Script>
        <![CDATA[
            import flash.globalization.LocaleID;
            import mx.collections.ArrayCollection;

            private var a:Array = new Array('Öhlund','Oehland','Zorn','Ohlin');
            [Bindable]
            private var names:ArrayCollection = new ArrayCollection(a);

            private function initApp():void {
                originalOrder.text = "Original Order: " + names.toString();
                sortNames(defaultSorter);
                label1.text = "Default Order: " + names.toString();
                sortNames(swedishSorter);
                label2.text = "Swedish Order: " + names.toString();
            }

            private function sortNames(sorter:SortingCollator):void {
                var changed:Boolean = false;
                while (!changed) {
                    changed = true;
                    for (var i:int = 0; i < names.length - 1; i++) {
                        var comparisonResult:int = sorter.compare(names[i],names[i+1]);
                        if (comparisonResult > 0) {
                            var s:String = names[i];
                            names[i] = names[i + 1];
                            names[i + 1] = s;
                            changed = false;
                        }
                    }
                }
            }
        ]]>
    </fx:Script>
    <s:Label id="originalOrder" paddingTop="10" fontWeight="bold"/>
    <s:Label id="label1"/>
    <s:Label id="label2"/>
</s:Application>
```

Matching is typically performed when the user searches for an item (for example, searching for a word in a document). When matching, you might want to ignore minor differences to increase the chances of finding relevant matches. For example, capitalization is commonly ignored. Diacritical marks are also often disregarded because not all users enter them as expected (either because their keyboard layout makes it difficult, or as the result of a spelling mistake).

You use the `<s:MatchingCollator>` tag to configure your matching rules. The following example shows how the locale and settings on the MatchingCollator can affect string comparisons:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- l10n/MatchingCollatorExample.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
               xmlns:s="library://ns.adobe.com/flex/spark"
               xmlns:mx="library://ns.adobe.com/flex/mx"
               minWidth="955" minHeight="600">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Declarations>
        <s:MatchingCollator id="matchingCollator"
            ignoreCase="false"
            ignoreCharacterWidth="false"
            ignoreDiacritics="{cb1.selected}"
            ignoreKanaType="false"
            ignoreSymbols="false"
            numericComparison="false"
            locale="{myDDL.selectedItem}"/>
    </fx:Declarations>

    <fx:Script>
```

```
        <![CDATA[
            private function doCompares():void {
                label1.text = matchingCollator.compare('ä','vu').toString();
                label2.text = matchingCollator.compare('a','ä').toString();
                label3.text = matchingCollator.compare('coté','côte').toString();
            }
        ]]>
    </fx:Script>
    <s:HGroup>
        <s:Label text="Select Locale ID: "/>
        <s:DropDownList id="myDDL"
            change="doCompares()"
            width="200"
            prompt="Select One">
            <mx:ArrayCollection>
                <fx:String>en-US</fx:String>
                <fx:String>fr-FR</fx:String>
            </mx:ArrayCollection>
        </s:DropDownList>
        <s:CheckBox id="cb1"
            label="Ignore Diacritics"
            change="doCompares()"/>
    </s:HGroup>
    <s:Form>
        <s:FormItem label="{matchingCollator.actualLocaleIDName}"/>
        <s:FormItem label="String1: ä, String2: vu">
            <s:Label id="label1" text=""/>
        </s:FormItem>
        <s:FormItem label="String1: a, String2: ä">
            <s:Label id="label2" text=""/>
        </s:FormItem>
        <s:FormItem label="String1: coté, String2: côte">
            <s:Label id="label3" text=""/>
        </s:FormItem>
    </s:Form>
    <s:Label text="-1: string1 is less than string 2; 0: strings are equal; 1: string1 is 
greater than string2"/>
</s:Application>
```

Additional collator examples are available on the Adobe Globalization blog.

Resource bundles

A *resource bundle* is a list of assets that is organized by locale. These assets can be just about anything, from strings, numbers, formats, and images to styles. You typically have a separate resource bundle for each locale that your application supports.

To localize an application with resource bundles, you first create properties files that define the localized assets. You then compile these properties files into the application as resource bundles, or create resource modules from the properties files and load them at run time. To compile resources into an application, you pass a comma-separated list of locales to the the `locale` compiler option. This compiler option has no effect on the spark.globalization.* classes.

You can also load pre-compiled resource modules and define resource bundles at run time. For more information on creating and using resource bundles in your applications, see “Resource Bundles” on page 2091.

Mirroring and bidirectional text

Introduction to mirroring and bidirectional text

here are two primary ways to control the appearance of an application that supports both left-to-right (LTR) and right-to-left (RTL) languages:

- Layout mirroring — Layout mirroring is the process of flipping the appearance of the layout controls. For example, in an RTL application, vertical scroll bars should appear on the left instead of the right. For horizontal scrollbars, the thumb should appear on the right side of the control instead of the left. Layout mirroring is commonly used to make a UI match the direction of an RTL language.
- Text direction — Text direction defines the direction that text flows in the text controls. For RTL languages such as Hebrew and Arabic, the characters should render from the right side to the left. This also includes bidirectional text support, where a control might need to render some of the text RTL, and some of the text LTR in the same control. The Spark Flex text controls handle directionality of the text internally. They do not use mirroring to render text.

To change an application's layout from LTR to RTL, set the `layoutDirection` property of the application object to "rtl". The direction of text is automatically set based on the characters used, but you should also set the `direction` style property to "rtl" if the majority of your text is RTL. This property instructs the text control to apply RTL rules to the text.

The following example lets you change the `layoutDirection` and `direction` style properties on the application from "ltr" to "rtl":

```
<?xml version="1.0" encoding="utf-8"?>
<!-- mirroring/DynamicMirroring.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
               xmlns:s="library://ns.adobe.com/flex/spark"
               xmlns:mx="library://ns.adobe.com/flex/mx"
               height="400" width="400">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            import mx.core.LayoutDirection;

            private function setDirectionProps():void {
                panel1.setStyle('direction', ddl1.selectedItem);
                panel1.setStyle('layoutDirection', ddl1.selectedItem);
            }
        ]]>
    </fx:Script>

    <s:Panel id="panel1" title="Panel With Non-Mirrored Content" width="350"
             layoutDirection="{LayoutDirection.LTR}">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <s:Label text="This panel contains content that is not mirrored."/>
        <s:Button label="This Button is not mirrored in the container"/>
        <s:DropDownList id="ddl1" requireSelection="true" selectedIndex="0"
change="setDirectionProps()">
            <s:ArrayList source="['ltr','rtl']"/>
        </s:DropDownList>
    </s:Panel>
</s:Application>
```

Mirroring is not supported when you set the `compatibility-version` compiler option to 3.0.0 or when the theme is Halo or Mobile. Mirroring is only supported by the Wireframe and Spark themes.

Layout mirroring

Layout mirroring refers to how containers and controls are drawn on the screen. The default direction is LTR. You can change any container or control that implements the ILayoutDirectionElement interface to lay out from right to left by setting the `layoutDirection` property to "rtl". This interface includes all controls that implement the IVisualElement interface as well as some assets that do not implement this interface.

The recommended method of using `layoutDirection` is to set it on the Application container so that all child containers and controls in the application inherit its value. You can set the `layoutDirection` property in one of the following ways:

- In MXML. For example:

  ```
  <s:Panel id="myPanel" layoutDirection="rtl">
  ```

- With the `setStyle()` method. For example:

  ```
  myPanel.setStyle("layoutDirection","rtl");
  ```

The following example shows two Panel containers. One sets the `layoutDirection` property to "rtl" and the other to "ltr":

```
<?xml version="1.0" encoding="utf-8"?>
<!-- mirroring/SimpleLayoutMirroring.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
               xmlns:s="library://ns.adobe.com/flex/spark"
               xmlns:mx="library://ns.adobe.com/flex/mx"
               height="400" width="400">

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            import mx.core.LayoutDirection;
        ]]>
    </fx:Script>

    <s:Panel title="Panel With Non-Mirrored Content" width="350"
             layoutDirection="{LayoutDirection.LTR}">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <s:Label text="This panel contains content that is not mirrored."/>
        <s:Button label="This Button is not mirrored in the container"/>
        <s:DropDownList requireSelection="true" selectedIndex="0">
            <s:ArrayList source="['Drop','Down','List']" />
        </s:DropDownList>
    </s:Panel>

    <s:Panel title="Panel With Mirrored Content" width="350"
             layoutDirection="{LayoutDirection.RTL}">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <s:Label text="This panel contains content that is mirrored."/>
        <s:Button label="This Button is mirrored inside the container"/>
        <s:DropDownList requireSelection="true" selectedIndex="0">
            <s:ArrayList source="['Drop','Down','List']" />
        </s:DropDownList>
    </s:Panel>
</s:Application>
```

Instead of using the strings "ltr" or "rtl", the `layoutDirection` style property can also take the following constants:

- `mx.core.LayoutDirection.LTR`
- `mx.core.LayoutDirection.RTL`

Text direction

Text direction refers to the direction that characters are rendered in text-based controls. Some languages, such as Hebrew and Arabic, are read from right to left. Most text-based controls auto-detect the direction of the text based on the character codes of the text content, but specifying the direction ensures that the punctuation follows the appropriate (RTL or LTR) rules.

As with the `layoutDirection` property, you typically set the `direction` property on the application or the parent container of the text-based control.

You can set the `direction` property in one of the following ways:

- In MXML. For example:

```
<s:Panel id="myPanel" direction="rtl">
```

- With the `setStyle()` method. For example:

```
myPanel.setStyle("direction","rtl");
```

The following example shows two Panel containers. One sets the `direction` property to RTL and the other to LTR:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- mirroring/SimpleTextMirroring.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
               xmlns:s="library://ns.adobe.com/flex/spark"
               xmlns:mx="library://ns.adobe.com/flex/mx"
               height="400" width="400">

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            import mx.core.LayoutDirection;
        ]]>
    </fx:Script>

    <s:Panel title="Panel With Non-Mirrored Content" width="350"
             direction="ltr">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <s:Label text="This panel contains content that is not mirrored."/>
        <s:Button label="This Button is not mirrored in the container."/>
        <s:DropDownList requireSelection="true" selectedIndex="0">
            <s:ArrayList source="['Drop','Down','List']" />
        </s:DropDownList>
    </s:Panel>

    <s:Panel title="Panel With Mirrored Content" width="350"
             direction="rtl">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <s:Label text="This panel contains content that is mirrored."/>
        <s:Button label="This Button is mirrored inside the container."/>
        <s:DropDownList requireSelection="true" selectedIndex="0">
            <s:ArrayList source="['Drop','Down','List']" />
        </s:DropDownList>
    </s:Panel>
</s:Application>
```

The `direction` style property only affects punctuation in this example. The characters themselves are not rendered from right to left because they use an LTR-based character set.

Support for setting the direction on text controls is built into text controls in the Spark component set because those text controls are based on FTE (Flash Text Engine). Text-based controls that are based on the TextField control do not support mirroring or bidirectional text. To use FTE with MX text-based controls, you must adjust your compiler settings. For more information, see "Mirroring with text controls" on page 2077.

Bidirectional text refers to text that contains both RTL and LTR content. For example, if you write a sentence in an RTL language such as Hebrew, but include the name of a company, such as Adobe. The compiler recognizes characters codes that use RTL and LTR and renders the text appropriately.

The following example shows bidirectional text:

```
<?xml version="1.0"?>
<!-- mirroring/BiDiText.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="addText()">

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import flashx.textLayout.formats.*;
            import spark.utils.TextFlowUtil;
            private function addText():void {
                myRT.textFlow = TextFlowUtil.importFromString("school is written " +
                    String.fromCharCode(0x0645, 0x062f, 0x0631, 0x0633, 0x0629) +
                    " in Arabic and " + String.fromCharCode(0x05E1, 0x05B5, 0x05E4, 0x05B6,
0x05E8) +
                    " in Hebrew.");
            }
        ]]>
    </fx:Script>

    <s:Panel title="Example of Bidirectional text">
        <s:RichText id="myRT" width="400" height="150"/>
    </s:Panel>
</s:Application>
```

In this example, the `direction` property is set to "rtl". This causes the punctuation to be reversed so that the period is on the left.

In some cases, you cannot set the `direction` style in MXML because some components (such as the ProgressBar and TileList controls) already define a `direction` property that defines other behavior. For more information, see "Overlapping direction properties" on page 2090.

Inheritance

The values of the `layoutDirection` and `direction` style properties are inherited by most components from their parent. As a result, you typically set these properties on the Application tag so that the properties are used consistently across the entire application. While it is possible to set these styles on individual components, this can be a cumbersome and mistake-prone approach.

In addition, if you set the style properties on individual components, you override the defaults set in the global.css file. These defaults define expected behavior. For example, you typically do not want to reverse the direction of an Image or VideoDisplay control when you mirror the contents of an application.

Some components, such as text-based controls, and the Image, BitmapImage, VideoPlayer, and VideoDisplay controls do not inherit the value of the `layoutDirection` style property. These components override the values of this property in the defaults.css file. They either do not support the property, support it in a different manner, or do not inherit the value because inheriting it would create unexpected results.

The following table describes the components that do not inherit the value of the `layoutDirection` style property:

Control	Description
BitmapImage, Image	The Image (both Spark and MX) and BitmapImage components do not inherit the value of the `layoutDirection` property from the container because Flex assumes that you do not want to mirror the contents. To override this behavior and reverse the contents of the MX Image and Spark BitmapImage controls, set the value of the `layoutDirection` property directly on the control. You cannot reverse the contents of the Spark Image control with the `layoutDirection` property. For more information, see “Images and video controls” on page 2081.
VideoDisplay, VideoPlayer	The VideoDisplay and VideoPlayer components do not inherit the value of the `layoutDirection` property for the same reason that the Image components do not: the assumption is that the contents should not be mirrored. However, you can override the default behavior by setting the `layoutDirection` property directly on the control. In this case, the VideoDisplay control mirrors the actual video being displayed. The VideoPlayer mirrors the subcontrols that are used to control the video but not the video itself.
Spark text-based controls, such as those based on the TextBase class (Label and RichText) and those including the RichEditableText control (RichEditableText, TextArea, and TextInput)	The reason that the Spark text-based controls do not inherit the value of the `layoutDirection` property is that they use FTE/TLF to auto-detect the direction of the text. The text characters are not mirrored in the same way that UI controls are mirrored. The input cursor for the TextArea and TextInput controls does not rely on the `layoutDirection` property, but rather on the value of the direction property to determine the starting position of the cursor when the control gains focus.

In addition to being a style, the `layoutDirection` property is defined on the ILayoutDirectionElement interface. All UIComponents inherit the properties of this interface. As a result, you can also set the `layoutDirection` as a property on an object. If a component's `layoutDirection` property is set to `null`, the component inherits the value from its parent. For components that implement the ILayoutDirectionElement interface, this means that setting `layoutDirection=null` is equivalent to `setStyle("layoutDirection", undefined).`

Components

This section describes the behavior of the components when you set `layoutDirection` to "rtl" on the Application container. In most cases, the behavior of Spark and MX controls is the same.

Basic UI controls

Control	Description
Alert	The Alert title is on the right. The text is not mirrored. Any icons are on the right. All buttons are arranged the opposite of their LTR order. For example, if buttons were "OK" and "Cancel", they appear as "Cancel" and "OK".
Button	The appearance of the Button is mirrored but the label text is not. If you use the Button control with an embedded icon, this icon is aligned on the right but the image itself is not reversed.
CheckBox	The label is rendered on the left. The check icon is not mirrored.
ColorPicker	The layout of the selector box and text input are reversed. The color grid is reversed, with the most common colors appearing on the right.

Control	Description
DateChooser	The direction of days and months are mirrored. The text for the days and numbers is not mirrored. The forward month arrow is on the left and back month arrow button is on the right.
DateField	The calendar icon appears on the left with the text input on the right. The calendar that opens looks like a mirrored DateChooser control. When you place a DateField control, be sure to leave enough room on the left side for the popup. When there is sufficient room on the left the DateChooser popup is aligned correctly. If there is not enough area on the left, the calendar that pops up can be cut off by the screen edge.
DownloadProgressBar	The DownloadProgressBar is not mirrored. It always fills from left to right.
Image	The contents of the Image control are not mirrored. To mirror the contents of an MX Image control, set the value of the `layoutDirection` property directly on the component. You cannot mirror the contents of the Spark Image control. Use the Spark BitmapImage or MX Image control instead.
Link	Button order is from right to left. All icons are aligned on the right of each button.
NumericStepper	The text in the input is aligned to the right. The navigation buttons are on the left. Numbers appear the same.
PopUpButton	The text is aligned to the right. The drop down icon is on the left.
PopUpMenuButton	See PopUpButton and Menu.
ProgressBar	The ProgressBar control fills in the track from right to left. The label is aligned to the right. The ProgressBar also has a direction style property that you can use to set the direction of the filling.
RadioButton	Labels are on the left of the radio icon.
RadioButtonGroup	See RadioButton control.
ScrollBar, HScrollBar, VScrollBar	Vertical scrollbars are the same, regardless of the value of the `layoutDirection` property. For horizontal scrollbars, the thumb defaults to the right, which is scroll position 0.
Slider, HSlider, VSlider	For the HSlider control, the slider thumb's starting point is reversed. The minimum value is at the right-most point on the slider, and the maximum value is at the left-most point.
Spinner	This component does not change when mirrored.
SWFLoader	The SWFLoader control mirrors its contents. In some cases, this might be undesireable. The workaround is to explicitly set the value of the `layoutDirection` property on the SWFLoader control when you do not want it to mirror the contents.
VideoDisplay	The contents of the VideoDisplay control are not mirrored, unless you explicitly set `layoutDirection` directly on the control.
VideoPlayer	The contents of the VideoPlayer control are never mirrored. The player controls are mirrored so that the slider thumb starts on the right and the location of the play button is on the right.

List-based controls

Control	Description
ButtonBar	Button order is from right to left. All icons are aligned on the right of each button.
ComboBox	In the editable field, text is aligned to the right.
DropDownList	The icon appears on the left side. List items are right aligned.
FileSystemComboBox	Same as the MX ComboBox control.
FileSystemList	Same as the MX List control.
List, HorizontalList	All items in the List are aligned to the right. ScrollBars are on the left (if they are necessary). For a horizontal list, item 0 begins on the right. Items are laid out right to left. A horizontal scroll bar thumb is positioned at `scrollPosition` 0 on the right. Note that for HorizontalList, the `direction` property requires a value of `TileBaseDirection.HORIZONTAL` or `TileBaseDirection.VERTICAL`. The `direction` style supports "ltr" and "rtl". The `direction` property on the MX List and Spark List controls cannot be set in ActionScript.

Containers

Control	Description
Accordion	The labels and icons are aligned to the right in the Accordion headers. All of the child controls of the Accordion panes inherit the `layoutDirection="rtl"` setting, unless the child controls override this value, either in the application or in the defaults.css file.
DividedBox	The first content area of a DividedBox is on the right.
Form	Form item labels are on the right on controls. The form heading is aligned right.
Grid	Grid items move from right to left and top to bottom.
HTML (AIR only)	The contents of the HTML control are not mirrored.
Panel	The title and any icons are aligned right. All of the child controls of the Panel container inherit the `layoutDirection="rtl"` setting, unless the child controls override this value, either in the application or in the defaults.css file.
TabNavigator	Tabs are laid out from right to left.
TileList	The first item is at the top right of the TileList. Items are laid out from right to left. The direction property requires a value of `TileBaseDirection.HORIZONTAL` or `TileBaseDirection.VERTICAL`. The `direction` style supports "ltr" and "rtl". The `direction` property on the TileList control cannot be set in ActionScript.
TitleWindow	The title is aligned on the right. The close button is aligned on the left.
Window	The title is aligned at the top right. All children are right aligned.
WindowedApplication (AIR only)	The WindowedApplication title is aligned at the top right. Controls of the WindowedApplication are at the top left. Status text is aligned on the right.

Data-driven controls

Control	Description
MX chart controls	For CartesianChart-based charting controls, the point of origin is the lower right. To align the DataTips to the right, use the `direction` style property. For more information, see "Mirroring charting controls" on page 2087.
DataGrid	Headers and all text are aligned right. Sort arrows are aligned left. Focus in editors moves from right to left. Column 0 is on the far right.
FileSystemDataGrid	Same as the MX DataGrid control.
FileSystemTree	Same as the MX Tree control.
Menu	Items are aligned right and submenus open to the left.
MenuBar	MenuBar data provider items are laid out from right to left. Submenus open to the left.
Tree	Items are aligned on the right. Items open to the left. The icons are reversed.

Text-based controls

The Spark text-based controls support bidirectionality. They auto-detect the direction of text based on the character codes. MX text-based controls do not support mirroring or bidirectionality. When using Spark text-based controls, you should set the `direction` property on the parent container or application. Setting the `direction` property causes the control to render punctuation properly as well as place the cursor in the correct location when the control gains focus.

For most text controls, changing the layout direction has no effect. This is mostly because most text controls do not have chrome that would require laying out differently. The following table describes the effects of changing `layoutDirection` on text controls:

Control	Description
Label	No change when `layoutDirection="rtl"`.
RichEditableText	No change when `layoutDirection="rtl"`.
RichText	No change when `layoutDirection="rtl"`.
RichTextEditor	No change when `layoutDirection="rtl"`. Note that the RichTextEditor control does not support mirroring or bidirectional text.
Text	No change when `layoutDirection="rtl"`. Note that the Text control does not support mirroring or bidirectional text.
TextArea	Spark TextArea: Text is aligned right. ScrollBars are on the left. Cursor starts on the right of the TextInput control, but only if `direction="rtl"`. MX TextArea: Does not support mirroring or bidirectional text. Use the Spark TextArea control instead.
TextInput	Spark TextInput: Text is aligned right. Cursor starts on the right of the TextInput control, but only if `direction="rtl"`. MX TextInput: Does not support mirroring or bidirectional text. Use the Spark TextInput control instead.

For more information, see "Mirroring with text controls" on page 2077.

Mirroring with text controls

Text in applications that use layout mirroring should generally read from right to left. Chrome on the text controls should lay out with an emphasis on right to left navigation.

The Flex compiler auto-detects the direction that text should read based on the Unicode values of the characters. When the characters use an RTL language such as Arabic or Hebrew, TLF-based text controls reverse the order in which they are written.

Flex adjusts the location of punctuation marks such as periods, exclamation points, and parentheses when the `direction` is set to "rtl". In addition, Flex also adjusts number separators, paragraph breaks, and soft hyphens, as well as other non-character entities so that their position makes sense. The algorithms for this are described in Description of the Unicode bidirectional algorithm.

The direction of the text itself is only reversed if the character set contains codes that instruct the compiler to read from RTL.

All text-based controls in the Spark component set support the `direction` property because they support FTE/TLF. Many text-based controls in the MX component set support the `direction` property.

If your application uses text-based controls in the MX component set such as MX Label, you must configure the compiler to use FTE, which supports bidirectional text. Otherwise, the text will render from LTR regardless of the character set you use. To ensure that MX controls use FTE in Flash Builder, select the "Use Flash Text Engine in MX Components" option. On the command line, you can apply the MXFTEText.css theme file:

```
mxmlc -theme+=themes/MXFTEText.css MyApp.mxml
```

Selecting this option causes most internal dependencies on UITextField to be replaced with UIFTETextField, which supports FTE. The MX TextInput, TextArea, and RichText text classes do not include this support. You should replace these controls with the equivalent Spark text-based controls.

For text controls that have columns, the `direction` style property also affects the column order. When `direction` is set to "rtl", the first column is on the right.

The MX RichTextEditor control does not support mirroring or bidirectional text.

Mirroring with skins

If you create custom skins, you should be aware of the effects on the skins when they are mirrored. In general you do not have to change your skins to use mirroring. In some cases, however, skins use absolute positioning to draw elements of the skin. You might need to edit the skin classes to make them appear correctly when setting `layoutDirection` to "rtl".

Mirroring is supported for components that use the Spark and Wireframe themes. It is not supported for components that use the Halo theme, or when you set the `compatibility-version` compiler option to 3.0.0.

Mirroring with effects

Effects that specify a direction, such as Wipe, or that incorporate a direction, such as WipeRight and WipeLeft, are not reversed when `layoutDirection` is set to "rtl". The effect always wipes in the direction that is defined by the effect, regardless of the value of the `layoutDirection` property.

The following example shows that when you change the `layoutDirection`, the direction of the Wipe does not change:

```
<?xml version="1.0"?>
<!-- mirroring\EffectMirroring.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
               xmlns:mx="library://ns.adobe.com/flex/mx"
               xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <s:states>
        <s:State name="default"/>
        <s:State name="vis"/>
    </s:states>

    <s:transitions>
        <s:Transition fromState="*" toState="*">
            <s:Sequence target="{myB}">
                <s:Wipe id="wipeEffect"
                        direction="right"
                        duration="1000"/>
            </s:Sequence>
        </s:Transition>
    </s:transitions>
    <fx:Script>
        <![CDATA[
            private function setDirectionProps():void {
                this.setStyle('layoutDirection', ddl1.selectedItem);
            }
        ]]>
    </fx:Script>

    <s:Panel title="Wipe Effect">
        <s:layout>
            <s:VerticalLayout paddingTop="15" paddingLeft="15"/>
        </s:layout>
        <s:Button id="myB" label="Wipe Effect"
          visible.default="false" visible.vis="true"/>
        <s:Button label="Show Button"
                  click="currentState='vis'"/>
        <s:Button label="Hide Button"
                  click="currentState='default'"/>
    </s:Panel>
    <s:DropDownList id="ddl1" requireSelection="true" selectedIndex="0"
change="setDirectionProps()">
        <s:ArrayList source="['ltr','rtl']"/>
    </s:DropDownList>
</s:Application>
```

Effects that specify x and y coordinates, such as Zoom and Move, apply the transform operations relative to the object. Because mirroring changes the location of the x coordinate, these effects are effectively reversed when the value of the `layoutDirection` property is changed.

The following example shows that when the `layoutDirection` changes, the zoom effect changes its destination point:

```
<?xml version="1.0"?>
<!-- mirroring\MoveEffectMirroring.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Declarations>
        <s:Move id="moveOut" target="{targetImg}" xBy="100"/>
        <s:Move id="moveBack" target="{targetImg}" xBy="-100"/>
    </fx:Declarations>
    <fx:Script>
        <![CDATA[
            private function setDirectionProps():void {
                this.setStyle('layoutDirection', ddl1.selectedItem);
            }
        ]]>
    </fx:Script>
    <s:Panel title="Move Effect Example" height="200" width="300">
        <s:Image id="targetImg" source="@Embed(source='../assets/logosmall.jpg')"/>
        <s:Button id="b1"
                  left="5" bottom="5"
                  label="Move Out" click="moveOut.play();"/>
        <s:Button id="b2"
                  left="120" bottom="5"
                  label="Move Back" click="moveBack.play();"/>
    </s:Panel>
    <s:DropDownList id="ddl1" requireSelection="true" selectedIndex="0"
change="setDirectionProps()">
        <s:ArrayList source="['ltr','rtl']"/>
    </s:DropDownList>
</s:Application>
```

When using coordinate-based effects with controls that do not inherit the `layoutDirection` style property, you might need to customize the target of the effect.

For example, if you apply the Scale effect to an Image control while the application is RTL, the Image's coordinates will not be mirrored. The result is that the Scale effect's point of origin is the upper left even when the application is RTL. To have the effect play correctly, you might need to explicitly set the Image control's `layoutDirection` to "rtl", but then the image itself is reversed as well.

The following example shows how the effect plays incorrectly when the layout for the application is RTL, but the layout for the image is not RTL:

```
<?xml version="1.0"?>
<!-- mirroring\ScaleEffectMirroring.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Declarations>
        <s:Scale id="scaleUp" target="{targetImg}" scaleXBy="2" scaleYBy="2"/>
        <s:Scale id="scaleDown" target="{targetImg}" scaleXBy="-2" scaleYBy="-2"/>
    </fx:Declarations>
    <fx:Script>
        <![CDATA[
            private function setAppDirection():void {
                this.setStyle('layoutDirection', ddl1.selectedItem);
            }
            private function setImageDirection():void {
                /* Note that this example uses an MX Image control rather than a Spark Image 
control.
                    Spark images cannot be reversed with the layoutDirection property. */
                targetImg.setStyle('layoutDirection', ddl2.selectedItem);
            }
        ]]>
    </fx:Script>
    <s:Panel title="Scale Effect Example" height="300" width="300">
        <s:layout>
            <s:VerticalLayout paddingTop="15" paddingLeft="15"/>
        </s:layout>

        <mx:Image id="targetImg" source="@Embed(source='../assets/logosmall.jpg')"/>
        <s:Button id="b1" label="Increase" click="scaleUp.transformX=-100;scaleUp.play();"/>
        <s:Button id="b2" label="Decrease" click="scaleDown.play();"/>
    </s:Panel>
    <s:HGroup>
        <s:Label text="Set Application's layoutDirection:"/>
        <s:DropDownList id="ddl1" requireSelection="true" selectedIndex="0" 
change="setAppDirection()">
            <s:ArrayList source="['ltr','rtl']"/>
        </s:DropDownList>
    </s:HGroup>
    <s:HGroup>
        <s:Label text="Set Image's layoutDirection:"/>
        <s:DropDownList id="ddl2" requireSelection="true" selectedIndex="0" 
change="setImageDirection()">
            <s:ArrayList source="['ltr','rtl']"/>
        </s:DropDownList>
    </s:HGroup>
</s:Application>
```

To workaround this issue, you should use two separate images, one for when the application’s layout is RTL and one for when the application’s layout is LTR. Then load the appropriate image when the layout changes.

Mirroring graphics and video

Images and video controls

Image and video controls do not inherit layout direction. The BitmapImage, Spark and MX Image, VideoPlayer, and VideoDisplay controls do not mirror their contents when you set the `layoutDirection` property on the application or parent container. These controls override the value of this property in the globals.css file because the expected behavior of images or videos is that the contents are not mirrored.

You can override this behavior in most cases, so that the contents of these controls is mirrored. You do this by setting the value of the `layoutDirection` property to “rtl” directly on the control. This is true for all the controls mentioned except Spark Image. The Spark Image control does not mirror its contents regardless of the value of the `layoutDirection` property because it is actually a child of the BitmapImage control (and image-related controls do not inherit the layout direction). To mirror the image, use the Spark BitmapImage or MX Image control.

As with images, icons are typically not mirrored, even if the component that uses the icon is reversed (except in some special cases, such as the disclosure icon in a Tree control).

To mirror the contents of the MX Image, BitmapImage, or VideoDisplay controls, set the `layoutDirection` property directly on the control. You cannot mirror the contents of the VideoPlayer control or the Spark Image control.

The following example sets the `layoutDirection` on the Application tag to "rtl", and then sets the `layoutDirection` property to "rtl" directly on several of the images. This example shows that the first image is not mirrored because it does not override the `layoutDirection` property and does not inherit its value from the Application container. The second image is also not mirrored because the Spark Image control does not reverse when the property is set on it. The third and fourth images are mirrored because the MX Image and Spark BitmapImage controls support setting `layoutDirection` directly on them.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- mirroring\MirroredImage.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
       xmlns:s="library://ns.adobe.com/flex/spark"
       xmlns:mx="library://ns.adobe.com/flex/mx"
       width="750"
       layoutDirection="rtl">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:Label text="application.layoutDirection = rtl"/>

    <s:HGroup>
        <s:Panel title="Spark Image with default layoutDirection" height="150" width="250">
            <s:layout>
                <s:VerticalLayout paddingTop="15" paddingLeft="15"/>
            </s:layout>
            <s:Image source="@Embed(source='../assets/logosmall.jpg')"/>
        </s:Panel>

        <s:Panel title="Spark Image with layoutDirection=rtl" height="150" width="250">
            <s:layout>
                <s:VerticalLayout paddingTop="15" paddingLeft="15"/>
            </s:layout>
```

```
      <s:Image source="@Embed(source='../assets/logosmall.jpg')" layoutDirection="rtl"/>
        </s:Panel>
    </s:HGroup>
    <s:HGroup>
        <s:Panel title="MX Image with layoutDirection=rtl" height="150" width="250">
            <s:layout>
                <s:VerticalLayout paddingTop="15" paddingLeft="15"/>
            </s:layout>
     <mx:Image source="@Embed(source='../assets/logosmall.jpg')" layoutDirection="rtl"/>
        </s:Panel>

        <s:Panel title="BitmapImage with layoutDirection=rtl" height="150" width="250">
            <s:layout>
                <s:VerticalLayout paddingTop="15" paddingLeft="15"/>
            </s:layout>
            <s:BitmapImage source="@Embed(source='../assets/logosmall.jpg')"
layoutDirection="rtl"/>
        </s:Panel>
    </s:HGroup>
</s:Application>
```

You can also cause the contents of image controls to be mirrored by setting the `scaleX` property to -1 rather than setting the `layoutDirection` property; for example:

```
sparkImage.scaleX = -1;
```

FXG and MXML graphics

FXG graphics and MXML graphics are mirrorred by default. When the application or parent container sets the `layoutDirection` property, the FXG component and the MXML graphic are mirrorred.

The following example shows a simple FXG component, and an MXML graphic, that inherit the application's `layoutDirection`, and are therefore mirrored:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- mirroring\MirroredFXG.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
       xmlns:s="library://ns.adobe.com/flex/spark"
       xmlns:mx="library://ns.adobe.com/flex/mx"
       xmlns:custom="*"
       layoutDirection="rtl"
       width="600" height="300">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:Label text="application.layoutDirection = rtl"/>
    <s:HGroup>
        <s:Panel title="FXG: layoutDirection = default" height="150" width="250">
            <s:layout>
                <s:VerticalLayout paddingTop="15" paddingLeft="15"/>
            </s:layout>
            <custom:ArrowAbsolute/>
        </s:Panel>
        <s:Panel title="MXML: graphic layoutDirection = default" height="150" width="250">
            <s:layout>
                <s:VerticalLayout paddingTop="15" paddingLeft="15"/>
            </s:layout>
            <!-- Use absolute coordinates. -->
            <s:Graphic>
                <!-- Use Use compact syntax with absolute coordinates. -->
                <s:Path data="
                        M 20 0
                        C 50 0 50 35 20 35
                        L 15 35
                        L 15 45
                        L 0 32
                        L 15 19
                        L 15 29
                        L 20 29
                        C 44 29 44 6 20 6">
                    <!-- Define the border color of the arrow. -->
                    <s:stroke>
                        <s:SolidColorStroke color="0x888888"/>
                    </s:stroke>
                    <!-- Define the fill for the arrow. -->
                    <s:fill>
                        <s:LinearGradient rotation="90">
                            <s:GradientEntry color="0x000000" alpha="0.8"/>
                            <s:GradientEntry color="0xFFFFFF" alpha="0.8"/>
                        </s:LinearGradient>
                    </s:fill>
                </s:Path>
            </s:Graphic>
        </s:Panel>
    </s:HGroup>
</s:Application>
```

This example uses the following FXG file as a custom component:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/comps/ArrowAbsolute.fxg -->
<Graphic xmlns="http://ns.adobe.com/fxg/2008" version="2">
    <!-- Use Use compact syntax with absolute coordinates. -->
    <Path data="
         M 20 0
         C 50 0 50 35 20 35
         L 15 35
         L 15 45
         L 0 32
         L 15 19
         L 15 29
         L 20 29
         C 44 29 44 6 20 6">
         <!-- Define the border color of the arrow. -->
         <stroke>
              <SolidColorStroke color="#888888"/>
         </stroke>
         <!-- Define the fill for the arrow. -->
         <fill>
              <LinearGradient rotation="90">
                   <GradientEntry color="#000000" alpha="0.8"/>
                   <GradientEntry color="#FFFFFF" alpha="0.8"/>
              </LinearGradient>
         </fill>
    </Path>
</Graphic>
```

You can set the `layoutDirection` of the parent container on the Graphic tag directly; for example:

```
<s:Graphic layoutDirection='rtl'>
```

Flex mirrors the contents of the BitmapFill class when you set the property on the container. This can cause undesireable results when you set the `layoutDirection` property on an application that supports both RTL and LTR. To workaround this issue, you can create two versions of the graphic. Then create a custom skin for your control that uses the background image and use states to pick the right one depending on the value of the application's `layoutDirection`.

Coordinate systems

When using graphics, you specify the start point and end point of paths. These locations are represented as coordinate X/Y pairs such as (0,0). The default location for (0,0) is the upper left corner of the container that you are drawing in. If you change the layout direction, the coordinates, too, are mirrored. As a result, the coordinates (0,0) in a container with `layoutDirection="rtl"` refers to the upper right corner of the container, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- mirroring/CoordinatesMirroring.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:HorizontalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import mx.core.LayoutDirection;
        ]]>
    </fx:Script>
     <mx:Panel title="LTR: from (0,0) to (100,100)"
        height="75%" width="40%" layout="horizontal"
        paddingTop="10" paddingBottom="10" paddingLeft="10" paddingRight="10">
        <s:Group>
           <s:Line xFrom="0" xTo="100" yFrom="0" yTo="100">
                 <s:stroke>
                      <s:SolidColorStroke color="0x000000" weight="1"/>
                 </s:stroke>
           </s:Line>
        </s:Group>
     </mx:Panel>
     <mx:Panel title="RTL: from (0,0) to (100,100)" layoutDirection="{LayoutDirection.RTL}"
        height="75%" width="40%" layout="horizontal"
        paddingTop="10" paddingBottom="10" paddingLeft="10" paddingRight="10">
        <s:Group>
           <s:Line xFrom="0" xTo="100" yFrom="0" yTo="100">
                 <s:stroke>
                      <s:SolidColorStroke color="0x000000" weight="1"/>
                 </s:stroke>
           </s:Line>
        </s:Group>
     </mx:Panel>
</s:Application>
```

This same logic applies to layout coordinates. When you set the x and y position of a component in an LTR panel, the coordinates start at the upper left. If the panel's layout direction is RTL, the coordinates start in the upper right. However, calling the `Menu.show(0,0)` method will not pop up a menu at the top right, but rather, the top left because global coordinates are used.

If you use the `localToGlobal()` and `globalToLocal()` methods, or the DisplayObject `transform` property, you should be aware of the difference between a component's `layoutMatrix` and `computedMatrix`. The `layoutMatrix` is used to calculate the component's layout relative to its siblings. The `computedMatrix` incorporates the `layoutMatrix` and an IVisualElement's `postLayoutTransformOffsets`, which include the mirroring transform. The `localToGlobal()` and `globalToLocal()` methods and the `transform.concatenatedMatrix` property reflect the computed matrix.

To transform a point to global coordinates using only the `layoutMatrix`, use the `MatrixUtil.getConcatenatedMatrix()` method, as the following example shows:

```
var myGlobalPoint =
MatrixUtil.getConcatenatedComputedMatrix(myIVisualElement).transformPoint(myPoint);
```

When working with coordinates, you should be aware of how the mirroring transform works. In an LTR application, X increases to the right and the origin is the upper left corner. In an RTL layout, X increases to the left and the origin is the upper right corner. This is accomplished internally by scaling the X-axis by -1 and translating the UIComponent by its width, after layout.

The effect of this mirroring transform is as follows:

```
element.x += width;
element.scaleX *= -1;
```

All of the IVisualElement classes implement the mirroring transform using the same mechanism that is used by the offsets transform. That means that they are combined with the layout transform after layout has occurred. The transforms do not affect the actual values of the UIComponent's `x` and `scaleX` properties.

Mirroring DataGrid controls

You can use mirroring with a DataGrid control by setting the `layoutDirection` property on the application. Like most controls, the DataGrid control inherits this value. Setting the layout direction to RTL causes the columns to be arranged from right to left (column 0 is the right-most). This also aligns the sort arrows to the left of the header text. If the DataGrid is editable and the user clicks on a cell, the focus starts on the right side of the grid.

If you use an RTL character set such as Hebrew or Arabic in the cells of a DataGrid control, you must set the "Use Flash Text Engine in MX components" check box in Flash Builder. Otherwise, the characters will not render correctly because the TextField control does not support bidirectionality.

To align the text in the cells to the right, reverse the direction of the header text, and reverse the text in the individual cells of a DataGrid, you must also set the `direction` style property to "rtl". You can set this on a parent container or on the DataGrid itself.

The following example sets both the `layoutDirection` and `direction` properties to "rtl" so that the entire Spark DataGrid is mirrored:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- mirroring\MirroredDataGrid.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
   xmlns:s="library://ns.adobe.com/flex/spark"
   xmlns:mx="library://ns.adobe.com/flex/mx"
   width="600" height="400"
   layoutDirection="rtl" direction="rtl">
    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;

            [Bindable]
            private var dp:ArrayCollection = new ArrayCollection([
                {Artist:'Train', Album:'Drops of Jupiter', Price:13.99},
                {Artist:'Charred Walls of the Damned', Album:'Ghost Town', Price:8.99},
                {Artist:'Bleading Deacons', Album:'Rule the Night', Price:11.99},
                {Artist:'Three Stooges', Album:'Greatest Hits', Price:9.99} ]);
        ]]>
    </fx:Script>

    <s:DataGrid id="myGrid" dataProvider="{dp}"
        width="350" height="150"/>
</s:Application>
```

Mirroring layouts

In a mirrored container, the roles of the left and right layout constraints are effectively reversed: the left constraint specifies the distance from the component's right edge to the right edge of the container, and the right constraint specifies the distance between the left edges.

Mirroring charting controls

To mirror charts, you set the `layoutDirection` property on the chart's parent container to RTL. Typically, you set it on the Application container. Charting controls inherit the value of this property set on the parent container.

In charts that are based on the CartesianChart class, such as the AreaChart, LineChart, and PlotChart controls, setting the `layoutDirection` property to "rtl" sets the point of origin at the lower right of the chart, rather than the lower left. For charts based on the PolarChart class, such as the PieChart control, setting the `layoutDirection` property to "rtl" has no effect on the point of origin.

The following example shows a chart that uses mirroring:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- mirroring\MirroredChart.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
       xmlns:s="library://ns.adobe.com/flex/spark"
       xmlns:mx="library://ns.adobe.com/flex/mx"
       creationComplete="srv.send()"
       layoutDirection="rtl"
       width="600" height="600">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Declarations>
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
    </fx:Declarations>
    <fx:Style>
        @namespace s "library://ns.adobe.com/flex/spark";
        @namespace mx "library://ns.adobe.com/flex/mx";
        @namespace charts "mx.charts.chartClasses.*";

        charts|DataTip {
            direction:rtl;
            paddingRight:-10;
            paddingLeft:5;
        }
    </fx:Style>

    <s:Panel title="Column Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <mx:ColumnChart id="myChart" dataProvider="{srv.lastResult.data.result}"
showDataTips="true">
```

```
            <mx:horizontalAxis>
                <mx:CategoryAxis id="haxis" categoryField="month" title="Month"/>
            </mx:horizontalAxis>
            <mx:verticalAxis>
                <mx:LinearAxis id="vaxis" title="Amount"/>
            </mx:verticalAxis>

            <mx:series>
                <mx:ColumnSeries
                    xField="month"
                    yField="profit"
                    displayName="Profit"/>
                <mx:ColumnSeries
                    xField="month"
                    yField="expenses"
                    displayName="Expenses"/>
            </mx:series>
        </mx:ColumnChart>
    </s:Panel>
</s:Application>
```

If you use an RTL character set such as Hebrew or Arabic in the text-based components of a chart control (such as the axis labels, axis titles, and DataTips), you must set the "Use Flash Text Engine in MX components" check box in Flash Builder. Otherwise, the text will render from left to right, regardless of the character set. In addition, you should be aware of some minor differences in the way charting controls use spacing and alignment when the `layoutDirection` is "rtl". For example, to right align the contents of DataTips, set the DataTip `direction` style property to "rtl". You might also need to adjust the padding properties to get the alignment you want. For example:

```
@namespace charts "mx.charts.chartClasses.*";
charts|DataTip {
    direction:rtl;
    paddingRight:-10;
    paddingLeft:5;
}
```

In addition, when the `layoutDirection` property is set to "rtl":

- Gutter padding — The left and right gutter style properties are reversed. The `gutterLeft` property changes the gutter padding on the right, and the `gutterRight` property changes the gutter padding on the left.
- Axis labels — Setting `labelAlign="left"` aligns the label to the right, and `labelAlign="right"` aligns the label to the left.
- Axis titles — The `textIndent` property is unaffected by the `layoutDirection` property. Axis titles do not support the `textAlign` property, so setting the `layoutDirection` property has no effect on this property.

Using the LocaleID class

The LocaleID class, available in Flash Player 10.1, provides methods and properties for using locale IDs. Locale IDs are strings that represent a particular locale. They can be useful when deciding whether to change the layout direction of an application.

The LocaleID class includes the `isRightToLeft()` method, which returns `true` if the currently set locale uses an RTL character code set, but otherwise returns `false`. You can use this method to set the values of the `layoutDirection` and `direction` properties. When you change locales in the following example, the application checks the `isRightToLeft()` method and sets the `layoutDirection` and `direction` properties on the Application object accordingly:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- mirroring\LocaleIDMirroringExample.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
            xmlns:s="library://ns.adobe.com/flex/spark"
            xmlns:mx="library://ns.adobe.com/flex/mx"
            width="300" height="300"
            layoutDirection="{localeBasedDirection}"
            direction="{localeBasedDirection}"
            creationComplete="updateSelection()">
    <fx:Script>
        <![CDATA[
            import flash.globalization.LocaleID;
            import mx.collections.ArrayCollection;
            [Bindable]
            public var localeBasedDirection:String;
            [Bindable]
            public var locID:LocaleID;
            [Bindable]
            public var myDP:ArrayCollection = new ArrayCollection(
                [ {name:"US", locale:"en_US"},
                    {name:"Israel", locale:"he_IL"},
                    {name:"France", locale:"fr_FR"} ]);

            private function updateSelection():void {
                locID = new LocaleID(localeIdList.selectedItem.locale);
                isRTLLabel.text = "RTL: " + locID.isRightToLeft().toString();
                getRegionLabel.text = "Region: " + locID.getRegion();
                getLanguageLabel.text = "Language: " + locID.getLanguage();

                if (locID.isRightToLeft()) {
                    localeBasedDirection = "rtl";
                } else {
                    localeBasedDirection = "ltr";
                }
            }
        ]]>
    </fx:Script>
    <s:Panel title="Select Locale" height="200" width="250">
        <s:layout>
            <s:VerticalLayout paddingLeft="10" paddingRight="10" paddingTop="10"/>
        </s:layout>
        <s:VGroup>
            <s:DropDownList id="localeIdList" selectedIndex="0"
                dataProvider="{myDP}"
                labelField="name"
                change="updateSelection();"/>
            <s:Label id="isRTLLabel"/>
            <s:Label id="getRegionLabel"/>
            <s:Label id="getLanguageLabel"/>
        </s:VGroup>
    </s:Panel>
</s:Application>
```

This example requires classes in the flash.globalization.* package, which are available in the 10.1 or later playerglobal.swc file. When compiling this example, be sure to set the target player version to 10.1 or later. In Flash Builder, this option is on the Compiler properties page. On the command-line, you can set the target Player version by using the `target-player` option; for example:

```
mxmlc -target-player=10.1 MyApp.mxml
```

In your applications, you will typically have some additional logic that sets the locale in your application, such as looking at the OS language code or accepting a user-configured setting. For information on setting locales in your application, see “Setting the locale” on page 2056. For more information about using the classes in the flash.globalization.* package, see Flash Player: Cultural diversity without complexity.

Mirroring with ToolTips and Error tips

The `layoutDirection` of the ToolTip class is same as the component that is attached to the ToolTip, or LTR, if the component does not implement the ILayoutDirectionElement interface.

Overlapping direction properties

Some components have a `direction` style property that is not related to text direction. These `direction` style properties typically take values not related to text direction. The compiler could throw an error if you try to set the `direction` property with these values. The following table lists these components:

Control	**Description**
mx.containers.Box	The `direction` property refers to the direction in which the container lays out its children.
mx.containers.FormItem	The `direction` property detemines whether the children of the FormItem are stacked vertically or placed horizontally.
mx.controls.ProgressBar	The `direction` property refers to the direction in which the bar expands towards completion. Possible values are "left" and "right". In general, you should set this to "right" when the application's layout is RTL.
mx.controls.scrollClasses.ScrollBar	The `direction` property detemines whether the scrollbar is for scrolling vertically or horizontally.
mx.controls.sliderClasses.Slider	The `direction` property detemines whether the slider is oriented vertically or horizontally. If you use an HSlider or VSlider, the control sets the value for you.
mx.containers.Tile	The `direction` property refers to the direction in which the container lays out its children.
mx.controls.listClasses.TileBase (which includes TileList and HorizontalList)	The `direction` property refers to the direction in which the container lays out its children.

Tips for using mirroring

Use the following tips when creating applications that use layout mirroring:

- Avoid setting the `layoutDirection` and direction properties on individual components. Set them on the Application container.
- Avoid using the alignment properties of individual components or blocks of text.
- Avoid using absolute positioning.

- If you want to mirror the contents of images (including icons) and videos, you should reverse the image or video in your image editing tools prior to importing them into your Flex application. The Spark and MX Image, BitmapImage, and VideoPlayer controls do not inherit the `layoutDirection` property from their parent container. The MX Image, Spark BitmapImage, and VideoDisplay controls do mirror their contents if you set `layoutDirection` on the control directly. The Spark Image control does not mirror its contents regardless of the value of its layout direction.
- Spark text controls do not use layout mirroring. Instead, they support bidirectionality of text internally. As a result, the primitive text controls such as Label, RichText, and RichEditableText do not support the `layoutDirection` property. You typically set the `direction` style property to change the directionality of the text in these controls.
- If you use text-based controls from the MX component set in your application, be sure to configure the compiler to use FTE to display the text. To do this in Flash Builder, select the "Use Flash Text Engine in MX components" check box. To do this on the command line, apply the MXFTEText.css theme file.
- For Spark text controls or FTE text in MX components, use the values `TextAlign.START` and `TextAlign.END` for the `textAlign` property, rather than `TextAlign.LEFT` and `TextAlign.RIGHT`. Using `START` and `END` will work in the expected manner, regardless of the direction of the text.
- In many components, navigating with the arrow keys changes depending on the directionality of the text. For example, the left arrow will navigate toward the beginning of the text and the right arrow key will navigate toward the end when the text is RTL.

Resource Bundles

Adobe® Flex® provides support for resource bundles in your applications.

Introduction to resource bundles

A *resource bundle* is a list of assets that is organized by locale. These assets can be just about anything, from strings, numbers, formats, and images to styles. You typically have a separate resource bundle for each locale that your application supports.

To localize an application with resource bundles, you first create properties files that define the localized assets. You then compile these properties files into the application as resource bundles, or create resource modules from the properties files and load them at run time.

Flex lets you change locales on the fly; if you compile more than one resource bundle into an application, you can toggle the resource bundle based on the locale. In addition, if you compile resource modules, you can load and unload the SWF files at run time based on the locale. You can even create new resource bundles programmatically.

How you load your resource bundles depends on how many locales your application supports:

- If your application supports just one or two locales, then you typically compile all the resources into the application. For more information, see “Using resource bundles” on page 2096.
- If your application supports many locales, you will likely want to load the appropriate resources at run time rather than compile all supported resources into the application at compile time. To do this, you compile your resource bundles into resource modules. For more information, see “Using resource modules” on page 2105.

If your application only needs to format numbers, currencies, and sort orders, you can use the built-in support for localization in the spark.globalization.* classes without using resource bundles.

"Localization" on page 2055

Lupo Manager, an AIR application that manages resource bundles

Creating resources

You define resource bundles in *resource properties files*. These properties files contain key/value pairs and are in UTF-8 format. You commonly use these properties files to specify the values of Strings in your applications, such as the label on a button or the items in a drop down list. The following example specifies the values for a form's labels in English:

```
# locale/en_US/RegistrationForm.properties
registration_title=Registration
submit_button=Submit Form
personname=Name
street_address=Street Address
city=City
state=State
zip=ZIP Code
thanks=Thank you for registering!
```

Resources can also embed binary assets such as audio files, video files, SWF files, and images. To embeds these assets in your properties files, you use the `Embed()` directive, just as you would include assets in a runtime style sheet. The following example embeds a JPG file as a resource:

```
flag=Embed("images/unitedstates.jpg")
```

You can also extract symbols from an embedded SWF file when using the `Embed()` directive, as the following example shows:

```
flag=Embed(source="FlagsOfTheWorld.swf", symbol="unitedstates")
```

To include custom classes, such as a programmatic skin, you can use the `ClassReference()` directive. The following example embeds the MySorter class in the sortingClasses.en_US package:

```
SORTER=ClassReference("sortingClasses.en_US.MySorter")
```

For information on how to use these various types of resources in your application, see "Using resource bundles" on page 2096.

You typically store resource properties files in a locale/*locale_name* subdirectory. You add this directory to your source path so that the compiler can find it when you compile your application, and append the locale to the `locale` compiler option. For information on how to compile resources into your Flex application, see "Compiling resources into Flex applications" on page 2092.

Compiling resources into Flex applications

After you create the resource properties files, you can either compile them as resource bundles into your application or you compile them into resource modules and load them at run time. If you compile the resources into the application, the compiler converts them to subclasses of the ResourceBundle class, and adds them to the application at compile time. If you compile the resources into resource modules, the compiler converts them to SWF files that you then load at run time on an as-needed basis.

For information on compiling and using resource modules, see "Using resource modules" on page 2105.

Compile resources into the application on the command line

1 Specify one or more locales to compile the application for with the `locale` compiler option. The value of this option is used by the `source-path` option to find the resource properties files. The `library-path` option also uses this value to include localized framework resources.

2 Specify the location of the resources with the `source-path` option. You can add the resources for more than one locale by using the `{locale}` token.

3 Set the value of the `allow-source-path-overlap` compiler option to `true`. This is optional, but if you do not set it, you might get a warning that the source path for the locale is a subdirectory of the project's source path.

In the following example, the LocalizedForm.mxml application uses a custom resource bundle for a single locale, en_US:

```
mxmlc -locale=en_US -source-path=c:\myapp\locale\{locale} -allow-source-path-overlap=true
c:\myapp\LocalizedForm.mxml
```

In Adobe® Flash® Builder™, you add the resource directories to the project's source path, and then add additional compiler options. The `source-path` option tells the compiler where to look for additional source files such as properties files.

Add resource directories to the project's source path in Flash Builder

1 Select Project > Properties.

2 Select the Source Path tab.

3 Click the Add Folder button. The Add Folder dialog box appears.

4 Navigate to the resource properties files' parent directory. Typically, you have locales in parallel directories under a parent directory such as /loc or /locale. For the en_US locale, you might have c:/myapp/loc/en_US directory. You will want to generalize the source path entry so that all locales are included. In this case, append `{locale}` to the end of the directory path. For example:

   ```
   c:/myapp/loc/{locale}
   ```

   This instructs the compiler to include all directories that match the `{locale}` token. In this case, en_US. If you add other locales, you only need to add them to the `locale` option and not the source path, as long as the new locale's resources are parallel to the existing locale's resources. For more information, see "Adding new locales" on page 2095.

5 Click OK to add this directory to your project's source path.

You then add the `locale` and `allow-source-path-overlap` options to the Additional Compiler Arguments field on the Flex Compiler pane in the project's properties, as the following example shows:

```
-locale=en_US -allow-source-path-overlap=true
```

The `locale` option instructs the compiler which resource properties files to convert into resource bundles. By default, all locales listed under the framework/bundles directory are supported (including en_US, de_DE, ru_RU, and ja_JP). If you want to use resource bundles for other locales, you must also generate the framework resource bundles for those locales and add those locale's to the `locale` option. For more information, see "Adding new locales" on page 2095.

The value of the `locale` option (in this case, en_US) is also used by the `library-path` option. If you specify multiple locales or change the locale, you will not be required to also change the library path.

The `allow-source-path-overlap` option lets you avoid a warning that the MXML compiler generates. You typically create a new subdirectory named locale under your project and then a subdirectory under that for each locale. You must explicitly add the locale directory to your source path. The directory where the application's MXML file is located is implicitly added to the source path. In the default Flash Builder project layout, this folder is the project directory and it is therefore the parent of the locale directory. By settings the allow-source-path-overlap option to `true`, you instruct the compiler not to warn you about overlapping values in the source path.

You can specify the locales in the flex-config.xml file by using the `<locale>` tag, as the following example shows:

```
<locale>
    <localeElement>en_US</localeElement>
</locale>
```

To add entries to your source path in the configuration file, you use the `<source-path>` child tag, as the following example shows:

```
<source-path>
    <path-element>locale/{locale}</path-element>
</source-path>
```

The `<source-path>` tag is commented out by default, so you must first uncomment the tag block.

Properties file syntax

Properties files are parsed as they are in Java. Each line typically takes the form of key=value. The following rules apply to properties files:

- Lines in properties files are not terminated by semi-colons or other characters.
- You can use an equals sign, a colon, or whitespace to separate the key from the value; for example:

  ```
  key = value
  key : value
  key value
  ```

- To add a comment to your properties file, start the line with a # or !. You can insert whitespace before the # or ! on a comment line. The following are examples of comments in a properties file:

  ```
  ! This is a comment.
  # This is a comment.
  ```

- Whitespace at the beginning of a value is stripped. Trailing whitespace is not stripped from the value.
- You can use standard escape sequences such as \n (newline), \r (return), \t (tab), \u0020 (space), and \\ (backslash).
- Backslash-space is an escape sequence for a space; for example, if a value starts with a space, you must write it as backslash-space or the compiler will interpret it as optional whitespace preceding the value. You are not required to escape spaces within a value. The following example starts the value with a space:

  ```
  key =\ value
  ```

- You can continue a line by ending it with a backslash. Leading whitespace on the next line is stripped.
- Backslashes that are not part of an escape sequence are removed. For example, \A is just A.
- You are not required to escape a double quote or a single quote.
- Lines that contain only whitespace are ignored.

Adding new locales

To add new locales to your projects:

1. Add the locale to the `locale` compiler option. This is typically a comma-separated list, as the following example shows:

    ```
    -locale=en_US,es_ES
    ```

    In Flash Builder, you add this in the Additional Compiler Arguments field of the Flex Compiler properties panel.

    If you edit the flex-config.xml file, you add locales by using the following syntax:

    ```
    <locale>
        <locale-element>en_US</locale-element>
        <locale-element>es_ES</locale-element>
    </locale>
    ```

2. Ensure that the new locale's resource properties files are in the source path. The source path entry for localized resources typically uses the `{locale}` token so that all new locales are automatically added to the source path, as long as those locales' resource directories have the same parent directory.

3. Create the framework resource bundles for the new locale, if the framework resource bundles do not already exist. You can see a list of the supported bundles by looking at the directory list under framework/bundles. The supported list includes en_US, ja_JP, fr_FR, ru_RU, and es_ES.

The `locale` option defines what locale's resources to include on the source path. It also instructs the compiler to include the localized framework resources for the specified locales. Framework components such as Label and Button use resources, just like your application and custom components can use resources. The resources required by these classes are located in the libraries like framework.swc or in separate resource bundle libraries. By default, framework resources for many common locales are included in the Flex SDK.

To use any supported locale, you do not need to do anything other than create properties files for your locale. For locales that are not included, such as en_IN, in addition to creating the new properties files, you must also create new framework locale files before compiling your Flex application.

To create a locale's framework resources, use the copylocale utility in the /sdk/bin directory. For Flash Builder, the copylocale utility is located in *flash_builder_install*/sdks/4.6.0/bin. You can only execute this utility from the command line.

The syntax for the copylocale utility is as follows:

```
copylocale original_locale  new_locale
```

For example, to create the framework locale files for the en_IN locale, use the following command:

```
copylocale en_US en_IN
```

This utility creates a new directory under frameworks/locale/*locale_name*. The name of this directory matches the name of the new locale. This directory is parallel to the other locale directories. In this example, it creates the locale/en_IN directory. This utility also creates SWC files in the new directory, including the framework_rb.swc and rpc_rb.swc files.

These resources must be in the library path. By default, the `locale/{locale}` entry is already set for your `library-path` compiler option, so you do not need to change any configuration options.

When you compile your application, and add the new locale to the `locale` option, the compiler includes the localized framework resources in the SWC files for that new locale.

About the ResourceBundle class

For each resource properties file, the Flex compiler generates a class that extends the ResourceBundle class, and adds that class to the application. The name of the class is the name of the properties file, with an underscore replacing the period in the filename.

The generated ResourceBundle class overrides a single method, `getContent()`, which returns an object that defines the values in the properties file. For example, if you use the RegistrationForm.properties file, the compiler generates the following class:

```
public class RegistrationForm_properties extends ResourceBundle {
    override protected function getContent():Object {
        var properties:Object = {};
        properties["registration_button"] = "Registration";
        properties["submit_button"] = "Submit Form";
        properties["personname"] = "Name";
        properties["street"] = "Street Address";
        properties["city"] = "City";
        properties["state"] = "State";
        properties["zip"] = "ZIP Code";
        properties["thanks"] = "Thank you for registering!";
        return properties;
    }
}
```

To view the generated classes, you can set the `keep-generated-actionscript` compiler option to `true` when you compile your application with an existing resource properties file.

You can write your own classes that extend the ResourceBundle class rather than create resource properties files that the compiler then uses to generate the resource bundle classes. You can then use those classes if you include them in your project. For more information, see "Creating resource bundles at run time" on page 2112.

Using resource bundles

After you create a resource properties file, you can use it in your Flex application as a resource bundle (the compiler converts properties files to subclasses of the ResourceBundle class when you compile your application). You can either bind values from the resource to an expression, or you can use methods of the ResourceBundle class to access those values.

There are two ways to access the values in resource bundles:

- `@Resource` directive
- Methods of the ResourceManager class

Using the `@Resource` directive to include resource bundles in your application is the simplest method. In the directive, you specify the name of the properties file and the key that you want to use. This method is simple to use, but is also restrictive in how it can be used. For example, you can only use the `@Resource` directive in MXML and you cannot change locales at run time. In addition, this directive only returns Strings.

The other way to access resource bundles is through the ResourceManager class. You can use the methods of the ResourceManager class in ActionScript, whereas you can only use the `@Resource` directive in MXML. These methods can return data types other than Strings, such as ints, Booleans, and Numbers. You can also use this class to switch locales at run time, so if you compiled multiple locales into the same application, you can change from one locale to the other.

The following sections describe how to use the `@Resource` directive and the ResourceManager class to access resource bundles in your Flex application.

Using the @Resource directive

In MXML, you can use the `@Resource` directive to access your resource bundles. You pass the `@Resource` directive the name of the resource bundle (the name of the properties file without the .properties extension) and the name of the key from the key/value pairs in the properties file. The directive returns a String of the key's value from your resource bundle.

The following example creates a form; the values for the labels in the form are extracted from the RegistrationForm.properties resource properties file.

```
<?xml version="1.0"?>
<!-- resourcebundles/LocalizedForm.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:Form>
        <s:FormItem label="@Resource(key='personname', bundle='RegistrationForm')">
            <s:TextInput/>
        </s:FormItem>
        <s:FormItem label="@Resource(key='street_address', bundle='RegistrationForm')">
            <s:TextInput/>
        </s:FormItem>
        <s:FormItem label="@Resource(key='city', bundle='RegistrationForm')">
            <s:TextInput/>
        </s:FormItem>
        <s:FormItem label="@Resource(key='state', bundle='RegistrationForm')">
            <s:TextInput/>
        </s:FormItem>
        <s:FormItem label="@Resource(key='zip', bundle='RegistrationForm')">
            <s:TextInput/>
        </s:FormItem>
    </s:Form>
</s:Application>
```

Because this application only uses a single locale, you compile it with the following compiler options:

```
-locale=en_US -allow-source-path-overlap=true -source-path=locale/{locale}
```

Accessing the values in a resource bundle with the `@Resource` directive is restrictive in that the directive can only be used in an MXML tag. In addition, you cannot change the locale at run time.

To use a class, such as a programmatic skin, as a resource, you use the `ClassReference()` directive in your properties file. The following example embeds the MyCheckBoxIcon_en_US class in the properties file:

```
CHECKBOXSKIN=ClassReference("MyCheckBoxIcon_en_US")
```

You then reference that class in your style properties, as the following example shows:

```
<mx:CheckBox selected="true"
    selectedUpIcon="@Resource(key='bundle1', 'CHECKBOXSKIN')"
    selectedDownIcon="@Resource(key='bundle1', 'CHECKBOXSKIN')"
    selectedOverIcon="@Resource(key='bundle1', 'CHECKBOXSKIN')"/>
```

To use a binary asset such as an image, you embed the image in the resource properties file. You can then use the asset anywhere that you might use an embedded image. To embed an image in the properties file, you use the `Embed` directive in your properties file, as the following example shows:

```
flag=Embed("images/unitedstates.gif")
```

The location of the image is relative to the location of the properties file. In this case, the images directory is under locale/en_US.

In your application, you use the `@Resource` directive anywhere a String might supply the location of the image. The following example uses the image as a source for the `<s:Image>` tag:

```
<?xml version="1.0"?>
<!-- resourcebundles/LocalizedFormResourceWithImage.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
     <s:layout>
        <s:VerticalLayout/>
    </s:layout>
   <s:Image source="@Resource(key='flag', bundle='RegistrationForm')"/>
    <s:Form>
        <s:FormItem label="@Resource(key='personname', bundle='RegistrationForm')">
            <s:TextInput/>
        </s:FormItem>
        <s:FormItem label="@Resource(key='street_address', bundle='RegistrationForm')">
            <s:TextInput/>
        </s:FormItem>
        <s:FormItem label="@Resource(key='city', bundle='RegistrationForm')">
            <s:TextInput/>
        </s:FormItem>
        <s:FormItem label="@Resource(key='state', bundle='RegistrationForm')">
            <s:TextInput/>
        </s:FormItem>
        <s:FormItem label="@Resource(key='zip', bundle='RegistrationForm')">
            <s:TextInput/>
        </s:FormItem>
    </s:Form>
</s:Application>
```

Using the ResourceManager

To use resource bundles in ActionScript, you use the methods of the ResourceManager class, such as `getString()` and `getClass()`. Using the ResourceManager is more flexible than using the `@Resource` directive because it lets you dynamically rather than declaratively set the values of properties from resources. It also lets you change locales at run time so that all localized resources in your application can be updated at once.

When using the ResourceManager, you must specify metadata that defines the resource bundles for your application. The syntax for this metadata is as follows:

```
<fx:Metadata>
    [ResourceBundle("Resource_file_name")]
</fx:Metadata>
```

For example:

```
<fx:Metadata>
    [ResourceBundle("RegistrationForm")]
</fx:Metadata>
```

For multiple resource bundles, add each one on a separate line inside the same `<fx:Metadata>` tag, as the following example shows:

```
<fx:Metadata>
    [ResourceBundle("RegistrationForm")]
    [ResourceBundle("StyleProperties")]
    [ResourceBundle("FormatterProperties")]
</fx:Metadata>
```

In an ActionScript class, you apply the metadata above the class name, as the following example shows:

```
[ResourceBundle("RegistrationForm")]
public class MyComponent extends UIComponent {
    ...
}
```

You can also bind expressions to the ResourceManager. These expressions are updated any time the locale changes.

The following example uses ActionScript to set the value of the Alert message, and binds the labels in the form to resources by using the ResourceManager’s `getString()` method.

```
<?xml version="1.0"?>
<!-- resourcebundles/LocalizedFormWithBinding.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script><![CDATA[
        import mx.resources.ResourceBundle;
        import mx.controls.Alert;
        private function registrationComplete():void {
            Alert.show(resourceManager.getString('RegistrationForm', 'thanks'));
        }
    ]]></fx:Script>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Metadata>
        [ResourceBundle("RegistrationForm")]
    </fx:Metadata>
    <s:Form>
        <s:FormItem label="{resourceManager.getString('RegistrationForm','personname')}">
            <s:TextInput/>
        </s:FormItem>
        <s:FormItem label="{resourceManager.getString('RegistrationForm','street_address')}">
            <s:TextInput/>
        </s:FormItem>
        <s:FormItem label="{resourceManager.getString('RegistrationForm','city')}">
            <s:TextInput/>
        </s:FormItem>
        <s:FormItem label="{resourceManager.getString('RegistrationForm','state')}">
            <s:TextInput/>
        </s:FormItem>
        <s:FormItem label="{resourceManager.getString('RegistrationForm','zip')}">
            <s:TextInput/>
        </s:FormItem>
    </s:Form>
    <s:Button id="b1"
        label="{resourceManager.getString('RegistrationForm','submit_button')}"
        click="registrationComplete()"/>
</s:Application>
```

To use a binary asset such as an image with the ResourceManager, you embed the image in the resource properties file. You can then use the asset anywhere that you might use an embedded image. To embed an image in the properties file, you use the `Embed` directive in your properties file, as the following example shows:

```
flag=Embed("images/unitedstates.gif")
```

The location of the image is relative to the location of the properties file. In this case, the images directory is under locale/en_US.

To use the image in your application, you use the ResourceManager's `getClass()` method. The following example uses the GIF file as both a skin for the Button control and a source for the `<s:Image>` tag:

```
<?xml version="1.0"?>
<!-- resourcebundles/LocalizedFormBindingWithImages.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp()">
    <fx:Script><![CDATA[
        import mx.resources.ResourceBundle;
        import mx.controls.Alert;
        private function initApp():void {
       b1.setStyle("downSkin", resourceManager.getClass("RegistrationForm", "flag"));
        }
        private function registrationComplete():void {
            Alert.show(resourceManager.getString('RegistrationForm', 'thanks'));
        }
    ]]></fx:Script>

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Metadata>
        [ResourceBundle("RegistrationForm")]
    </fx:Metadata>
    <s:Image source="{resourceManager.getClass('RegistrationForm', 'flag')}"/>
    <s:Form>
```

```
        <s:FormItem label="{resourceManager.getString('RegistrationForm','personname')}">
            <s:TextInput/>
        </s:FormItem>
       <s:FormItem label="{resourceManager.getString('RegistrationForm','street_address')}">
            <s:TextInput/>
        </s:FormItem>
        <s:FormItem label="{resourceManager.getString('RegistrationForm','city')}">
            <s:TextInput/>
        </s:FormItem>
        <s:FormItem label="{resourceManager.getString('RegistrationForm','state')}">
            <s:TextInput/>
        </s:FormItem>
        <s:FormItem label="{resourceManager.getString('RegistrationForm','zip')}">
            <s:TextInput/>
        </s:FormItem>
    </s:Form>
    <s:Button id="b1"
        label="{resourceManager.getString('RegistrationForm','submit_button')}"
        click="registrationComplete()"/>
</s:Application>
```

To use a class, such as a programmatic skin, as a resource, you use the `ClassReference()` directive in your properties file. The following example embeds the MyCheckBoxIcon_en_US class in the properties file:

```
CHECKBOXSKIN=ClassReference("MyCheckBoxIcon_en_US")
```

You can bind the value of the `getClass()` method for programmatic skins, as the following example shows:

```
<mx:CheckBox selected="true"
    selectedUpIcon="{resourceManager.getClass('bundle1','CHECKBOXSKIN')}"
    selectedDownIcon="{resourceManager.getClass('bundle1','CHECKBOXSKIN')}"
    selectedOverIcon="{resourceManager.getClass('bundle1','CHECKBOXSKIN')}"/>
```

For more information about the ResourceManager, see “About the ResourceManager” on page 2105.

Changing locales at run time with the ResourceManager

A common use of localization is to provide multiple locales for a single application, and to let the user switch the locale at run time. You can compile all possible locales into the application and then choose from among them. This solution is not very flexible because you can only select from locales that you added to the application at compile time. This solution can also lead to larger applications because the resource properties files and all of their dependencies must be compiled into the application.

You can also compile resource properties files into resource module SWF files, and then dynamically load those SWF files at run time. These modules provide all the resources for the locales. The advantage to this approach is that the application SWF file is smaller because the resources are externalized, but it requires an additional network request for each resource module that the client loads. For information on using resource modules, see “Using resource modules” on page 2105.

You change the locale at run time by changing the value of the ResourceManager’s `localeChain` property. This property takes an Array as its value. The Array’s first element is the current locale (such as en_US or es_ES).

To be able to change the locale at run time without using resource modules, you compile all the available locales into the application at compile time by including them as part of the `locale` option. This compiler option takes a comma-separated list of locales. If you add a second locale, such as es_ES, change the `locale` option to the following:

```
-locale=en_US,es_ES
```

The Flex application uses the list of locales in the `localeChain` property to determine precedence when getting values from resource bundles. If a value does not exist in the first locale in the list, the Flex application looks for that value in the next locale in the list, and so on.

Before compiling additional locales into an application, you must generate the framework resources for that locale, if they are not already created. You do this with the copylocale command-line utility. For more information, see "Adding new locales" on page 2095.

The order of the locales on the command line can be important. The application defaults to the first locale in the list if you do not specifically set the value of the ResourceManager's `localeChain` property when the application initializes.

The following example lets you select a new locale from the ComboBox control. When you change that value, the application updates the `localeChain` property. The application's locale-specific assets, such as the form labels, flag image, and alert message should change to the new locale.

```
<?xml version="1.0"?>
<!-- resourcebundles/BasicLocaleChain.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp()">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script><![CDATA[
        import mx.resources.ResourceBundle;
        import mx.controls.Alert;
        [Bindable]
        private var locales:Array = [ "es_ES","en_US" ];
        private function initApp():void {
        b1.setStyle("downSkin", resourceManager.getClass("RegistrationForm", "flag"));

            // Initialize the ComboBox to the first locale in the locales Array.
            localeComboBox.selectedIndex = locales.indexOf(resourceManager.localeChain[0]);
        }
        private function registrationComplete():void {
            Alert.show(resourceManager.getString('RegistrationForm', 'thanks'));
        }
        private function comboChangeHandler():void {
            // Set the localeChain to either the one-element Array
            // [ "en_US" ] or the one-element Array [ "es_ES" ].
            resourceManager.localeChain = [ localeComboBox.selectedItem ];

            // This style is not bound to the resource bundle, so it must be reset when
            // the new locale is selected.
        b1.setStyle("downSkin", resourceManager.getClass("RegistrationForm", "flag"));
        }
    ]]></fx:Script>
    <fx:Metadata>
        [ResourceBundle("RegistrationForm")]
    </fx:Metadata>
    <s:Image source="{resourceManager.getClass('RegistrationForm', 'flag')}"/>
    <mx:ComboBox id="localeComboBox"
        dataProvider="{locales}"
        change="comboChangeHandler()"/>
    <s:Form>
```

```
        <s:FormItem label="{resourceManager.getString('RegistrationForm','personname')}">
            <s:TextInput/>
        </s:FormItem>
        <s:FormItem label="{resourceManager.getString('RegistrationForm','street_address')}">
            <s:TextInput/>
        </s:FormItem>
        <s:FormItem label="{resourceManager.getString('RegistrationForm','city')}">
            <s:TextInput/>
        </s:FormItem>
        <s:FormItem label="{resourceManager.getString('RegistrationForm','state')}">
            <s:TextInput/>
        </s:FormItem>
        <s:FormItem label="{resourceManager.getString('RegistrationForm','zip')}">
            <s:TextInput/>
        </s:FormItem>
    </s:Form>
    <s:Button id="b1"
        label="{resourceManager.getString('RegistrationForm','submit_button')}"
        click="registrationComplete()"/>
</s:Application>
```

When you compile this example application, you must add both locales to the `locale` option, as the following list of compiler options shows:

```
-locale=en_US,es_ES -allow-source-path-overlap=true -source-path=locale/{locale}
```

Because this application uses multiple locales, you must prepare properties files for each one. You should have the following files in your project to use this example:

```
/main/BasicLocaleChain.mxml
/main/locale/en_US/RegistrationForm.properties
/main/locale/en_US/images/unitedstates.gif
/main/locale/es_ES/RegistrationForm.properties
/main/locale/es_ES/images/spain.gif
```

The contents of the properties files for this example should be similar to the following:

```
# /locale/en_US/RegistrationForm.properties
registration_title=Registration
submit_button=Submit Form
personname=Name
street_address=Street Address
city=City
state=State
zip=ZIP Code
thanks=Thank you for registering!
flag=Embed("images/unitedstates.gif")

# /locale/es_ES/RegistrationForm.properties
registration_title=Registro
submit_button=Enviar el formulario
personname=Nombre
street_address=Dirección de calle
city=Ciudad
state=Estado
zip=Código postal
thanks=¡Gracias por inscribirse!
flag=Embed("images/spain.gif")
```

If you do not bind the properties in your application to your resources, then those values are not updated when the locale changes.

When you compile an application for multiple locales, the ResourceManager's `localeChain` property is initialized to the locales specified by the `locale` compiler option. For example, if the `locale` option is `-locale=en_US,es_ES`, the application defaults to the English resources because en_US is listed first. You can override this default initial value at run time by specifying the value of the `localeChain` as an application parameter in the `flashVars` variable in the HTML template.

If you write your own HTML template, you can pass variables as `flashVars` properties in the `<object>` and `<embed>` tags. The following example specifies that the es_ES locale is the first in the `localeChain` property's Array:

```
<object id='mySwf'
    classid='clsid:D27CDB6E-AE6D-11cf-96B8-444553540000'
    codebase='http://fpdownload.macromedia.com/get/flashplayer/current/swflash.cab'
    height='100%'
    width='100%'>
    <param name='src' value='BasicLocaleChain.swf'/>
    <param name='flashVars' value='localeChain=es_ES,en_US'/>
    <embed name='mySwf'
        src='FlashVarTest.swf'
        pluginspage='http://www.adobe.com/go/getflashplayer'
        height='100%'
        width='100%'
        flashVars='localeChain=es_ES,en_US'
    />
>
```

If you are using SWFObject 2, the default template that Flex uses, define and pass the `flashVars` object to the `embedSWF()` JavaScript method, as the following example shows:

```
<script type="text/javascript" src="swfobject.js"></script>
        <script type="text/javascript">
            var swfVersionStr = "0";
            var xiSwfUrlStr = "";
            var flashvars = {};
            flashvars.localeChain="es_ES,en_US"
            var params = {};
            params.quality = "high";
            params.bgcolor = "#ffffff";
            params.allowscriptaccess = "sameDomain";
            var attributes = {};
            attributes.id = "TestProject";
            attributes.name = "TestProject";
            attributes.align = "middle";
            swfobject.embedSWF(
                "TestProject.swf", "flashContent",
                "100%", "100%",
                swfVersionStr, xiSwfUrlStr,
                flashvars, params, attributes);
</script>
```

This initializes the value of the `localeChain` property to `["es_ES", "en_US"]`.

For more information about using `flashVars` properties, see "Passing request data with flashVars properties" on page 229.

About the ResourceManager

The ResourceManager manages all resource bundles, regardless of their source. They can be loaded as resource modules, compiled into the application, or created programmatically.

The ResourceManager class is a Singleton. All components that extend UIComponent, Formatter, or Validator have a `resourceManager` property, which lets you access this manager. If you create other classes that need to use the ResourceManager, you can call the `ResourceManager.getInstance()` method to get a reference to it.

Whenever you set the value of the `localeChain` property, the ResourceManager dispatches a `change` event. This event causes values that are bound to resource properties to be updated. You can manually dispatch this event by calling the ResourceManager's `update()` method. The `change` event causes the following to occur:

- Binding expressions involving resource-access methods of ResourceManager such as `getString()` are updated.
- Components that extend UIComponent, Formatter, or Validator execute their `resourcesChanged()` method. This is how components such as CurrencyFormatter can update their default value for resource-backed properties such as `currencySymbol`. If you are writing another kind of class that needs to respond to resource changes, you can listen for `change` events from the ResourceManager.

The `localeChain` property is an Array so that the ResourceManager can support incomplete locales. For example, suppose you localize an application for English as spoken in India (by using the "en_IN" locale). Most of the resources are the same as for U.S. English (the en_US locale), so there is no reason to duplicate them all in the en_IN locale's resources. The en_IN locale's properties files need only to have the resources that differ between the en_US and en_IN locales. If the ResourceManager has bundles for both en_US and en_IN and you set the value of the `localeChain` property to `["en_IN", "en_US"]`, the ResourceManager searches for a resource first in the en_IN bundle. If the resource is not found there, then the ResourceManager searches for the resource in the en_US bundle. If the ResourceManager does not find the resource you specify in any locale, its methods return null.

The most commonly used method of the ResourceManager for resource access is the `getString()` method. However, the ResourceManager supports other data types. You can get resources typed as Numbers, Booleans, Uints, and ints by using other methods, as the following example shows:

```
resourceManager.getNumber("myResources", "PRICE"); // Returns a Number like 19.99.
resourceManager.getInt("myResources", "AGE"); // Returns an int like 21.
resourceManager.getUint("myResources", "COLOR"); // Returns a Uint like 0xFF33AA.
resourceManager.getBoolean("myResources", "SENIOR") // Returns the Boolean like true.
```

You can also use methods such as `getClass()`, `getString()`, `getObject()`, and `getStringArray()`.

Using resource modules

Resource modules are SWF files, separate from your application SWF file, that contain resources bundles for a single locale. Your application can preload one or more resource modules as it starts up, before it displays its user interface. It can also load resource modules later, such as in response to the user selecting a new locale. The ResourceManager interacts with all resource bundles the same, whether the bundles it manages were originally compiled into the application or loaded from resource modules.

Resource modules can be a better approach to localization than compile-time resources because you externalize the resource modules that can be loaded at run time. This creates a smaller application SWF file, but then requires that you load a separate SWF file for each resource module that you use. The result can be an increased number of network requests and an aggregate application size that is larger than if you compiled the locale resources into the application. However, if you have many locales, then loading them separately should save resources in the long run.

You are limited as to when you can use resources in resource modules during the application initialization sequence. The earliest that you can access a resource bundle in a resource module is during the application's preinitialize event handler. You should not try to access a resource at class initialization time or during preloading.

Creating resource modules

To create a resource module, you must do the following:

- Determine the required resource bundles
- Create the resource module SWF file

The following sections describe these tasks.

Determining the required resource bundles to include in a resource module

Before you can compile a resource module, you must know which resource bundles to put into it. In other words, you must know which resource bundles your application — and all of its framework classes — actually require. This includes not just the custom resource bundles that you create, but also the framework resource bundles that are required by the application.

To determine which resource bundles an application needs, you use the `resource-bundle-list` compiler option. When you compile an application, this option outputs a list of the needed bundles by examining the `[ResourceBundle]` metadata on all of the classes in your application.

The `resource-bundle-list` option takes a filename as its argument. This filename is where the compiler writes the list of bundles. On the Macintosh OS X, you must specify an absolute path for this option. On all other operating systems, you can specify a relative or absolute path.

When using the `resource-bundle-list` option, you must also set the value of the `locale` option to an empty string.

The following command-line example generates a resource bundle list for the application MyApp:

```
mxmlc -locale= -resource-bundle-list=myresources.txt MyApp.mxml
```

In this example, the compiler writes a file called myresources.txt. This file contains a list similar to the following:

```
bundles = RegistrationForm collections containers controls core effects skins styles
```

In Flash Builder, you add the `locale` and `resource-bundle-list` options to the Additional Compiler Arguments field on the Flex Compiler pane in the project's properties. On Windows, the output file's location is relative to the Flash Builder directory, not the project's directory. You can specify an absolute path instead. On Macintosh, the option must be an absolute path.

If you use custom resource bundles, those will be included in this list. In this example, the name of the resource properties file is RegistrationForm. The others are bundles containing framework resources.

You use this list to instruct the compiler which resource bundles to include when you compile a resource module.

Compiling a resource module

To compile a resource module, you must use the mxmlc command-line compiler. You cannot compile resource modules by using Flash Builder. The output is a SWF file that you can then load at run time.

To compile a resource module on the command line, use the following guidelines:

- Do not specify an MXML file to compile.
- Specify the `include-resource-bundles` option.
- Specify the locale by using the `locale` option.
- Add the locales to the source path.

The `include-resource-bundles` option takes a comma-separated list of resource bundles to include in the resource module. You generated this list of required resource bundles in "Determining the required resource bundles to include in a resource module" on page 2106.

When compiling a resource module, you must also specify the locale by using the `locale` option.

The following example compiles a resource module for the en_US locale:

```
mxmlc -locale=en_US
    -source-path=locale/{locale}
    -include-resource-bundles=RegistrationForm,collections,containers,controls,core,
     effects,skins,styles
    -output en_US_ResourceModule.swf
```

You can compile the resources for only a single locale into each resource module. As a result, you cannot specify more than one locale for the `locale` option.

You should use a common naming convention for all of your locales' resource modules. For example, specify the locale in the SWF file's name, but keep the rest of the file name the same for all locales. This is because when you load the resource module, you want to be able to dynamically determine which SWF file to load. In the previous example, the resource module for the en_US locale is named en_US_ResourceModule.swf. If you then generated a resource module for the es_ES locale, it would be named es_ES_ResourceModule.swf.

Loading resource modules at run time

To load a resource module at run time, you use the ResourceManager's `loadResourceModule()` method. After the resource module has finished loading, you set the value of the ResourceManager's `localeChain` property to the newly-loaded locale.

The ResourceManager's `loadResourceModule()` method asynchronously loads a resource module. It works similarly to the `loadStyleDeclarations()` method of the StyleManager, which loads style modules.

The `loadResourceModule()` method takes several parameters. The first parameter is the URL for the resource modules's SWF file. This is the only required parameter. The second parameter is `update`. You set this to `true` or `false`, depending on whether you want the resource bundles to immediately update in the application. For more information, see "Updating resource modules" on page 2110. The final two parameters are `applicationDomain` and `securityDomain`. These parameters specify the domains into which the resource module is loaded. In most cases, you should accept the default values (`null`) for these parameters. The result is that the resource module is loaded into child domains of the current domains.

The `loadResourceModule()` method returns an instance of the IEventDispatcher class. You can use this object to dispatch ResourceEvent types based on the success of the resource module's loading. You have access to the `ResourceEvent.PROGRESS`, `ResourceEvent.COMPLETE`, and `ResourceEvent.ERROR` events of the loading process.

You should not call the `loadResourceModule()` method and then immediately try to use the resource module because the resource module's SWF file must be transferred across the network and then loaded by the application. As a result, you should add a listener for the ResourceManager's `ResourceEvent.COMPLETE` event. When the `ResourceEvent.COMPLETE` event is dispatched, you can set the `localeChain` property to use the newly-loaded resource module.

The following example loads a resource module when the user selects the locale from the ComboBox control. It builds the name of the SWF file (in this case, it is either en_US_ResourceModule.swf or es_ES_ResourceModule.swf), and passes that file name to the `loadResourceModule()` method.

```
<?xml version="1.0"?>
<!-- resourcebundles/ResourceModuleApp.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp()">

            <s:TextInput/>
        </s:FormItem>
        <s:FormItem label="{resourceManager.getString('RegistrationForm','zip')}">
            <s:TextInput/>
        </s:FormItem>
    </s:Form>

    <s:Button id="b1"
        label="{resourceManager.getString('RegistrationForm','submit_button')}"
        click="registrationComplete()"/>

</s:Application>
```

To compile an application that uses only resource modules, do not specify any locales to be compiled into the application. You do this by setting the value of the `locale` option to an empty String. For example, on the command line, you can compile an application named MyApp.mxml with the following command:

```
mxmlc -locale= MyApp.mxml
```

In Flash Builder, you add the following option to the Additional Compiler Arguments field on the Flex Compiler pane in the project's properties:

```
-locale=
```

If you compile an application that uses both compiled-in resources and resource modules, then you specify the locale(s) for the compiled-in resources with the `locale` option.

You should try to avoid loading the same resource module more than once in the application. To do this, you can use the ResourceManager's `getLocales()` method. This method returns an Array of locales. You can compare this list against the resource module's locale that you are about to load.

You can find out which resource bundles exist for a specified locale by using the `getBundleNamesForLocale()` method.

You can get a reference to a particular locale's resource bundle by calling the `getResourceBundle()` method. Once you have a reference to a ResourceBundle, you can use a for-in loop to iterate over its content object. For more information, see "Enumerating resources" on page 2117.

Loading remote resource modules

Loading a remote resource module typically requires a crossdomain.xml file that gives the loading application permission to load the SWF file. You can do without a crossdomain.xml file if your application is in the local-trusted sandbox, but this is usually restricted to SWF files that have been installed as applications on the local machine. For more information about crossdomain.xml files, see "Using cross-domain policy files" on page 125.

Also, to use a remote resource module, you must compile the loading application with network access (have the `use-network` compiler option set to `true`, the default). If you compile and run the application on a local file system, you might not be able to load a remotely accessible SWF file.

Updating resource modules

The second parameter of the `loadResourceModule()` method is `update`. Set the `update` parameter to `true` to force an immediate update of the resource bundles in the application. Set it to `false` to avoid an immediate update of the resource bundles in the application. The resources are updated the next time you call this method or the `unloadResourceModule()` method with the `update` property set to `true`.

Each time you call the `loadResourceModule()` method with the `update` parameter set to `true`, Adobe Flash Player and AIR reapply all resource bundles in the application, which can degrade performance. If you load multiple resource modules at the same time, you should set the `update` parameter to `false` for all but the last call to this method. As a result, Flash Player and AIR only apply the resource bundles once for all new resource module SWF files rather than once for each new resource module SWF file.

Preloading resource modules at run time

You can load a resource module when the application starts up by calling the `loadResourceModule()` method from your application initialization code, and then specifying the value of the `localeChain` property after the module loads. This is useful if you have a default locale that you want all users to start the application with. However, you can also specify the locale that the application should load on startup by passing `flashVars` properties in the HTML wrapper. This lets you specify a locale based on some run time value such as the `Accept-Language` HTTP header or the `Capabilities.language` property in ActionScript.

The following table describes the `flashVars` properties that you pass to set the preloaded resource modules:

flashVars property	Description
`localeChain`	A comma-separated list of locales that initializes the `localeChain` property of the ResourceManager class. If the `localeChain` property is not explicitly set, then it is initialized to the list of locales for which the application was compiled, as specified by the `locale` compiler option.
`resourceModuleURLs`	A comma-separated list of URLs from which resource modules will be sequentially preloaded. Resource modules are loaded by the same class as RSLs, but are loaded after the RSLs. The URLs can be relative or absolute.

As with URL parameters, you must separate these values with an ampersand (&). You must also ensure that the values are URL encoded.

If you write your own HTML template, you can pass variables as `flashVars` properties in the `<object>` and `<embed>` tags. The following example specifies that the es_ES locale's resource module is preloaded when the application launches:

```
<object id='mySwf'
    classid='clsid:D27CDB6E-AE6D-11cf-96B8-444553540000'
    codebase='http://fpdownload.macromedia.com/get/flashplayer/current/swflash.cab'
    height='100%'
    width='100%'>
    <param name='src' value='ResourceModuleApp.swf'/>
    <param name='flashVars'
        value='resourceModuleURLs=es_ES_ResourceModule.swf&localeChain=es_ES'/>
    <embed name='mySwf'
        src='ResourceModuleApp.swf'
        pluginspage='http://www.adobe.com/go/getflashplayer'
        height='100%'
        width='100%'
        flashVars='resourceModuleURLs=es_ES_ResourceModule.swf&localeChain=es_ES'
    />
>
```

If you are using the SWFObject 2 template that Flex uses by default, define and pass the `flashVars` object to the `embedSWF()` JavaScript method, as the following example shows:

```
<script type="text/javascript" src="swfobject.js"></script>
        <script type="text/javascript">
            var swfVersionStr = "0";
            var xiSwfUrlStr = "";
            var flashvars = {};
      flashvars.resourceModuleURLs="es_ES_resourceModule.swf"
     flashvars.localeChain="es_ES"
            var params = {};
            params.quality = "high";
            params.bgcolor = "#ffffff";
            params.allowscriptaccess = "sameDomain";
            var attributes = {};
            attributes.id = "TestProject";
            attributes.name = "TestProject";
            attributes.align = "middle";
            swfobject.embedSWF(
                "TestProject.swf", "flashContent",
                "100%", "100%",
                swfVersionStr, xiSwfUrlStr,
                flashvars, params, attributes);
</script>
```

Using a combination of compile-time resources and resource modules

You might have a default locale that you want all users of your application to start with. You can compile this locale's resources into the application. You can then load external resource modules if the user changes the locale.

To do this, you compile the resource module as you normally would. When you compile the application, rather than specifying an empty String for the `locale` option, you set it to the locale that you want to compile into the application. This compiled-in locale's resource bundles become the default bundles when the application starts. You can then load a resource module SWF file as you normally would at run time.

Unloading resource modules at run time

You can unload a resource module when you are no longer using it. For example, if the user changes to a different locale, you can unload the resource module for one locale after loading the resource module for the new locale. This can reduce the memory footprint used by the application.

To unload a resource module, you can use the ResourceManager's `unloadResourceModule()` method. This removes the resource module's SWF file from memory. Its resources cannot be used until that module is reloaded.

Resource module SWF files are cached by the browser just like any other SWF file. As a result, if you unload a resource module, and then later want to reload it, Flash Player and AIR will load it from the browser's cache rather than make another network request. If the browser's cache was cleared, though, then Flash Player and AIR will load the resource module's SWF file with a network request again.

You can unload individual resource bundles rather than the entire resource module. You do this with the ResourceManager's `removeResourceBundle()` method. This method takes a locale and the resource bundle's name, which you can access with the `getBundleNamesForLocale()` method. Rather than iterate over the resource bundle names, you can use the `removeResourceBundlesForLocale()` method, which removes all resource bundles for a locale.

Creating resource bundles at run time

You can edit or create resource bundles programmatically. The process for creating a resource bundle is as follows:

1. Create a new ResourceBundle with the `new` operator.
2. Set the resource key/value pairs on the `content` object of the new ResourceBundle.
3. Add the bundle to the ResourceManager with the `addResourceBundle()` method.
4. Call the ResourceManager's `update()` method to apply the new changes.

The following example creates a new resource bundle for the fr_FR locale with two values:

```
var moreResources:ResourceBundle = new ResourceBundle("fr_FR", "moreResources");
moreResources.content["OPEN"] = "Ouvrez";
moreResources.content["CLOSE"] = "Fermez";
resourceManager.addResourceBundle(moreResources, false);
resourceManager.update();
```

After you add the resource bundle to the ResourceManager, you can use the ResourceManager's methods to find the new resources; for example:

```
resourceManager.localeChain = [ "fr_FR" ];
trace(resourceManager.getString("moreResources", "OPEN")); // outputs "Ouvrez"
```

If you use the `addResourceBundle()` method to add another bundle with the same locale and bundle name, the new one will overwrite the old one. However, creating new bundle values does not update the application. You must also call the ResourceManager's `update()` method to update existing resource bundles.

The following example replaces some of the existing resources in the en_US locale's RegistrationForm resource bundle with new values:

```
<?xml version="1.0"?>
<!-- resourcebundles/CreateReplacementBundle.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp()">
    <fx:Script><![CDATA[
        import mx.resources.ResourceBundle;
        import mx.controls.Alert;
        [Bindable]
        private var locales:Array = [ "es_ES","en_US" ];
        private function initApp():void {
            /* Initialize the ComboBox to the first locale in the locales Array. */
            localeComboBox.selectedIndex = locales.indexOf(resourceManager.localeChain[0]);
        }
        private function registrationComplete():void {
            Alert.show(resourceManager.getString('RegistrationForm', 'thanks'));
        }
        private function comboChangeHandler():void {
            /* Set the localeChain to either the one-element Array
               [ "en_US" ] or the one-element Array [ "es_ES" ]. */
            resourceManager.localeChain = [ localeComboBox.selectedItem ];
        }

        private function createReplacementBundle():void {
            var newRB:ResourceBundle = new ResourceBundle("en_US", "RegistrationForm");

            newRB.content["registration_title"] = "Registration Form";
            newRB.content["submit_button"] = "Submit This Form";
            newRB.content["personname"] = "Enter Your Name Here:";
            newRB.content["street_address"] = "Enter Your Street Address Here:";
            newRB.content["city"] = "Enter Your City Here:";
            newRB.content["state"] = "Enter Your State Here:";
            newRB.content["zip"] = "Enter Your ZIP Code Here:";

            resourceManager.addResourceBundle(newRB);
            resourceManager.update();
        }
    ]]></fx:Script>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Metadata>
        [ResourceBundle("RegistrationForm")]
    </fx:Metadata>
    <s:Image source="{resourceManager.getClass('RegistrationForm', 'flag')}"/>
    <mx:ComboBox id="localeComboBox"
        dataProvider="{locales}"
        change="comboChangeHandler()"/>
    <s:Form>
        <s:FormItem label="{resourceManager.getString('RegistrationForm','personname')}">
            <s:TextInput/>
        </s:FormItem>
        <s:FormItem label="{resourceManager.getString('RegistrationForm','street_address')}">
            <s:TextInput/>
        </s:FormItem>
        <s:FormItem label="{resourceManager.getString('RegistrationForm','city')}">
            <s:TextInput/>
        </s:FormItem>
        <s:FormItem label="{resourceManager.getString('RegistrationForm','state')}">
            <s:TextInput/>
        </s:FormItem>
        <s:FormItem label="{resourceManager.getString('RegistrationForm','zip')}">
            <s:TextInput/>
        </s:FormItem>
    </s:Form>

    <s:Button id="b1"
        label="{resourceManager.getString('RegistrationForm','submit_button')}"
        click="registrationComplete()"/>

    <s:Button id="b2"
        label="Change Bundle"
        click="createReplacementBundle()"/>

</s:Application>
```

You can also programmatically create a new locale and new resource bundles for that locale. However, you should only create a new locale programmatically if you compiled with that locale's framework resources, as described in "Adding new locales" on page 2095.

If you programmatically create your own bundles for a new locale but do not create any framework bundles for that locale prior to compiling the application, you will get run-time exceptions when the framework components try to access framework bundles for the new locale. For example, suppose you programmatically create bundles for the fr_FR locale but do not compile with the fr_FR framework bundles. If you then set the `localeChain` property to `["fr_FR"]`, you will get run-time exceptions when the framework components try to access framework resources for the fr_FR locale. As a result, if you plan on creating bundles for the fr_FR locale at run time, you should compile the application with the fr_FR framework bundles. You can then set the `localeChain` property to `["fr_FR"]` without getting run-time errors.

When programmatically creating bundles, you cannot put the class of a run-time loaded image into the bundle because its class did not exist at compile time. Classes representing images are created only at compile time, for embedded images. As a result, you should explicitly set the source of an image rather than get the source of that image from a resource bundle.

The following example creates a new bundle for the fr_FR locale at run time. It explicitly assigns the source of the image when the fr_FR locale is selected rather than loading it from the resource bundle because the image's class was not available at compile time.

```
<?xml version="1.0"?>
<!-- resourcebundles/CreateNewLocaleAndBundle.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp()">
    <fx:Script><![CDATA[
        import mx.resources.ResourceBundle;
        import mx.controls.Alert;
        import flash.display.*;
        [Bindable]
        private var locales:Array;
        private function initApp():void {
            locales =  [ "es_ES","en_US" ];

            /* Initialize the ComboBox to the first locale in the locales Array. */
            localeComboBox.selectedIndex = locales.indexOf(resourceManager.localeChain[0]);

            updateFlag();
        }
        private function registrationComplete():void {
            Alert.show(resourceManager.getString('RegistrationForm', 'thanks'));
        }
        private function comboChangeHandler():void {
            /* Set the localeChain to either the one-element Array
               [ "en_US" ] or the one-element Array [ "es_ES" ]. */
            resourceManager.localeChain = [ localeComboBox.selectedItem ];
            updateFlag();
        }

        private var newRB:ResourceBundle;

        private function updateFlag():void {
            if (resourceManager.localeChain[0] == "fr_FR") {
                /* Explicitly change the value of the flagImage source when the
                   locale is fr_FR because there was no class at compile time. */
                flagImage.source = "../assets/france.gif";
            } else {
                /* Get the class from the resource bundle; this assumes that the classes
                   for all other locales were embedded in the resource bundles at
                   compile time. */
              flagImage.source = resourceManager.getClass('RegistrationForm', 'flag');
            }
        }

        private function createNewBundle():void {
            locales.push("fr_FR");
            newRB = new ResourceBundle("fr_FR", "RegistrationForm");
            newRB.content["registration_title"] = "La Forme d'Enregistration";
            newRB.content["submit_button"] = "Soumettez La Forme";
            newRB.content["personname"] = "Nom";
            newRB.content["street_address"] = "Rue";
            newRB.content["city"] = "Ville";
            newRB.content["state"] = "Etat";
            newRB.content["zip"] = "Code postal";
          newRB.content["thanks"] = "Merci de l'enregistrement!";
```

```
            updateFlag();
            resourceManager.addResourceBundle(newRB);
            resourceManager.update();
        }

        private function resetApp():void {
            resourceManager.removeResourceBundlesForLocale("fr_FR");
            initApp();
            resourceManager.update();
        }
    ]]></fx:Script>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Metadata>
        [ResourceBundle("RegistrationForm")]
    </fx:Metadata>
    <s:Image id="flagImage"/>
    <mx:ComboBox id="localeComboBox"
        dataProvider="{locales}"
        change="comboChangeHandler()"/>
    <s:Form>
        <s:FormItem label="{resourceManager.getString('RegistrationForm','personname')}">
            <s:TextInput/>
        </s:FormItem>
        <s:FormItem label="{resourceManager.getString('RegistrationForm','street_address')}">
            <s:TextInput/>
        </s:FormItem>
        <s:FormItem label="{resourceManager.getString('RegistrationForm','city')}">
            <s:TextInput/>
        </s:FormItem>
        <s:FormItem label="{resourceManager.getString('RegistrationForm','state')}">
            <s:TextInput/>
        </s:FormItem>
        <s:FormItem label="{resourceManager.getString('RegistrationForm','zip')}">
            <s:TextInput/>
        </s:FormItem>
    </s:Form>
    <s:Button id="b1"
        label="{resourceManager.getString('RegistrationForm','submit_button')}"
        click="registrationComplete()"/>
    <mx:HRule width="100%" strokeWidth="1"/>

    <s:HGroup>
        <s:Button id="b2" label="Add New Bundle" click="createNewBundle();"/>
        <s:Button id="b3" label="Reset" click="resetApp();"/>
    </s:HGroup>
</s:Application>
```

Adding, removing, or changing individual resources

You can add, remove, or change individual resources within a resource bundle in ActionScript. To do this, you first get a reference to the ResourceBundle with the `getResourceBundle()` method. You pass the locale and the name of the resource bundle to this method. You then edit the `content` property of the ResourceBundle, which is an object with key/value pairs for its resources.

The following example adds a new resource to the RegistrationForm resource bundle:

```
var rb:ResourceBundle =
    ResourceBundle(resourceManager.getResourceBundle("en_US", "RegistrationForm"));
rb.content["cancel_button"] = "Cancel";
```

You can change an existing value by specifying the key, as the following example shows:

```
rb.content["cancel_button"] = "Quit";
```

To delete a resource from a resource bundle, you use the `delete` keyword, followed by the key in the `content` object. The following example deletes the `cancel_button` resource that was added in the previous example:

```
delete rb.content["cancel_button"];
```

Enumerating resources

You can enumerate all resources in a resource bundle by using a `forin` loop in ActionScript. To do this, you get a reference to the resource bundle, and then loop over the `content` object.

Methods that you might use when enumerating resources include `getLocales()`, `getBundleNamesForLocale()`, and `getResourceBundle()`.

The `getLocales()` method returns an Array such as `["en_US", "ja_JP"]` which contains, in no particular order, all of the locales for bundles that exist in the ResourceManager. The `getBundleNamesForLocale()` method returns an Array such as `["controls", "containers"]` which contains all of the bundle names for the specified locale. The `getResourceBundle()` method takes a locale and a bundle name and returns a reference to the specified resource bundle.

The following example prints the keys and values for all resource bundles in all locales in the ResourceManager. This includes the framework bundles for the locales, in addition to any custom resources such as RegistrationForm.properties.

```
<?xml version="1.0"?>
<!-- resourcebundles/EnumerateAllBundles.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="enumerateBundles()">
    <fx:Script><![CDATA[
        import mx.resources.ResourceBundle;
        import mx.controls.Alert;
        private function registrationComplete():void {
            /* Use the ResourceManager to set localized values in ActionScript. */
            Alert.show(resourceManager.getString('RegistrationForm', 'thanks'));
        }

        private function enumerateBundles():void {
            for each (var locale:String in resourceManager.getLocales()) {
                ta1.text += "****************************************\n";
                ta1.text += "locale: " + locale + "\n";
                ta1.text += "****************************************\n";
                for each (var bundleName:String in
resourceManager.getBundleNamesForLocale(locale)) {
                    ta1.text += "  -------------------------------------\n";
                    ta1.text += "  bundleName: " + bundleName + "\n";
                    var bundle:ResourceBundle =
                      ResourceBundle(resourceManager.getResourceBundle(locale, bundleName));
                    for (var key:String in bundle.content) {
                        ta1.text += "    -" + key + ":" + bundle.content[key]  + "\n";
                    }
                }
            }
        }
    ]]></fx:Script>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Metadata>
        [ResourceBundle("RegistrationForm")]
    </fx:Metadata>
    <s:Form>
        <s:FormItem label="@Resource(key='personname', bundle='RegistrationForm')">
            <s:TextInput/>
        </s:FormItem>
        <s:FormItem label="@Resource(key='street_address', bundle='RegistrationForm')">
            <s:TextInput/>
        </s:FormItem>
        <s:FormItem label="@Resource(key='city', bundle='RegistrationForm')">
            <s:TextInput/>
        </s:FormItem>
        <s:FormItem label="@Resource(key='state', bundle='RegistrationForm')">
            <s:TextInput/>
        </s:FormItem>
        <s:FormItem label="@Resource(key='zip', bundle='RegistrationForm')">
            <s:TextInput/>
        </s:FormItem>
    </s:Form>
    <s:Button id="b1"
        label="@Resource(key='submit_button', bundle='RegistrationForm')"
        click="registrationComplete()"/>

    <s:TextArea id="ta1" width="100%" height="100%"/>
</s:Application>
```

Preventing memory leaks in modules and sub-applications

The ResourceManager is a singleton that holds a reference to all resource bundles in the system. This includes resource bundles used by sub-applications and modules. When a sub-application or module defines a new resource bundle that is not in the application domain of the main application, the ResourceManager creates a reference from the main application to the application domain of the sub-application or module. Because of this reference, the resource bundle cannot be garbage collected, which can result in extra memory being allocated but not used.

To avoid this situation, set the `addResourceBundle()` method's `useWeakReference` parameter to `true` in the sub-application or module. This creates a weak reference between the ResourceManager and the resource bundle, so that the resource bundle can be garbage collected. If the `useWeakReference` property is set to `false` (the default), the resource bundle will not be garbage collected. To prevent the resource bundle from being garbage collected until the right time, create a hard reference to it; remove that reference when you are ready remove the resource bundle or the module that uses it.

Custom formatting with resource bundles

The way applications present dates, times, and currencies varies greatly for each locale. For example, the U.S. standard for representing dates is month/day/year, whereas the European standard for representing dates is day/month/year. One of the more common localization tasks is to provide the formatting values for times, dates, and currencies.

The Spark formatters support the formats of all locales supported by the client's operating system. However, in some cases, you might want to override the behavior of these controls or provide your own fallback mechanism. You can use values in the resource bundles to set properties on Flex controls such as the DateTimeFormatter and CurrencyFormatter.

The following properties file sets the values that the DateTimeFormatter and CurrencyFormatter will use for the en_US locale:

```
# locale/en_US/FormattingValues.properties
CHROMECOLOR=0x0000FF
DATE_FORMAT=MM/dd/yy
TIME_FORMAT=L:NN A
CURRENCY_PRECISION=2
CURRENCY_SYMBOL=$
THOUSANDS_SEPARATOR=,
DECIMAL_SEPARATOR=.
```

For the British locale, the properties file might appear as follows:

```
# locale/es_ES/FormattingValues.properties
CHROMECOLOR=0xFF0000
DATE_FORMAT=dd/MM/yy
TIME_FORMAT=HH:NN
CURRENCY_PRECISION=2
CURRENCY_SYMBOL=£
THOUSANDS_SEPARATOR=.
DECIMAL_SEPARATOR=,
```

The following example uses resources bundles to set up the formatters:

```
<?xml version="1.0"?>
<!-- resourcebundles/FormattingExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp(event)"
    chromeColor="{resourceManager.getUint('FormattingValues', 'CHROMECOLOR')}">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Declarations>
        <s:DateTimeFormatter id="dateFormatter"
           dateTimePattern="{resourceManager.getString('FormattingValues', 'DATE_FORMAT')}"/>
        <s:DateTimeFormatter id="timeFormatter"
        dateTimePattern="{resourceManager.getString('FormattingValues', 'TIME_FORMAT')}"/>
        <s:CurrencyFormatter id="currencyFormatter"
            useCurrencySymbol="true"
            useGrouping="true"
          currencySymbol="{resourceManager.getString('FormattingValues', 'CURRENCY_SYMBOL')}"
            groupingSeparator="{resourceManager.getString('FormattingValues',
'THOUSANDS_SEPARATOR')}"
            decimalSeparator="{resourceManager.getString('FormattingValues',
'DECIMAL_SEPARATOR')}"/>
    </fx:Declarations>
    <fx:Script><![CDATA[
        import mx.resources.ResourceBundle;
        [Bindable]
        private var locales:Array = [ "en_US","es_ES"];
        [Bindable]
        private var dateValue:String;
        [Bindable]
        private var timeValue:String;
        [Bindable]
        private var currencyValue:String;
        private var d:Date = new Date();
        private function initApp(e:Event):void {
       localeComboBox.selectedIndex = locales.indexOf(resourceManager.localeChain[0]);
            applyFormats(e);

            // Updating the localeChain does not reapply formatters. As a result, you must
            // apply them whenever the ResourceManager's change event is triggered.
            resourceManager.addEventListener(Event.CHANGE, applyFormats);

        }
        private function comboChangeHandler():void {
            // Changing the localeChain property triggers a change event, so the
            // applyFormats() method will be called whenever you select a new locale.
            resourceManager.localeChain = [ localeComboBox.selectedItem ];
        }

        private function applyFormats(e:Event):void {
            dateValue = dateFormatter.format(d);
            timeValue = timeFormatter.format(d);
            currencyValue = currencyFormatter.format(1000);
        }
    ]]></fx:Script>
    <fx:Metadata>
        [ResourceBundle("FormattingValues")]
    </fx:Metadata>
    <mx:ComboBox id="localeComboBox"
        dataProvider="{locales}"
        change="comboChangeHandler()"/>

    <s:Form>
        <s:FormItem label="Date">
            <s:TextInput id="ti1" text="{dateValue}"/>
        </s:FormItem>
        <s:FormItem label="Time">
            <s:TextInput text="{timeValue}"/>
        </s:FormItem>
        <s:FormItem label="Currency">
            <s:TextInput text="{currencyValue}"/>
        </s:FormItem>
    </s:Form>
</s:Application>
```

Adding styles and fonts to localized resources

To localize styles, you can bind the value of the style property to a value from the resource bundle. For example, if the resource property file defines the value of a `FONTCOLOR` key (`FONTCOLOR=0xFF0000`), you can use it by binding its value to the style property in your application, as the following examples show:

```
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    chromeColor="{resourceManager.getUint('MyStyles', 'color')}">
```

If you are using the ResourceManager to reference the value in the resource bundle, then be sure to use the appropriate method. For example, if the value is a color like 0xFF0000, use the ResourceManager's `getUint()` method. If the value is a class, like a programmatic skin, then use the `getClass()` method.

For color styles, you must use hex notation (such as 0xFF0000) rather than the VGA color names (such as red, blue, or fuchsia) in the resource properties files when binding a color style to a resource.

You can also localize the fonts that an application uses. For example, if the locale is ja_JP, then you would want to use a font that supports Japanese characters, but if the locale is en_US, then a font that supports the much smaller English character set would be adequate.

One approach to localizing fonts in your applications is to embed all the fonts and then get the name of the font's class selector from the resource bundle. In the resource properties file, you could set the values of the font, as the following example shows:

```
# /locale/en_US/FontProps.properties
TEXTSTYLE=myENFont
# /locale/ja_JP/FontProps.properties
TEXTSTYLE=myJAFont
```

In your application's style sheet, you embed both fonts, as the following example shows:

```
<fx:Style>
    @font-face {
        src: url("ENFont.ttf");
        fontFamily: EmbeddedENFont;
}
    @font-face {
        src: url("JAFont.ttf");
        fontFamily: EmbeddedJAFont;
    }
    .myENFont{
        fontFamily: EmbeddedENFont;
    }
    .myJAFont{
        fontFamily: EmbeddedJAFont;
    }
</fx:Style>
```

In your MXML tags, you can use the `styleName` property to apply the appropriate class selector, as the following example shows:

```
<s:RichText styleName="{resourceManager.getString('FontProps', 'TEXTSTYLE')}"/>
```

Another approach to localizing fonts is to use style modules, and load them at run time based on which locale is selected. To do this, for each font/locale combination, you compile a style module that embeds the font and sets any necessary selectors. The style module could be as simple as the following:

```
@font-face {
    src:url("../assets/MyENFont.ttf");
    fontFamily: myFontFamily;
    advancedAntiAliasing: true;
}
.global {
       fontFamily: myFontFamily;
}
```

When you compile the style module's SWF file, you can name it anything you want, but if you give it a name that contains the locale, you can then use that name programatically in your application. For example, name the style module MyStyleSheet_en_US.swf for the en_US locale and MyStyleSheet_ja_JP.swf for the ja_JP locale.

In your application, where you handle the resource bundle update logic, you can include logic that unloads the existing style module and loads a new one based on the current locale. You could also add the name of the style sheet to your resource bundle and extract it from that when the locale changes.

For more information on using style modules, see "Loading style sheets at run time" on page 1547.

Accessible applications

Accessibility overview

You create accessible content by using accessibility features included with Flex, by taking advantage of ActionScript designed to implement accessibility, and by following recommended design and development practices.

Visually impaired users, for example, might rely on assistive technology such as screen readers, which provide an audio version of screen content, or screen magnifiers, which display a small portion of the screen at a larger size, effectively reducing the visible screen area. Hearing-impaired users might read text and captions in the document in place of audio content. Other considerations arise for users with mobility or cognitive impairments.

The following list of recommended practices is not exhaustive, but suggests common issues to consider. Depending on your audience's needs, additional requirements may arise.

Visually impaired users For visually impaired users, keep in mind the following design recommendations:

- Design and implement a logical tab order for the tabs.
- Design the document so that constant changes in content do not unnecessarily cause screen readers to refresh. For example, you should group or hide looping elements.
- Provide captions for narrative audio. Be aware of audio in your document that might interfere with a user being able to listen to the screen reader.
- Use percentage sizing so that your applications scale properly at smaller screen sizes. This allows users of screen magnifiers to see more of your application at one time. Also take into account that many visually impaired users run applications with lower screen resolutions than other users.
- Ensure that foreground and background colors contrast sufficiently to make text readable for people with low vision.
- Ensure that controls don't depend on the use of a specific pointer device, such as a mouse or trackball.
- Ensure that components are accessible by keyboard. All Flex components defined as accessible include keyboard navigation. For a list of these components and the available keyboard commands for each, see "Accessible components and containers" on page 2130.

Color-blind users For color-blind users, ensure that color is not the only means of conveying information.

Users with mobility impairment For users with mobility impairment, keep in mind the following design recommendations:

- Ensure that controls don't depend on the use of a specific pointer device.
- Ensure that components are accessible by keyboard. All Flex components defined as accessible include keyboard navigation. For a list of these components and the available keyboard commands for each, see "Accessible components and containers" on page 2130.

Hearing-impaired users For hearing-impaired users, ensure that you add captions to audio content.

Users with cognitive impairment For users with cognitive impairments, such as dyslexia, keep in mind the following design recommendations:

- Ensure an uncluttered, easy-to-navigate design.
- Provide graphical imagery that helps convey the purpose and message of the application. These graphics should enhance, not replace, textual or audio content.
- Provide more than one method to accomplish common tasks.

About worldwide accessibility standards

Many countries, including the United States, Australia, Canada, Japan, and countries in the European Union, have adopted accessibility standards based on those developed by the World Wide Web Consortium (W3C). W3C publishes *Web Content Accessibility Guidelines*, a document that prioritizes actions that designers should take to make web content accessible. For information about the Web Accessibility Initiative, see the W3C website at www.w3.org/WAI.

In the United States, the law that governs accessibility is commonly known as Section 508, which is an amendment to the U.S. Rehabilitation Act. Section 508 prohibits federal agencies from buying, developing, maintaining, or using electronic technology that is not accessible to those with disabilities. In addition to mandating standards, Section 508 lets government employees and the public sue agencies in federal court for noncompliance.

For additional information about Section 508, see the U.S. government-sponsored website at www.section508.gov.

Viewing the Flex Accessibility web page

This topic contains an introduction to the accessibility features in Flex and to developing accessible applications. For the latest information on creating and viewing accessible Flex content, including supported platforms, known issues, screen reader compatibility, articles, and accessible examples, see the Flex Accessibility web page at www.adobe.com/go/flex_accessibility.

About screen reader technology

A screen reader is software designed to navigate through a website and read the web content aloud. Visually impaired users often rely on this technology. You can create content designed for use with screen readers for Microsoft® Windows® platforms only. Users who view your content must have Adobe® Flash® Player 9 or later, and Firefox or Internet Explorer on Windows 2000 or Windows XP or later.

JAWS, from Freedom Scientific, is one example of screen reader software. You can access the JAWS page on the Freedom Scientific website at www.hj.com/fs_products/software_jaws.asp. Another commonly used screen reader program is Window-Eyes, from GW Micro. To access the latest information on Window-Eyes, visit the GW Micro website at www.gwmicro.com.

***Note:** Flex support is most comprehensive in the JAWS screen reader. JAWS version 10 or later is strongly recommended.*

Screen readers help users understand what is contained in a web page or Flex application. Based on the keyboard shortcuts that you define, you can let users easily navigate through your application by using the screen reader.

Because different screen reader applications use various methods to translate information into speech, your content will vary in how it's presented to each user. As you design accessible applications, keep in mind that you have no control over how a screen reader behaves. You can only mark up the content in your applications so that you expose the text and ensure that screen reader users can activate the controls. This means that you can decide which objects in the application are exposed to screen readers, provide descriptions for the objects, and decide the order in which the objects are exposed to screen readers. However, you cannot force screen readers to read specific text at specific times or control the manner in which that content is read.

To use a JAWS screen reader with a Flex application, users must download a set of scripts before invoking the Flex application. For more information, see "Configuring a JAWS screen reader for Flex applications" on page 2129.

Flash Player and Microsoft Active Accessibility

Adobe Flash Player uses Microsoft Active Accessibility (MSAA), which provides a descriptive and standardized way for applications and screen readers to communicate. MSAA is available for Windows operating systems only. For more information on Microsoft accessibility technology, visit the Microsoft accessibility website at www.microsoft.com/enable/.

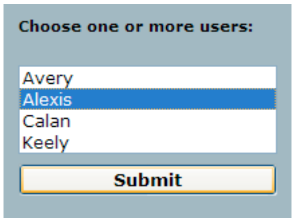
The Flash Player ActiveX control for Internet Explorer on Windows version 9 and later supports MSAA. The Flash Player plug-in for Firefox on Windows version 9.0.115 and later also supports MSAA. All versions of Windows standalone players do not support MSAA.

Flex supports a debugger version of Flash Player that can display debugging information during run time and generate profiling information so that you can more easily develop applications. However, the debugger version of Flash Player does not support accessibility.

Important: *MSAA is currently not supported in the opaque windowless and transparent windowless modes. (These modes are options in the HTML Publish Settings panel, available for use with the Windows version of Internet Explorer 4.0 or later, with the Flash ActiveX control.) If your content must be accessible to screen readers, avoid using these modes.*

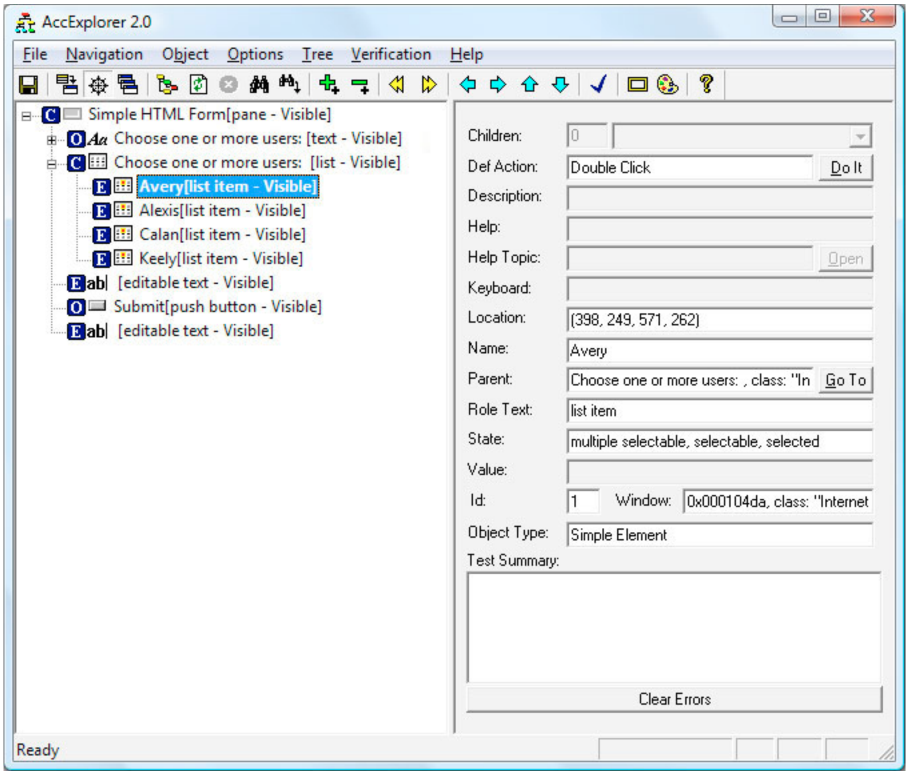
How MSAA works

MSAA is essentially a middleware architecture that conveys an object model of an application. This is most easily explained by an example. The following screenshot shows an HTML form, as displayed in a browser:



HTML form in a browser

Here is a screen capture that shows the object tree exposed by the browser to assistive technology:



Simple HTML Form[pane - Visible]

Test Summary:

Accessibility object tree

And finally, here is how JAWS for Windows 9.0, a popular screen reader for Windows, reads this form after loading the page in Internet Explorer:

```
Simple HTML Form.
Choose one or more children:
Extended select list box:
Avery, one of four.
Submit Button.
```

This example shows a simple, basic screen reader operation. A screen reader is a very complicated program that does much more than announce page contents; it speaks words under the mouse cursor, provides hundreds of keyboard shortcuts, and keeps track of user state in myriad ways.

MSAA under the surface

When Internet Explorer or Firefox loads a new page, it sends an event notification to the MSAA system. A screen reader, as an MSAA client, has registered with MSAA to receive event notifications, so the screen reader becomes aware that the browser has changed its object tree. The screen reader sends a special window message (WM_GETOBJECT) to the browser, asking for its root object.

The browser responds by sending back a pointer to a COM interface of type IAccessible. This interface has methods that allow the screen reader to ask for object properties, such as type, name, description, value, and visibility.

IAccessible also has methods for traversing the object tree in various ways—abstractly, in terms of tab order, in terms of geometric relationship, or in terms of pixel locations. Finally, IAccessible allows clients to manipulate UI objects programmatically, pressing buttons and altering selection and focus. The screen reader now traverses the tree of IAccessible objects, building up a tree of COM pointers.

For each object discovered, the screen reader determines the type of object (is it a container? button? textfield? and so on), the object's name, and possibly a few other properties. The screen reader now has enough information to construct its narrative text and feed it into the text-to-speech engine.

The browser, in order to be a proper MSAA server, has two main responsibilities. It must implement the IAccessible interface for every significant onscreen object that it displays, and it must notify the MSAA system whenever any part of the object tree changes. The Flash Player handles these two responsibilities for Flash content.

Accessible object model in Flash Player

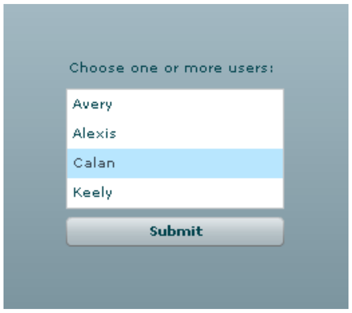
The Flash Player's accessible object tree consists of a single top-level container (the root accessible object) containing a flat collection of the following types of objects:

- **Text**: Regions of dynamic or static text in the movie. The principal property of a text object is its name, which, in keeping with MSAA convention, is equal to the contents of the text string being displayed. A text object may also have an associated description string. The Flash Player also makes an attempt to deduce labeling relationships between text and input text fields (text immediately above or to the left of an input text field is be taken as a label for that field), and between text and buttons (text entirely inside a button will be taken as a label for that button). Any text that is deduced to be a label will be omitted from the accessible object tree, and the content of that text will be used as the name of the object that it labels. Labels are never assigned to buttons or text fields that have author-supplied names.
- **Input text fields**: An input text object has a value, and optionally a name, a description string and a keyboard shortcut string. As described above, an input text object's name may come from a text object that is deduced to label it.
- **Buttons**: A button object has a state (pressed or not pressed), supports a programmatic default action that causes the button to depress momentarily, and may optionally have a name, a description string, and a keyboard shortcut string. As described above, a button object's name may come from a text object that is deduced to label it. Movie clips used as buttons in Flash Player are described by the player to MSAA as buttons, not as movie clips. The child objects inside buttons are note normally looked at by the player for accessibility purposes—buttons are "leaves" in the accessible object tree. There is one exception: for buttons that do not have author-supplied names, the player will look through the button's child elements (just one child-level deep) for a text element. If a text element is found, it is taken as a label for the button.
- **Simple movie clips**: All non-scripted movie clips at all levels are classified into one of two categories: simple or non-simple. A movie clip is simple if it does not have any other accessible objects (text, input text, buttons, or components) as children at any level of depth. Non-simple clips are not given any representation in the object tree; instead, their accessible-object contents are promoted into the flat top-level list of accessible objects. Simple clips, on the other hand, do show up in the object tree, expressed to MSAA as an image or animation widget. If a simple clip contains other simple clips, only the topmost simple clip is included in the object tree. A simple clip has a state (animated or not animated), and may optionally have a name and a description string. Note that all video regions are also treated as simple movie clips.
- **Scripted movie clips**: Flex (and Flash Professional) UI components present a special problem for the accessible object model in Flash Player. They are movie clips or sprites built from collections of text, input text, shapes, and buttons, but if Flash Player exposed those individual objects to MSAA, the meaning of the overall component would be lost. For this reason, a Flex UI (or Flash Professional) component may require a custom accessibility implementation. A movie clip or sprite that provides its own accessibility implementation is called a scripted movie clip, and it appears in the accessible object tree. The details of the accessibility implementation depend on the kind of component being implemented and are up to the component developer.

The Flash Player provides the flash.accessibility.AccessibilityImplementation class as a base class for creating custom accessibility implementations for Flex UI components in ActionScript 3. In Flex, this class is extended by mx.accessibility.AccImpl which serves as the base class for accessibility implementations in Flex components. A new accessibility implementation can be created by extending mx.accessibility.AccImpl for each new component.

When a Flex project is compiled with Generate accessible SWF file set to true, the Flex compiler automatically enables accessibility implementations for the components in the project that have them. At runtime, when Flash Player discovers a component that has a custom accessibility implementation, it will treat that component as a scripted movie clip.

The following example shows a screenshot of a simple Flex form:



A simple Flex form

When the project is compiled with Generate accessible SWF file set to false, the object tree exposed by the browser to assistive technology contains only text and simple movie clips, as shown in the following image:

Accessibility object tree for an accessible Flex application

The methods of the flash.accessibility.AccessibilityImplementation class are a subset of the IAccessible interface, adapted slightly for ease of use. The Flash Player IAccessible interface for a scripted movie clip simply passes most calls from MSAA through to the flash.accessibility.AccessibilityImplementation subclass instance for that component. For example, when a screen reader needs to determine the default action of a mx.controls.Button component instance on the Stage in Flash Player, it calls the IAccessible method `get_accDefaultAction()` on the IAccessible interface exposed by the Flash Player for that component instance. The request is passed through to the `get_accDefaultAction()` method of the mx.accessibility.ButtonAccImpl accessibility implementation class instance, which returns the appropriate default action String for a button control, which is “Press.” The article Custom Accessibility Implementations explains in more detail how to build custom accessibility implementations for Flex components.

Configuring Flex applications for accessibility

Enabling accessibility in Flex

By default, Flex accessibility features are disabled. When you enable accessibility, you enable the application to communicate with a screen reader.

You can use one of the following methods to enable accessibility:

- Enable accessibility by default for all Flex applications so that all requests return accessible content.

  To enable accessibility for all Flex applications, edit the flex-config.xml file to set the `accessible` property to `true`, the default value, as the following example shows:

  ```
  <compiler>
      ...
      <accessible>true</accessible>
      ...
  <compiler>
  ```

- Enable accessibility in Adobe Flash Builder project properties.

  If you are using Adobe Flash Builder to develop Flex applications, you can enable accessibility by selecting the Generate accessible SWF file option in the Flex Compiler section of the project properties dialog. When you select this option, the compiler node within the .actionScriptProperties file located in the project directory is modified to generate accessible SWF files:

  ```
  <compiler additionalCompilerArguments="-locale en_US"
      generateAccessible="true">
  ```

- Enable accessibility by using the mxmlc command-line compiler.

  When you compile a file by using the mxmlc command-line compiler, you can use the `-accessible` option to enable accessibility, as the following example shows:

  ```
  mxmlc -accessible c:/dev/myapps/mywar.war/app1.mxml
  ```

  For more information on the command-line compiler, see “Flex compilers” on page 2164.

  When you compile a file by using the mxmlc command-line compiler, you can use a configuration variable to notify the compiler to generate the SWF file with accessibility enabled. The command-line syntax for the mxmlc.exe compiler allows the addition of `–compiler.accessible` (or just `–accessible`) to enable accessibility, as shown in the following examples:

  ```
  mxmlc –compiler.accessible c:/dev/myapps/ appl.mxml
  ```

  ```
  mxmlc -accessible c:/dev/myapps/appl.mxml
  ```

If you are building applications for Adobe LiveCycle Data Services ES and are deploying the application as MXML files, you can enable accessibility on an individual request by setting the `accessible` query parameter to `true`, as the following example shows:

```
http://www.mycompany.com/myflexapp/app1.mxml?accessible=true
```

If you edited the flex-config.xml file to enable accessibility by default, you can disable it for an individual request by setting the `accessible` query parameter to `false`, as the following example shows:

```
http://www.mycompany.com/myflexapp/app1.mxml?accessible=false
```

For more information on the command-line compiler, see “Flex compilers” on page 2164.

Configuring a JAWS screen reader for Flex applications

To use the JAWS screen reader with a Flex application, users must download scripts from the Adobe accessibility website before invoking a Flex application. Screen readers work best when in Forms mode, which lets users interact directly with the Flex application. These scripts let users switch between Virtual Cursor mode and Forms mode by using the Enter key from almost anywhere within a Flex application. If necessary, users can exit Forms mode by using the standard JAWS keystrokes.

Users can download these scripts, and the installation instructions, from the Adobe website at www.adobe.com/go/flex_accessibility.

To verify that the Flex scripts for JAWS are correctly installed, users can press the Insert+Q keys when JAWS is running. If the scripts are installed correctly, users hear "Updated for Adobe Flex 4" in the voice response to this keystroke.

It is important that you direct users with visual impairments to the script download page so that they have the necessary scripts to use JAWS effectively.

Accessible components and containers

To accelerate building accessible applications, Adobe built support for accessibility into Flex MX components and containers. These components and containers automate many of the most common accessibility practices related to labeling, keyboard access, and testing. They also help ensure a consistent user experience across rich Internet applications.

Accessible Spark components

Flex comes with the following set of accessible components and containers in the Spark component set.

Component	Screen reader behavior
ButtonBar control	Use the Tab key to move focus among the button of the ButtonBar control. Press the Spacebar to activate a button of the ButtonBar control. To cancel activating a button, press the Tab key to move the focus off the button control before releasing the Spacebar.
Button control	Press the Spacebar to activate the Button control. To cancel activating a button, press the Tab key to move the focus off the Button control before releasing the Spacebar.
CheckBox control	Press the Spacebar to activate the check box items. For more information on keyboard navigation, see “CheckBox control user interaction” on page 659.
ComboBox control	For more information on keyboard navigation, see “Spark ComboBox control user interaction” on page 541.
DropDownList control	For more information on keyboard navigation, see “Spark DropDownList control user interaction” on page 536.
List control	Screen reader navigation is the same as for keyboard navigation. For more information on keyboard navigation, see “Keyboard navigation” on page 953. For information on creating data tips (tool tips for individual list elements), see “Displaying DataTips” on page 946. For information on creating scroll tips (tool tips that provide information while the user scrolls through a list), see “Displaying ScrollTips” on page 947.
NumericStepper control	The name of a NumericStepper is, by default, an empty string. When wrapped in a FormItem element, the name is the FormItem's label. To override this behavior, set the Number ic Stepper control’s `accessibilityName` property. The name of each child button is: "More" and "Less". For more information on keyboard navigation, see “User interaction” on page 697.
Panel container	Screen reader announces the panel title only when Forms mode is inactive.
RadioButton control	With one radio button selected within a group, press the Enter key to enter that group. Use the arrow keys to move between items in that group. Press the Down and Right Arrow keys to move to the next item in a group; press the Up and Left Arrow keys to move to a previous item in the group. When using a screen reader, select a radio button by using the Spacebar key. For more information on keyboard navigation, see “RadioButton user interaction” on page 712.

Component	**Screen reader behavior**
RadioButtonGroup control	Screen reader navigation is the same as for the RadioButton control.
RichEdiableText control	Use the Home key to move to the beginning of a line. Use the End key to move to the end of a line. Use the Control-Home to move to the beginning of the text. Use the Control-End key to move to the end of the text.
Slider controls	The name of a HSlider or VSlider is, by default, an empty string. When wrapped in a FormItem element, the name is the FormItem's label. To override this behavior, set the Slider's `accessibilityName` property. The name of each child of the Slider control is: • "Page left" for HSlider; "Page up" for VSlider. • Position". • "Page right" for HSlider; "Page down" for VSlider. For more information on keyboard navigation, see “Keyboard navigation” on page 693.
Spinner control	The name of a Spinner control is, by default, an empty string. When wrapped in a FormItem element, the name is the FormItem's label. To override this behavior, set the Spinner `accessibilityName` property. The name of each child button is: "More" and "Less". For more information on keyboard navigation, see “User interaction” on page 697.
TabBar control	The name of a TabBar is, by default, an empty string. When wrapped in a FormItem element, the name is the FormItem's label. To override this behavior, set the TabBar's `accessibilityName` property.The name of each tab in the TabBar is its label. The TabBar and its individual tabs accept focus. A tab is not automatically pressed when focus is changed by arrow keys. To select a focused tab, use the spacebar.
TextArea control	Use the Home key to move to the beginning of a line. Use the End key to move to the end of a line. Use the Control-Home to move to the beginning of the text. Use the Control-End key to move to the end of the text.
TextInput control	Use the Home key to move to the beginning of a line. Use the End Up key to move to the end of a line.

Component	**Screen reader behavior**
TitleWindow container	The name of a TitleWindow is, by default, the title that it displays. To override this behavior, set the TitleWindow's `accessibilityName` property. A TitleWindow does not accept focus. A screen reader announces the TitleWindow control only when Forms mode is inactive.
ToggleButton control	Press the Spacebar to activate the control. To cancel activating a button, press the Tab key to move the focus off the control before releasing the Spacebar. The name of a ToggleButton is, by default, the label that it displays. When wrapped in a FormItem element, this label will be combined with the FormItem's label. To override this behavior, set the ToggleButton's `accessibilityName` property. To provide two separate names for the different states of an icon based ToggleButton, separate both names by a comma in the `accessibilityName` property. For example, `accessibilityProperty="Mute,Unmute"` When using state specific names like this, the button does not expose the "pressed" state when pressed.
VideoPlayer control	The name of a VideoPlayer is, by default, "VideoPlayer". When wrapped in a FormItem element, the name is the FormItem's label. To override this behavior, set the controls `accessibilityName` property. The name of each child control is: • Play/Pause control: "Play" or "Pause" • Scrub control: "Scrub Bar" • Play time indicator: the displayed text • Mute control: "Muted" or "Not muted" • Volume control: "Volume Bar" • Full Screen control: "Full Screen" To override the names of these child controls, reskin the VideoPlayer and set the `accessibilityName` of the controls. Use the Tab key to move focus among the child controls. Use the Spacebar to activate the Play/Pause control and the Full Screen control. Use the arrow keys to modify the Scrub Bar and Volume Bar controls.

Accessible MX Components

Flex comes with the following set of accessible components and containers in the MX component set.

Component	**Screen reader behavior**
Accordion container	Press the arrow keys to move the focus to a different panel, and then use the Spacebar or Enter key to select that panel. Use the Page Up and Page Down keys to move between individual panels of the container. When a screen reader encounters an Accordion container, it indicates each panel with the word *tab*. It indicates the current panel with the word *active*. For more information on keyboard navigation, see “Accordion container Keyboard navigation” on page 640.
AdvancedDataGrid control	The AdvancedDataGrid control supports the accessibility features in the DataGrid and Tree controls and provides additional features. For more information, see “Accessibility for the AdvancedDataGrid control” on page 2135. For more information on standard keyboard navigation, see “Keyboard navigation” on page 1450.
Alert control	In Forms mode, the text in the Alert control and the label of its default button are announced. When not in Forms mode, the text in the Alert control is announced twice when you press the Down Arrow.
Button control	Press the Spacebar to activate the Button control. To cancel activating a button, press the Tab key to move the focus off the Button control before releasing the Spacebar. When a screen reader encounters a Button control, activation varies, depending on the screen reader. In JAWS 6.10, the Spacebar activates Button controls when Forms mode is active. When Forms mode is inactive, the Spacebar or Enter key can be used to activate Button controls.
CheckBox control	Press the Spacebar to activate the check box items. For more information on keyboard navigation, see “CheckBox control user interaction” on page 659.
ColorPicker control	Announced as "colorpicker combo box." Open by using Control+Down Arrow, and close by using Control+Up Arrow. When open, you can use the four arrow keys to move among the colors. When open, the Enter key sets the color value to the currently selected color, as will Control+Up Arrow. When open, the Escape key closes the drop-down area and resets the color value to the previously selected color value.
ComboBox control	For more information on keyboard navigation, see “ComboBox control user interaction” on page 961.
DataGrid control	Press the arrow keys to highlight the contents, and then move between the individual characters within that field. When using a screen reader in forms mode, use the Tab key to move between editable TextInput fields in the DataGrid control. For more information on keyboard navigation, see “MX DataGrid control user interaction” on page 972.
DateChooser control	Press the Up, Down, Left, and Right Arrow keys to change the selected date. Use the Home key to reach the first enabled date in the month and the End key to reach the last enabled date in a month. Use the Page Up and Page Down keys to reach the previous and next months. For more information on keyboard navigation, see “User interaction” on page 675.
DateField control	Use the Control+Down Arrow keys to open the DateChooser control and select the appropriate date. When using a screen reader in Forms mode, use the same keystrokes as for keyboard navigation. When a screen reader encounters a DateChooser control in Forms mode, it announces the control as “DropDown Calendar *currentDate*, to open press Control Down, ComboBox,” where *currentDate* is the currently selected date. For more information on keyboard navigation, see “User interaction” on page 675.
Form container	For information on keyboard navigation, see “Defining a default button” on page 592.

Component	**Screen reader behavior**
Image control	An Image control with a tool tip defined is read by a screen reader only when Forms mode is inactive. The Image control is not focusable in Forms mode, or by the keyboard.
Label control	A Label control is read by a screen reader when it is associated with other controls, or when the Forms mode is inactive. The Label control is not focusable in Forms mode, or by the keyboard.
LinkButton control	LinkButton control activation when using a screen reader varies, depending on the screen reader. In JAWS 6.10, press the Spacebar to activate a LinkButton control when in Forms mode. When Forms mode is inactive, use the Spacebar or Enter key to activate the control. For more information on keyboard navigation, see "LinkButton control user interaction" on page 696.
List control	Screen reader navigation is the same as for keyboard navigation. For more information on keyboard navigation, see "List control user interaction" on page 950. For information on creating data tips (tool tips for individual list elements), see "Displaying DataTips" on page 946. For information on creating scroll tips (tool tips that provide information while the user scrolls through a list), see "Displaying ScrollTips" on page 947.
Menu control	Screen reader navigation is the same as for keyboard navigation. For more information on keyboard navigation, see "Menu control user interaction" on page 1001.
MenuBar control	Screen reader navigation is the same as for keyboard navigation. For more information on keyboard navigation, see "Menu control user interaction" on page 1001.
Panel container	Screen reader announces the panel title only when Forms mode is inactive.
RadioButton control	With one radio button selected within a group, press the Enter key to enter that group. Use the arrow keys to move between items in that group. Press the Down and Right Arrow keys to move to the next item in a group; press the Up and Left Arrow keys to move to a previous item in the group. When using a screen reader, select a radio button by using the Spacebar key. For more information on keyboard navigation, see "RadioButton user interaction" on page 712.
RadioButtonGroup control	Screen reader navigation is the same as for the RadioButton control.
Slider control	In forms mode the control is announced along with the orientation of the control (left-right or up-down) and the current value. The control uses the following keys for a left-right slider: • Left Arrow / Right Arrow—move slider to lower/higher value. • Page Up / Page Down—move slider to top/ bottom of range. • Down Arrow/Up Arrow—move slider to lower/higher value. • Home/End—move slider to top/ bottom of range. The control uses the following keys for an up/down slider: • Down Arrow/Up Arrow—move slider to lower/higher value. • Home/End—move slider to top/ bottom of range.
TabNavigator container	When a screen reader encounters a TabNavigator container pane, it indicates each pane with the word *tab*. It indicates the current pane with the word *active*. When a pane is selected, the user moves to that panel by pressing the Enter key. Press the arrow keys to move the focus to a different panel, and then use the Spacebar or Enter key to select that panel. Use the Page Up and Page Down keys to move between individual panels of the container. For more information on keyboard navigation, see "TabNavigator container Keyboard navigation" on page 638.

Component	**Screen reader behavior**
Text control	A Text control is not focusable and is read by screen readers only when Forms mode is inactive.
TextArea control	Use the Home key to move to the beginning of a line. Use the End key to move to the end of a line. Use the PageUp key to move to the beginning of the text. Use the PageDown key to move to the end of the text.
TextInput control	Use the Home or Page Down key to move to the beginning of a line. Use the End or Page Up key to move to the end of a line.
TitleWindow container	A screen reader announces the TitleWindow control only when Forms mode is inactive.
ToolTipManager	When a screen reader is used, the contents of a tool tip are read after the item to which the tool tip is attached gets focus. Tool tips attached to nonaccessible components (other than the Image control) are not read.
Tree control	Press the Up and Down Arrow keys to move between items in a Tree control. To open a group, press the Right Arrow key or Spacebar. To close a group, press the Left Arrow key or Spacebar. For more information on keyboard navigation, see “Editing a node label at run time” on page 983and “Tree user interaction” on page 983.

Accessibility for the AdvancedDataGrid control

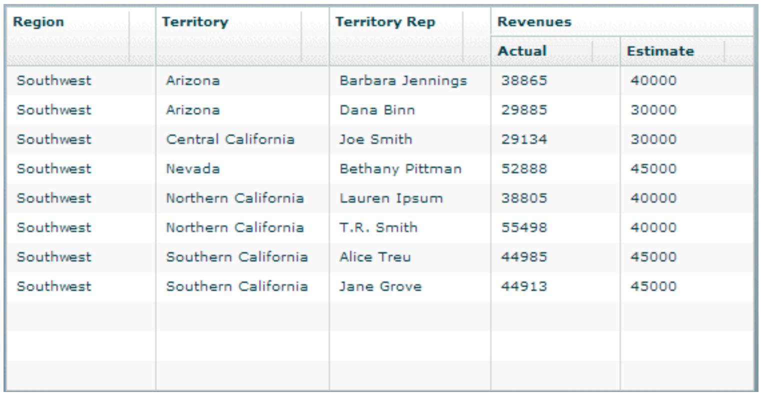
The AdvancedDataGrid control supports the accessibility features in the DataGrid and Tree controls and adds additional features to support accessibility.

Cell and header navigation

For AdvancedDataGrid header cells, each header cell is selectable and reported individually. Pressing the Up Arrow key when in the first row of the control shifts the focus to the header cell.

When focus is moved to a header cell, the screen reader reports: "From: Column 1 press space to sort ascending on this field. Press Control+space to add this field to sort."

The following figure shows an AdvancedDataGrid control that uses a column group for the Revenues column. If the control defines a column group, then the screen reader reports the header information as: "Revenues: Column 1, spans 2 columns."



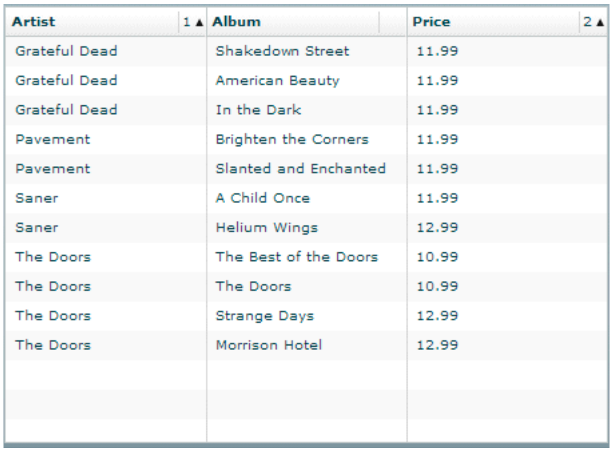
Region	Territory	Territory Rep	Revenues	
			Actual	Estimate
Southwest	Arizona	Barbara Jennings	38865	40000
Southwest	Arizona	Dana Binn	29885	30000
Southwest	Central California	Joe Smith	29134	30000
Southwest	Nevada	Bethany Pittman	52888	45000
Southwest	Northern California	Lauren Ipsum	38805	40000
Southwest	Northern California	T.R. Smith	55498	40000
Southwest	Southern California	Alice Treu	44985	45000
Southwest	Southern California	Jane Grove	44913	45000

The data reported for body cells depends on the setting of the `selectionMode` property of the AdvancedDataGrid control, as described in the following table:

Selection mode	**Screen reader output**
`singleRow`	Information corresponding to the entire row.
`singleCell`	Information corresponding to the selected cell only.

Example navigation of flat data

The following image shows an AdvancedDataGrid control displaying flat data:



Artist 1 ▲	Album	Price 2 ▲
Grateful Dead	Shakedown Street	11.99
Grateful Dead	American Beauty	11.99
Grateful Dead	In the Dark	11.99
Pavement	Brighten the Corners	11.99
Pavement	Slanted and Enchanted	11.99
Saner	A Child Once	11.99
Saner	Helium Wings	12.99
The Doors	The Best of the Doors	10.99
The Doors	The Doors	10.99
The Doors	Strange Days	12.99
The Doors	Morrison Hotel	12.99

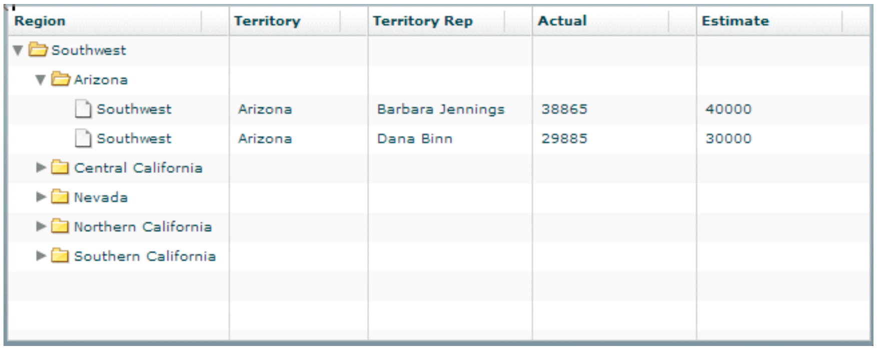
In this example:

- When you press the Tab key to move focus to the control, the screen reader reports: "ListBox."
- Pressing the Down Arrow and Up Arrow keys navigates the rows of the control.
    - When the `selectionMode` property is set to `singleRow`, the screen reader reports all the data in the row, for example: "Artist: Grateful Dead, Album: Shakedown Street, Price: 11.99."
    - When the `selectionMode` property is set to `singleCell`, the screen reader reports only the selected cell's data. For the cell in the first column of the row, the screen reader reports: "Artist: Grateful Dead, Row 1." The row information is reported only when focus is on the first column, not for other columns in the row. Therefore, for the second cell, the screen reader reports: "Album: ShakeDown Street."
- Pressing the Up Arrow key when the focus is on the first row of the control moves the focus to the header cell. The screen reader reports: "From: Column 1 press space to sort ascending on this field. Press control space to add this field to sort."
    - Pressing the Spacebar sorts the column.
    - Multicolumn sorting is supported. The sort order is reported in case of multicolumn sorting.

  For example, if the Album column is sorted and the sort order is 2, the screen reader reports: "Album: Column 2 sorted ascending, sort order 2 Press space to sort descending on this field. Press Control+space to add this field to sort."

Example navigation of hierarchical data

The following image shows an AdvancedDataGrid control displaying hierarchical data:



Region	Territory	Territory Rep	Actual	Estimate
▼ Southwest				
▼ Arizona				
Southwest	Arizona	Barbara Jennings	38865	40000
Southwest	Arizona	Dana Binn	29885	30000
▶ Central California				
▶ Nevada				
▶ Northern California				
▶ Southern California				

In this example:

- When you press the Tab key to move focus to the control, the screen reader reports: "Treeview."
- Pressing the Shift+Control+Right Arrow keys opens a node.
- Pressing the Down Arrow key moves the focus to the next row.

  If you move focus to the first row under Arizona, the screen reader reports: "Level2. Region: Southwest, Territory: Arizona, TerritoryRep: Barbara Jennings, Actual: 38865, Estimate: 40000, 1 of 2. Press Control+Shift+Right Arrow to open, Control+Shift+Left Arrow to close. Open."

Creating tab order and reading order

There are two aspects of tab indexing order—the *tab order* in which a user navigates through the web content, and the *reading order* in which things are read by the screen reader.

Flash Player uses a tab index order from left to right and top to bottom. However, if this is not the order you want to use, you can customize both the tab order and the reading order by using the InteractiveObject.tabIndex property. (In ActionScript, the `tabIndex` property is synonymous with the reading order.)

Tab order You can use the `tabIndex` property of every component to create a tab order that determines the order in which objects receive input focus when a user presses the Tab key.

Reading order You can use the `tabIndex` property to control the order in which the screen reader reads information about the object. To create a reading order, you assign a value to the `tabIndex` property for every component in your application. You should set the `tabIndex` property for every accessible object, not just the focusable objects. For example, you must set the `tabIndex` property for a Text control even though a user cannot tab to it. If you do not set the `tabIndex` property for every accessible object, Flash Player puts that object at the end of the tab order, rather than in its appropriate tab order location.

Scrolling to a component when tabbing

As a general rule, you should structure your application so that all components fit in the available screen area; otherwise you will have to adds vertical or horizontal scroll bars as necessary. Scroll bars let users move around the application to access components outside of the screen area.

If your application uses scroll bars, tabbing through the application components does not automatically scroll the application to make the currently selected component visible. You can add logic to your application to automatically scroll to the currently selected component, as the following example shows:

```
<?xml version="1.0"?>
<!-- accessibility\ScrollComp.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    creationComplete="setupFocusViewportWatcher();">

    <fx:Script>
        <![CDATA[

        import mx.core.Container;
        import mx.core.EdgeMetrics;

        [Bindable]
        public var cards: Array = [
            {label:"Visa", data:1},
            {label:"Master Card", data:2},
            {label:"American Express", data:3} ];

        [Bindable]
        public var selectedItem:Object;

        [Bindable]
        public var forListDP:Array = [
            {label:'Apple', data:10.00},
            {label:'Banana', data:15.00},
            {label:'Melon', data:3.50},
            {label:'Kiwi', data:7.65},
            {label:'123', data:12.35 },
            {label:'some', data:10.01 }];

        // Set up the event listener for the focusIn event.
        public function setupFocusViewportWatcher():void {
            addEventListener("focusIn", makeFocusedItemVisible);
        }

        public function makeFocusedItemVisible(event:FocusEvent):void {
            // Target is the actual object that has focus.
            var target:InteractiveObject = InteractiveObject(event.target);

            // OriginalTarget is the component that has focus as some
            // component actually delegate true focus to an internal object.
            var originalTarget:InteractiveObject =
        InteractiveObject(focusManager.findFocusManagerComponent(target));

            // The viewable portion of a container
            var viewport:Rectangle = new Rectangle();
            do {
                // Cycle through all parents looking for containers.
                if (target.parent is Container) {
                    var viewportChanged:Boolean = false;
                    var c:Container = target.parent as Container;
                    // Get the viewable area in the container.
                    var vm:EdgeMetrics = c.viewMetrics;
                    viewport.x = vm.left;
                    viewport.y = vm.top;
                    viewport.width =
                        c.width / c.scaleX - vm.left - vm.right;
                    viewport.height =
                        c.height / c.scaleY - vm.top - vm.bottom;

                    // Calculate the position of the target in the container.
                    var topLeft:Point = new Point(0, 0);
                    var bottomRight:Point =
                new Point(originalTarget.width, originalTarget.height);
                    topLeft = originalTarget.localToGlobal(topLeft);
                    topLeft = c.globalToLocal(topLeft);
                    bottomRight = originalTarget.localToGlobal(bottomRight);
                    bottomRight = c.globalToLocal(bottomRight);

                    // Figure out if we have to move the scroll bars.
                    // If the scroll bar moves, the position of the component
                    // moves as well. This algorithm makes sure the top
                    // left of the component is visible if the component is
                    // bigger than the viewport.
                    var delta:Number;
                    if (bottomRight.x > viewport.right) {
                        delta = bottomRight.x - viewport.right;
                        c.horizontalScrollPosition += delta;
                        topLeft.x -= delta;
                        viewportChanged = true;
                    }
                    if (topLeft.x < viewport.left) {
                        // leave it a few pixels in from the left
                        c.horizontalScrollPosition -=
                            viewport.left - topLeft.x + 2;
                        viewportChanged = true;
                    }

                    if (bottomRight.y > viewport.bottom) {
                        delta = bottomRight.y - viewport.bottom;
                        c.verticalScrollPosition += delta;
                        topLeft.y -= delta;
                        viewportChanged = true;
                    }

                    if (topLeft.y < viewport.top) {
                        // leave it a few pixels down from the top
                        c.verticalScrollPosition -=
                            viewport.top - topLeft.y + 2;
                        viewportChanged = true;
                    }

                    // You must the validateNow() method to get the
                    // container to move the component before working
                    // on the next parent.
                    // Otherwise, your calculations will be incorrect.
                    if (viewportChanged) {
                        c.validateNow();
                    }
                }

                target = target.parent;
            }
        }
```

```
            while (target != this);
        }
        ]]>
    </fx:Script>

    <fx:Declarations>
        <fx:Model id="statesModel" source="assets/states.xml"/>
    </fx:Declarations>

```

Creating accessibility with ActionScript

For accessibility properties that apply to the entire document, use the flash.accessibility.AccessibilityProperties class. For more information on this class, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

The following table lists some of the relevant properties of the AccessibilityProperties class.

Property	**Type**	**Description**
`description`	String	Specifies a description for the component that is read by the screen reader.
`forceSimple`	Boolean	Hides the children of a component from a screen reader when set to `true`. The default value is `false`.
`name`	String	Specifies a description of the component that is read by the screen reader. When accessible objects do not have a specified name, a screen reader uses a generic word, such as *Button*.
`shortcut`	String	Indicates a keyboard shortcut associated with this display object.
`silent`	Boolean	Hides a component from a screen reader when set to `true`. The default value is `false`.

Modifying these properties has no effect by itself. You must also use the `Accessibility.updateProperties()` method to inform screen reader users of Flash Player content changes. Calling this method causes Flash Player to reexamine all accessibility properties, update property descriptions for the screen reader, and, if necessary, send events to the screen reader that indicate changes occurred.

When updating the accessibility properties of multiple objects at once, you must include only a single call to the `Accessiblity.updateProperties()` method. (Excessive updates to the screen reader can cause some screen readers to become too verbose and can impact your application’s performance.)

Implementing screen reader detection with the Accessibility.isActive() method

To create content that behaves in a specific way if a screen reader is active, you can use the ActionScript Accessibility.active property, which is set to a value of `true` if a screen reader is present, and `false` otherwise. You can then design your content to perform in a way that is compatible with screen reader use, such as by hiding child elements from the screen reader.

For example, you could use the `Accessibility.active` property to decide whether to include unsolicited animation. *Unsolicited animation* means animation that happens without the screen reader doing anything. This can be very confusing for screen readers.

For more information on the Accessibility class, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Creating a custom accessibility implementation

Flex component developers need to be able to provide their own accessibility implementations for custom components. Flash Player provides the flash.accessibility.AccessibilityImplementation class as a base class for creating custom accessibility implementations for Flex and Flash UI components in ActionScript 3. In Flex, this class is extended by mx.accessibility.AccImpl which serves as the base class for accessibility implementations in Flex components.

You create a new accessibility implementation by extending mx.accessibility.AccImpl for each new component. The methods of the flash.accessibility.AccessibilityImplementation class are a subset of the IAccessible interface, adapted slightly to make life easier. The Flash Player's IAccessible interface for a scripted movie clip passes most calls from MSAA through to the flash.accessibility.AccessibilityImplementation subclass instance for that component. Accessibility implementations must also send event notifications to MSAA in a variety of situations. Event notifications are sent by using the `flash.accessibility.Accessibility.sendEvent()` method.

The way in which an accessibility implementation implements the IAccessible interface and the events that it sends depend on the kind of component being implemented. Consider two primary forms of guidance: First, the MSAA documentation has a list of guidelines for accessible object implementations according to component type. Second, an accessibility implementations's behavior should match as closely as possible the behavior exhibited by the equivalent form element (if any such element exists) in an HTML page inside Internet Explorer or Firefox or in the Windows operating system. This behavior can be examined using the AccExplorer, Inspect32, and AccEvent tools, available in the Microsoft Active Accessibility 2.0 SDK.

Collectively, these two forms of guidance constitute an MSAA model for IAccessible implementations. This model is loosely specified. The only definitive test of an IAccessible implementation is to test it with the latest versions of screen readers.

This article explains how to define a custom accessibility implementation for a component. For this example, we'll add an accessibility implementation to the mx.controls.PopUpButton and, by extension, the mx.controls.PopUpMenuButton class. First, create a new Flex project named “PopUpMenuButton.” Be sure to enable accessibility in the project using one of the methods explained in “Configuring Flex applications for accessibility” on page 2128. Follow along with the article to create a new implementation, or download the finished source files for the project.

For an overview of the PopUpButton and PopUpMenuButton controls, see “PopUpButton control” on page 702 and “PopUpMenuButton control” on page 1003. See also mx.controls.PopUpButton and mx.controls.PopUpMenuButton in the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Add accessibility mix-ins to component class definition

Defining a custom accessiblity implementation for a component requires changes the component's class file. Copy the PopUpButton class file from its location in the Flex SDK source code, /sdks/4.6.0/frameworks/projects/framework/src/mx/controls/PopUpButton.as to a directory in the source folder for the project, /mx/controls/PopUpButton.as.

Next, copy the included files /sdks/4.6.0/frameworks/projects/framework/src/mx/core/Version.as to /mx/core/Version.as and /sdks/4.6.0/frameworks/projects/framework/src/mx/styles/metadata/IconColorStyles.as to /mx/styles/metadata/IconColorStyles.as so that the project compiles without errors. When the project is compiled, the Flex compiler will override the existing PopUpButton class contained within the Flex framework, with the modified class in project folder, which will support accessibility. Open the PopUpButton class file that you just copied over from the Flex SDK. At line 168 in the code, add the following meta tag:

```
[AccessibilityClass(implementation="mx.accessibility.PopUpButtonAccImpl")]
```

The `[AccessibilityClass]` meta tag lets the compiler know which class serves as the accessibility implementation for this component. Add the following code to create a placeholder for the static `createAccessibilityImplementation()` method at line 244, just before the PopUpButton constructor:

```
…
    //-------------------------------------------------------------------- ----
    //
    //  Class mixins
    //
    //--------------------------------------------------------------------           ----
    /**
     *  Placeholder for mixin by PopUpButtonAccImpl.
     */
     mx_internal static var createAccessibilityImplementation:Function;
…
```

This `createAccessibilityImplementation()` method will be assigned by the PopUpButtonAccImpl accessibility implementation class we'll create. At line 469, among the overridden methods from UIComponent class, add the following `initializeAccessibility()` method:

```
/**
 *  @inheritDoc
 */
  override protected function initializeAccessibility():void
    {
        if (PopUpButton.createAccessibilityImplementation != null)
        PopUpButton.createAccessibilityImplementation(this);
    }
```

The `initializeAccessibility()` method is invoked by the `UIComponent.initialize()` method to initialize accessibility for a component instance at runtime.

Create the accessibility implementation class definition

To define the PopUpButtonAccImpl class, copy the ButtonAccImpl class file from its location in the Flex SDK source code, /sdks/4.6.0/frameworks/projects/framework/src/mx/accessibility/Button.as, to a directory in the source folder for the project. Save the file with a new file name, /mx/accessibility/PopUpButtonAccImpl.as.Open the PopUpButtonAccImpl class file that you copied over from ButtonAccImpl class in the Flex SDK. Update the `import` statement block to import the PopUpButton, Menu, AccessibilityProperties and Rectangle classes:

```
...
package mx.accessibility
{
import flash.accessibility.Accessibility;
import flash.accessibility.AccessibilityProperties;
import flash.events.Event;
import flash.events.KeyboardEvent;
import flash.geom.Rectangle;
import flash.ui.Keyboard;
import mx.controls.Menu;
import mx.controls.PopUpButton;
import mx.core.UIComponent;
import mx.core.mx_internal;
...
```

At line 61 in the code, update the class definition to read:

```
...
    public class PopUpButtonAccImpl extends AccImpl
...
```

At line 93 in the code update the `hookAccessibility` method to read:

```
...
    private static function hookAccessibility():Boolean
    {
        PopUpButton.createAccessibilityImplementation =
            createAccessibilityImplementation;
        return true;
    }
...
```

The `hookAccessibility()` method defines the PopUpButton class's static `createAccessibilityImplementation()` method to use the method of the same name defined in the PopUpButtonAccImpl class. It is called once at runtime when the PopUpButtonAccImpl class initializes and defines the static `accessibilityHooked` property.Replace the `createAccessibilityImplementation()` method at line 149 with the following:

```
...
    mx_internal static function createAccessibilityImplementation(
                                                    component:UIComponent):void
    {
        component.accessibilityImplementation = new PopUpButtonAccImpl(component);
    }
...
```

The `createAccessibilityImplementation()` method assigns a new PopUpButtonAccImpl instance to the `accessibilityImplementation` property of a given component instance.Add the following four static state and role constants at line 122:

```
...
    /**
     * The object is hot-tracked by the mouse, which means that its appearance
     * has changed to indicate that the pointer is located over it.
     */
     private static const STATE_SYSTEM_HOTTRACKED:uint = 0x00000080;

    /**
     *  Object displays a pop-up menu or window when invoked.
     */
     private static const STATE_SYSTEM_HASPOPUP:uint = 0x40000000;

    /**
     * The role represents a button that has a drop-down list icon directly adjacent
     * to the button.
     */
     private static const ROLE_SYSTEM_SPLITBUTTON:uint = 0x3e;

    /**
     * The object represents a button that drops down a list of items.
     */
     private static const ROLE_SYSTEM_BUTTONDROPDOWN:uint = 0x38;
...
```

System roles and states are predefined for all components in MSAA. The hexidecimal values for the constants can be found in the *ActionScript 3.0 Reference for the Adobe Flash Platform* under AccessibilityImplementation Constants. The MSAA documentation has a list of guidelines for accessible object implementations that documents which constants are used by which component types. Unfortunately, the User Interface Element Reference for MSAA omits the pop-up button. To figure out the appropriate role and state constants for the PopUpButton Accessibility Implementation, use the AccExplorer, Inspect32, and AccEvent tools that are available in the Microsoft Active Accessibility 2.0 SDK to examine a similar existing component in Windows. Fortunately, Flash Builder and the Eclipse plug-in use the pop-up button for a number of items in the main toolbar.

Launch Inspect32. Move your mouse over the Run icon button in the Flash Builder main toolbar. The Inspect32 tool updates to reveal the following information:

```
How found:Mouse move (199,85)
    hwnd=0x0006038A 32bit class="ToolbarWindow32" style=0x5601A945 ex=0x100000

window : sizeable,moveable,focusable"Desktop" : client : normal"Desktop" : window : normal
    [ No Parent ]
```

The Inspect32 tool reveals that the pop-up button should have the role `split button` and one child named `Open` with the role `drop down button`. When you mouse over the control or give it keyboard focus, the control’s state is `hot tracked`. In Flash terminology, “hot tracked” is a mouseover, or the button “over” state. A search on http://msdn.microsoft.com/ for "SplitButton accessibility" returns a more detailed and useful description of the SplitButton control's accessibiliy implementation: Working with Active Accessibility in the 2007 Office Fluent User Interface: The SplitButton Control. This more detailed description states that we should also expose the state of the child drop-down button that opens a popup menu as `has popup`.

Update the PopUpButtonAccImpl constructor function at line 199 to read:

```
...
    //----------------------------------------------------------------------- ---
-
    //
    //  Constructor
    //
    //------------------------------------------------------------------------ - ----
    /**
     * Creates a new PopUpButtonAccImpl instance for the specified PopUpButton component    .
     *
     * <p>Direct calls to the AccImpl subclass constructors are unneccessary.
     * When a Flex project is compiled with Generate accessible SWF file set to
     * <code>true</code>,
     * the compiler instantiates the accessibility implementations for the components
     * used in the project that have them by calling the static
     * <code>enableAccessibility()</code> method. </p   >
     *
     * @param master The UIComponent instance that this PopUpButtonAccImpl instance
     * is making accessible.
     *
     * @see ../../../html/help.html?content=accessible_4.html Configuring Flex
     * applications for accessibility
     */
    public function PopUpButtonAccImpl(master:UIComponent)
    {
        super(master);
        role = ROLE_SYSTEM_SPLITBUTTON;
    }
...
```

The constructor function defines the `role` property for the PopUpButtonAccImpl as `ROLE_SYSTEM_SPLITBUTTON` (0x3e). Update the `eventsToHandle()` method at line 237 to include any additional events to which the PopUpButtonAccImpl should listen from its master component. In this example, the events should be the same as for the ButtonAccImpl, `"click"` and `"labelChanged"`.

```
...
    //----------------------------------
    //  eventsToHandle
    //----------------------------------
    /**
     *  @inheritDoc
     */
    override protected function get eventsToHandle():Array
    {
        return super.eventsToHandle.concat([ "click", "labelChanged" ]);
    }
...
```

Update the `get_accRole()` method at line 247 to read as follows:

```
...
    /**
     * IAccessible method for returning system role for the component.
     * System roles are predefined for all the components in MSAA.
     * <p>A PopUpButton component, ( <code>childID == 0</code> ), reports
     * the role <code>ROLE_SYSTEM_SPLITBUTTON</code> (0x3E).
     * The PopUpButton's drop down arrow ( <code>childID == 1</code> )
     * reports the role <code>ROLE_SYSTEM_BUTTONDROPDOWN</code> (0x3B).</p>
     *
     * @param childID An unsigned integer corresponding to one of the component's child
     * elements as defined by
     * <code><a href="#getChildIDArray()">getChildIDArray()</a></code>.
     *
     * @return Role associated with the component.
     * @tiptext Returns the system role for the component
     * @helpid 3009
     *
     * @see ../../flash/accessibility/constants.html#roles AccessibilityImplementation
Constants: Object Roles
     * @see http://msdn.microsoft.com/en-us/library/ms696113(VS.85).aspx Microsoft
Accessibility Developer Center: IAccessible::get_accRole
     */
    override public function get_accRole(childID:uint):uint
    {
        if (childID == 0)
            return role;

        return ROLE_SYSTEM_BUTTONDROPDOWN;
    }
...
```

The `get_accRole()` method should return the appropriate role constant for the master component or for one of its children. The PopUpButtonAccImpl returns `ROLE_SYSTEM_SPLITBUTTON` (0x3e), while its child drop-down button returns `ROLE_SYSTEM_BUTTONDROPDOWN` (0x38).Add the following `get_accValue()` method override at line 272:

```
...
    /**
     * IAccessible method for returning the value of the PopUpButton
     * which is spoken out by the screen reader.
     * The PopUpButton should return value that would be applied when clicked.
     * For example, the value of the PopUpButton's label property.
     *
     * @param childID An unsigned integer corresponding to one of the component's
     * child elements as defined by
     * <code><a href="#getChildIDArray()">getChildIDArray()</a></code>.
     *
     *  @return Value String
     *
     *  @see http://msdn.microsoft.com/en-us/library/ms697312(VS.85).aspx Microsoft
Accessibility Developer Center: IAccessible::get_accValue
     *  @see http://msdn.microsoft.com/en-
us/library/bb404170.aspx#ActiveAccessibility2007OfficeFluentUI_TheSplitButtonControl Working
with Active Accessibility in the 2007 Office Fluent User Interface: The SplitButton Control
     */
    override public function get_accValue(childID:uint):String
    {
        var accValue:String;
        // local reference to the master component as a PopUpButton
        var popUpButton:PopUpButton = PopUpButton(master);

        if(childID == 0){
        // the PopUpButton component itself

            // local reference to the label
            var label:String = popUpButton.label;

            if(popUpButton.popUp
                && popUpButton.popUp is Menu
                && label != null
                && label != ""){
                // If the popUp exists and is a Menu and
                // the label exists and is not an empty string...

                var popUpMenu:Menu = popUpButton.popUp as Menu;
                if(popUpMenu.itemToLabel(popUpMenu.selectedItem) == label){
                // If the label matches the popUp menu's selectedIndex,
                // return the label as the accValue.
                    accValue = label;
                    if(popUpButton.accessibilityProperties &&
popUpButton.accessibilityProperties.shortcut){
                        // If a keyboard shortcut is defined in the
                        // PopUpButton's .accessibilityProperties object,
                        // append it to the returned accValue.
                        accValue + = "("+popUpButton.accessibilityProperties.shortcut+")";
                    }
                }

            }
        }

        return accValue;
    }
...
```

The `get_accValue()` method returns the appropriate value for the component or for one of its child elements. If the PopUpButton component's `label` property is equal to the label of the `selectedItem` in its popUp menu, the `get_accValue()` method should return the value of the `label` property. Update the `get_accState()` method at line 321 to read:

```
...
    /**
     * IAccessible method for returning the state of the PopUpButton.
     * States are predefined for all the components in MSAA.
     * Values are assigned to each state.
     * Depending upon the PopUpButton being pressed or released, its popUp being present
     * and opened or closed, and the PopUpButton being hovered over or focused,
     * a value is returned.
     *
     * @param childID An unsigned integer corresponding to one of the component's
     * child elements as defined by
     * <code><a href="#getChildIDArray()">getChildIDArray()</a></code>.
     *
     * @return State indicating whether the PopUpButton is pressed or released.
     *
     * @see #getChildIDArray()
     * @see flash.accessibility.AccessibilityImplementation#get_accState()
     * @see ../../flash/accessibility/constants.html#states AccessibilityImplementation
Constants: Object State Constants
     * @see http://msdn.microsoft.com/en-us/library/ms696191(VS.85).aspx Microsoft
Accessibility Developer Center: IAccessible::get_accState
     */
     override public function get_accState(childID:uint):uint
    {
        // the normal default state
        var accState:uint = 0;

        // local reference to the master component as a PopUpButton
        var popUpButton:PopUpButton = PopUpButton(master);

        if(childID == 1){
        // the drop-down button

            if(popUpButton.popUp){
            // if the PopUpButton's popUp property is defined,
            // indicate that the drop-down button has a pop up.
                accState = STATE_SYSTEM_HASPOPUP;
            }

            if(popUpButton.mx_internal::isShowingPopUp == true){
            // if the popUp is showing,
            // indicate that the drop-down button is pressed
                accState |= STATE_SYSTEM_PRESSED;
            }

        } else {
        // the PopUpButton component itself

            // the component state inherited from AccImpl
            // unavailable, normal, focusable, or focused
            accState = getState(childID);

            if (popUpButton.selected) { // if the popUpButton is selected,
            // indicate that popUpButton is pressed
```

```
                accState |= STATE_SYSTEM_PRESSED;
            }
        }

        var mouseX:Number = master.mouseX;
        var mouseY:Number = master.mouseY;
        var bounds:Rectangle = master.getBounds(master);
        if((mouseX >= bounds.x
            && mouseX <= (bounds.x + bounds.width)
            && mouseY >= bounds.y
            && mouseY <= (bounds.y + bounds.height))
            || (popUpButton.focusManager.getFocus() == popUpButton)){
            // if the parent popUpButton component or child drop-down button
            // has either mouse or keyboard focus,
            // indicate that it is hot-tracked.
            accState |= STATE_SYSTEM_HOTTRACKED;
        }
        return accState;
    }
...
```

The `get_accState() method` should return the appropriate state constant or state constants for the master component or for one of its children. If the PopUpButton has a `popUp` property, its child drop-down button should have the state `STATE_SYSTEM_HASPOPUP` (0x40000000). If the popUp is showing, the drop-down button should also have the state `STATE_SYSTEM_PRESSED` (0x00000008). If the PopUpButton itself is selected, it should have the state `STATE_SYSTEM_PRESSED` (0x00000008). Both the PopUpButton and its child drop-down button should have the state `STATE_SYSTEM_HOTTRACKED` (0x00000080) when a user mouses over the PopUpButton or when it has keyboard focus.Add the following `getChildIDArray()` method override at line 398:

```
...
    /**
     * Method to return an array of childIDs.
     *
     * @return An array of unsigned integer IDs with a length of one
     * for the drop-down menu button.
     */
    override public function getChildIDArray():Array
    {
        var childIDs:Array = [1];

        return childIDs;
    }
...
```

The `getChildIDArray`() method returns an array containing the unsigned integer IDs of all child elements in the accessibility implementation. The length of the array may be zero. The IDs in the array should appear in the same logical order as the child elements they represent. This method is mandatory for any accessibility implementation that can contain child elements; otherwise, do not implement it. For the PopUpButtonAccImpl, the `getChildIDArray()` method returns an array containing a single element with a value of 1, which represents the PopUpButton's child drop-down button element.Update the `get_accDefaultAction()` method at line 410 to return the appropriate default action for the master component or for one of its children. For the PopUpButton component itself, the method returns “Press”. For the component's child drop-down button, the method returns “Open.”

```
...
    /**
     * IAccessible method for returning the default action of the PopUpButton,
     * which is Press for the component itself and Open for its child drop-down
     * menu button.
     *
     * @param childID An unsigned integer corresponding to one of the component's
     * child elements as defined by
     *  <code><a href="#getChildIDArray()">getChildIDArray()</a></code>.
     *
     *  @return DefaultAction String
     *
     *  @see http://msdn.microsoft.com/en-us/library/ms696144(VS.85).aspx Microsoft
Accessibility Developer Center: IAccessible::get_accDefaultAction
     */
    override public function get_accDefaultAction(childID:uint):String
    {
        if(childID == 0){
            return "Press";
        }
        return "Open";
    }
...
```

Update the `addDoDefaultAction()` method at line 439 to read as follows:

```
...
    /**
     * IAccessible method for performing the default action of the PopUpButton, which is Press
for the component itself and Open for its child drop-down menu button.
     *
     * @param childID An unsigned integer corresponding to one of the component's
     * child elements as defined by
     *  <code><a href="#getChildIDArray()">getChildIDArray()</a></code>.
     *
     *  @see http://msdn.microsoft.com/en-us/library/ms696119(VS.85).aspx Microsoft
Accessibility Developer Center: IAccessible::accDoDefaultAction
     */
    override public function accDoDefaultAction(childID:uint):void
    {
        var popUpButton:PopUpButton = master as PopUpButton;
        if (childID==0)
        {
            var event:KeyboardEvent = new KeyboardEvent(KeyboardEvent.KEY_DOWN);
            event.keyCode = Keyboard.SPACE;
            master.dispatchEvent(event);

            event = new KeyboardEvent(KeyboardEvent.KEY_UP);
            event.keyCode = Keyboard.SPACE;
            master.dispatchEvent(event);

        } else if(childID == 1){

            if(popUpButton.mx_internal::isShowingPopUp == true){
                popUpButton.close();
            } else {
                popUpButton.open();
            }
        }
    }
...
```

The `accDoDefaultAction()` method executes the default action for the master component or for one of its children. For the PopUpButton component itself, the method simulates a button click. For the child drop-down button element, the method either opens or closes the popUp. Update the getName() method at line 463 to read as follows:

```
...
    /**
     * Method for returning the name of the PopUpButton which is spoken out by
     * the screen reader.
     *  The PopUpButton should return the label inside as the name of the PopUpButton.
     *  The child drop-down button should return "Open" or "Close".
     *
     * @param childID An unsigned integer corresponding to one of the component's
     * child elements as defined by
     *  <code><a href="#getChildIDArray()">getChildIDArray()</a></code>.
     *
     * @return Name string corresponding to the PopUpButton label.
     * "Open" or "Close" for the child drop-down button.
     */
    override protected function getName(childID:uint):String
    {
        var popUpButton:PopUpButton = master as PopUpButton;
        var popUp:UIComponent = popUpButton.popUp as UIComponent;

        if(popUp && popUp is Menu){
        // a tweak to add Context as the name of the popUp menu if no other name is defined
            if(!popUp.accessibilityProperties){
                popUp.accessibilityProperties = new AccessibilityProperties();
            }
            if(popUp is Menu && popUp.accessibilityProperties.name == ""){
                popUp.accessibilityProperties.name = "Context";
            }
        }
        if(childID == 1){
        // For the drop-down button, if the popUp is showing, return Close,
        // otherwise return Open.
            return (popUpButton.mx_internal::isShowingPopUp == true) ? "Close" : "Open";
        }

        // For the popUpButton component itself, return the label property.
        var label:String = popUpButton.label;
        return label != null && label != "" ? label : "";
    }
...
```

The `getName()` method returns the appropriate name for the master component or for one of its children. For the PopUpButton component itself, the method should return its label property as its name. The component's child drop-down button returns either “Open” or “Close”, depending on whether or not the popUp is showing. For the PopUpButton, this method also adds “Context” as the name of the popUp menu if no other name has been defined.Add the following `accLocation()` method at line 498:

```
...
    /**
     * IAccessible method for returning the bounding box of a the PopUpButton
     * or its child drop-down arrow.
     *
     * @param childID An unsigned integer corresponding to one of the component's
     * child elements as defined by
     *  <code><a href="#getChildIDArray()">getChildIDArray()</a></code>.
     *
     *  @return The PopUpButton or its drop-down button.
     *
     *  @see http://msdn.microsoft.com/en-us/library/ms696118(VS.85).aspx Microsoft
Accessibility Developer Center: IAccessible::accLocation
     */
    override public function accLocation(childID:uint):*
    {

        // the master component
        var location:* = master;

        if(childID == 1){
        // calculate the rectangle location of the child drop-down button
            var popUpButton:PopUpButton = master as PopUpButton;
            var popUpButtonRect:Rectangle = popUpButton.getRect(popUpButton);
            var arrowButtonsWidth:Number =
popUpButton.mx_internal::getArrowButtonsWidth();
            location = new Rectangle(
                                popUpButtonRect.x + popUpButton.width -
arrowButtonsWidth,
                                popUpButtonRect.y,
                                arrowButtonsWidth,
                                popUpButton.height
                            );
        }

        return location;

    }
...
```

The `accLocation()` method returns the bounding box of the master component, or that of one of its children, relative to the master component's stage. The PopUpButton returns itself as the its bounding box location. Its child drop-down button returns its bounding box as a Rectangle with its bounds determined programmatically.Update the `eventHandler()` method at line 535 to handle any events to which the PopUpButtonAccImpl should listen from its master component. In this example, the handled events should be the same as for the ButtonAccImpl, `"click"` and `"labelChanged"`.

```
...
    /**
     * Override the generic event handler.
     * Each AccImpl subclass must implement this method
     * to listen for events from its master component.
     *
     *  @param event The event object.
     *
     *  @see mx.accessibility.AccImpl#eventHandler()
     */
    override protected function eventHandler(event:Event):void
    {
        switch (event.type)
        {
            case "click":
            {
                Accessibility.sendEvent(master, 0, EVENT_OBJECT_STATECHANGE);
                Accessibility.updateProperties();
                break;
            }

            case "labelChanged":
            {
                Accessibility.sendEvent(master, 0, EVENT_OBJECT_NAMECHANGE);
                Accessibility.updateProperties();
                break;
            }

        }
    }
...
```

The `eventHandler()` method handles events from the master component and sends the appropriate object or system event to MSAA using the `flash.accessibility.Accessibility.sendEvent()` method. Depending on the object or system event it receives, the MSAA system will call the IAccessible method to retrieve the appropriate value from the object that sent the event.

Testing the accessibility implementation

Once you've added the accessibility mix-in methods to your component and have created the AccImpl subclass, you can test the accessibility implementation.Copy the following MXML code sample into the default MXML application for your PopUpMenuButton Flex project. The application is a slightly modified version of the PopUpMenuButton example described in the article PopUpMenuButton control. The modification adds event handlers to retain the `selectedItem` in the popUp menu when the menu is opened and closed, which allows you to test the `PopUpButtonAccImpl.get_accValue()` method.

```
<?xml version="1.0"?>
<!-- m  enus/Pop U pMenuButton Control.mxml     - - >
 <s:Application xm lns :fx = "http://ns.adobe.co m/mx ml/2009"
    xmlns:s="library: //ns. adobe.com/flex/spark"
    xmlns:mx=" librar y:// n s.adob e .com/flex/mx"
    viewSourceURL="srcview/index.html">

    <fx:Script>
        <![CDATA [
            import mx.events.DropdownEvent;
            impor t  mx.events.MenuEvent;
            import mx.controls.Menu;

            private var selectedIndex:int = 2;

            // The initData function sets the initial value of the button
            // label by setting the Menu subcontrol's selectedIndex property.
            // You must cast the popUp property to a Menu.
            private function initData():void {
                var menu:Menu = Menu(pb2.popUp);
                menu.selectedIndex = selectedIndex;
                pb2.addEventListener(MenuEvent.ITEM_CLICK, itemClickHandler);
                pb2.addEventListener(DropdownEvent.OPEN, openHandler);
                pb2.addEventListener(DropdownEvent.CLOSE, closeHandler);
            }

            private function itemClickHandler(event:MenuEvent):void {
            var menu:Menu = Menu(event.currentTarget.popUp);
            selectedIndex=menu.selectedIndex;
            }

            private function openHandler(event:DropdownEvent):void {
                var menu:Menu = Menu(pb2.popUp);
                menu.selectedIndex = selectedIndex;
            }

            private function closeHandler(event:DropdownEvent):void {
                var menu:Menu = Menu(pb2.popUp);
                selectedIndex = (selectedIndex != menu.selectedIndex) ?
                menu.selectedIndex : selectedIndex;
                menu.selectedIndex = selectedIndex;
            }
        ]]>
    </fx:Script>
    <fx:XML format="e4x" id="dp2">
        <root>
            <editItem label="Cut"/>
            <editItem label="Copy"/>
            <editItem label="Paste"/>
            <separator type="separator"/>
            <editItem label="Delete"/>
        </root>
    </fx:XML>
    <mx:PopUpMenuButton id="pb2"
        dataProvider="{dp2}"
        labelField="@label"
        showRoot="false"
        creationComplete="initData();" />
</s:Application>
```

Compile and debug the application in either Internet Explorer or Firefox. Open the MSAA SDK Tool Inspect32. Focus on the Flash movie in the browser window and navigate to focus on the PopUpMenu instance in your application using the the keyboard or the mouse. Inspect32 should track your focus and update its display window with information similar to the following:

```
How found:Focus [o:0xFFFFFFFC,c:0x1]
    hwnd=0x000C0976 32bit class="MacromediaFlashPlayerActiveX" style=0x56000000 ex=0x0

Ancestors:none [mnfd] : client : focusable
    [ No Parent ]
```

Inspect32 reveals how the PopUpButton Accessibility Implementation exposes itself to MSAA, as an object with the role “split button,”, with name and value equal to “Paste,” having the default action “Press.”

The object's state includes “focused” and “hot tracked”. It contains a single child with the role “drop down button,” that has the name “Open.” The child object's state includes “hot tracked” and “has popup.” Inspect32 also allows you to test navigation and interaction programmatically.

For example, with the application in focus, type Ctrl+Shift+F12 to navigate to the next item or type Ctrl+Shift+F11 to navigate to the previous item in the MSAA hierarchy. Use Ctrl+Shift+F12 and/or Ctrl+Shift+F11 to set focus on the PopUpMenuButton instance's child drop down button. Type Ctrl+Shift+F2 to execute the default action for the drop down button. This action should open the popUp menu. The drop down button name should change to “Close,” and its state should indicate “pressed.” Type Ctrl+Shift+F2 again to close the menu.

Once you're fairly confident that your accessibility implementation is returning appropriate values for its IAccessible methods, you should test again using a screen reader that is capable of interpreting Flash applications, such as Freedom Scientific's JAWS or GW Micro's Window-Eyes.

It is not uncommon for a component to behave unexpectedly when testing it with a screen reader. For example, the keyboard command Ctrl+Down arrow, which is used in the PopUpButton component to open the popUp menu, is also the standard keyboard command in JAWS to move one paragraph down in the text.

Using Ctrl+Shift+Down arrow instead of Ctrl+Down arrow will open the menu, but it's not obvious to the user. A better solution is to update the PopUpButton component, to allow it to open by pressing the Down arrow.Update the `PopUpButton.keyDownHandler()` method at line 907 in the PopUpButton class file for the PopUpMenuButton Flex project to read:

```
...
    override protected function keyDownHandler(event:KeyboardEvent):void
    {
        super.keyDownHandler(event);

        // listen for both Ctrl+Down Arrow and Down Arrow events
        // if the popUp menu is not already showing
        if ((event.ctrlKey && event.keyCode == Keyboard.DOWN)
        || (event.keyCode == Keyboard.DOWN &&!showingPopUp))
        {
            openWithEvent(event);
            event.stopPropagation();
        }
        else if ((event.ctrlKey && event.keyCode == Keyboard.UP) ||
                (event.keyCode == Keyboard.ESCAPE))
        {
            closeWithEvent(event);
            event.stopPropagation();
        }
        else if (event.keyCode == Keyboard.ENTER &&mp; showingPopUp)
        {
            // Redispatch the event to the popup
            // and let its keyDownHandler() handle it.
            _popUp.dispatchEvent(event);
            closeWithEvent(event);
            event.stopPropagation();
        }
        else if (showingPopUp &&
            (event.keyCode == Keyboard.UP ||
            event.keyCode == Keyboard.DOWN ||
            event.keyCode == Keyboard.LEFT ||
            event.keyCode == Keyboard.RIGHT ||
            event.keyCode == Keyboard.PAGE_UP ||
            event.keyCode == Keyboard.PAGE_DOWN))
        {
            // Redispatch the event to the popup
            // and let its keyDownHandler() handle it.
            _popUp.dispatchEvent(event);
            event.stopPropagation();
        }
    }
...
```

Another peculiarity of JAWS is that it announces the role of the PopUpMenuButton component as a “button” as opposed to a “split button.” Even if you are providing a correct accessibility implementation to MSAA, if it is of a system role that does not have a precedent in Flex or Flash, like the PopUpButton, the screen reader may not have been scripted to understand how to interpret an object with that system role in a Flash application. The short term solution is to add the system role to the name returned by the `PopUpButtonAccImpl.getName()` method.

Update the `getName()` method at line 463 in the PopUpButtonAccImpl class definition to read:

```
...
    /**
     * Method for returning the name of the PopUpButton that is spoken
     * by the screen reader.
     *  The PopUpButton should return the label inside as the name of the PopUpButton.
     *  The child drop-down button should return "Open" or "Close".
     *
     *  @param childID An unsigned integer corresponding to one of the component's
     * child elements as defined by
     *  <code><a href="#getChildIDArray()">getChildIDArray()</a></code>.
     *
     *  @return Name string corresponding to the PopUpButton label.
     * "Open" or "Close" for the child drop-down button.
     */
    override protected function getName(childID:uint):String
    {
        var popUpButton:PopUpButton = master as PopUpButton;
        var popUp:UIComponent = popUpButton.popUp as UIComponent;

        if(popUp && popUp is Menu){
```

```
        // a tweak to add Context as the name of the popUp menu if no other name is defined
            if(!popUp.accessibilityProperties){
                popUp.accessibilityProperties = new AccessibilityProperties();
            }
            if(popUp is Menu && popUp.accessibilityProperties.name == ""){
                popUp.accessibilityProperties.name = "Context";
            }
        }
        if(childID == 1){
        // For the drop-down button, if the popUp is showing, return Close,
        // otherwise return Open.
            return (popUpButton.mx_internal::isShowingPopUp == true) ? "Close" : "Open";
        }

        // For the popUpButton component itself, return the label property.
        var label:String = popUpButton.label;
        return label != null && label != "" ? label + " Split Button" : "Split Button";

    }
...
```

Accessibility for hearing-impaired users

To provide accessibility for hearing-impaired users, you can include captions for audio content that is integral to the comprehension of the material presented. A video of a speech, for example, would probably require captions for accessibility, but a quick sound associated with a button probably would not require a caption.

Testing accessible content

When you test your accessible applications, follow these recommendations:

- Ensure that you have enabled accessibility. For more information, see “Configuring Flex applications for accessibility” on page 2128.
- Test and verify that users can navigate your interactive content effectively by using only the keyboard. This can be an especially challenging requirement, because different screen readers work in different ways when processing input from the keyboard, which means that your content might not receive keystrokes as you intended. Ensure that you test all keyboard shortcuts.
- Ensure that graphic content has alternative representation by checking for tool tips on every image.
- Ensure that your content is resizable or sized to work with screen magnifiers. It should clearly present all material at smaller sizes.
- Ensure that any substantive audio is captioned. To test for content loss, try using your application with your sound muted or wearing headphones that pipe in unrelated music.
- Ensure that you use a clean and simple interface to help screen readers and users with cognitive impairments navigate through your application. Give your application to people who have never seen it before and watch while they try to perform key tasks without any assistance or documentation. If they fail, consider modifying your interface.
- Test your application with a screen reader, or have it tested by users of screen readers.

Chapter 8: Developer tools

Building overview

About the Flex development tools

Configuration files

You must be familiar with the ways to configure your development environment. Adobe Flex Software Development Kit (SDK) primarily provide XML files that you use to configure the settings. The flex-config.xml file defines the default compiler options for the compilers.

In addition to server and compiler configuration settings, you can also modify the messaging and data management settings, the JVM heap size, Adobe® Flash® Player settings, and logging and caching settings.

For more information about configuring your Flex SDK environment, see "SDK configuration" on page 96.

Compilers

Flex includes application compilers and component compilers. You use the application compilers to compile SWF files from MXML and other source files. You use the component compilers to compile SWC files from component files. You can then use SWC files as dynamic or static libraries with your Flex applications.

The application compilers take the following forms:

- Adobe® Flash™ Builder™ project compiler. The Flash Builder application compiler is opened by Flash Builder for Flex Projects and ActionScript Projects.
- mxmlc command-line compiler. You launch the mxlmc compiler from the command line to create a SWF file that you then deploy to a website.
- fcsh compiler shell. Provides an optimized environment for using the mxmlc command-line compiler. For more information, see "Using fcsh, the Flex compiler shell" on page 2207.

The component compilers take the following forms:

- Flash Builder library project compiler. The Flash Builder component compiler is opened by Flash Builder for Flex library projects.
- compc command-line compiler. You open the compc compiler from the command line to create SWC files. You can use these SWC files as static component libraries, themes, or runtime shared libraries (RSLs).

For information on using the compilers, see "Flex compilers" on page 2164.

Debugger

To test your applications, you run the application SWF files in a web browser or the stand-alone Flash Player. If you encounter errors in your applications, you can use the debugging tools to set and manage breakpoints in your code; control application execution by suspending, resuming, and terminating the application; step into and over the code statements; select critical variables to watch; evaluate watch expressions while the application is running; and so on.

Flex provides the following debugging tools:

Flash Builder debugger The Flash Builder Debugging perspective provides all of the debugging tools you expect from a robust, full-featured development tool. You can set and manage breakpoints; control application execution by suspending, resuming, and terminating the application; step into and over the code; watch variables; evaluate expressions; and so on. For more information, see Debugging Tools in Flash Builder.

The fdb command-line debugger The fdb command-line debugger provides a command-line interface to the debugging experience. With fdb, you can step into code, add breakpoints, check variables, and perform many of the same tasks you can with the Flash Builder visual debugger. For more information, see "Command-line debugger" on page 2209.

AIR Debug Launcher (ADL) ADL is a command line debugger for Adobe® AIR™ applications that you can use outside of Flash Builder.

Loggers

You can log messages at several different points in a Flex application's life cycle. You can log messages when you compile the application, when you deploy it to a web application server, or when a client runs it. You can log messages on the server or on the client. These messages are useful for informational, diagnostic, and debugging activities.

Flex includes the following logging mechanisms that you use when working with Flex applications.

Client-side logging When you use the debugger version of Flash Player or start your AIR application using AIR Debug Launcher, you can use the trace() global method to write out messages or configure a TraceTarget to customize log levels of applications for data services-based applications. For more information, see "Client-side logging and debugging" on page 2227.

Compiler logging When compiling your Flex applications from the command line and in Flash Builder, you can view deprecation and warning messages, and sources of fatal errors. For more information, see "Compiler logging" on page 2237.

About application files

Flex applications can use many types of application files such as classes, component libraries, theme files, and Runtime Shared Libraries (RSLs).

Component classes

You can use any number of component classes in your Flex applications. These classes can be MXML or ActionScript files. You can use classes to extend existing components or define new ones.

Component classes can take the form of MXML, ActionScript files, or as SWC files. In MXML or ActionScript files, the components are not compiled but reside in a directory structure that is part of your compiler's source path. SWC files are described in "SWC files" on page 2162.

Component libraries are not dynamically linked unless they are used in a Runtime Shared Library (RSL). Component classes are statically linked at compile time, which means that they must be in the compiler's source path. For information about creating and using custom component classes, see *"Custom Flex components" on page 2356*.

Related links

SWC files

A *SWC* file is an archive file for Flex components and other assets. SWC files contain a SWF file and a catalog.xml file. The SWF file inside the SWC file implements the compiled component or group of components and includes embedded resources as symbols. Flex applications extract the SWF file from a SWC file, and use the SWF file's contents when the application refers to resources in that SWC file. The catalog.xml file lists of the contents of the component package and its individual components.

You compile SWC files by using the component compilers. These include the compc command-line compiler and the Flash Builder Library Project compiler. SWC files can be component libraries, RSLs, theme files, and resource bundles.

To include a SWC file in your application at compile time, it must be located in the library path. For more information about SWC files, see "About SWC files" on page 2205.

Component libraries

A component library is a SWC file that contains classes and other assets that your Flex application uses. The component library's file structure defines the package system that the components are in.

Typically, component libraries are statically linked into your application, which means that the compiler compiles it into the SWF file before the user downloads that file.

To build a component library SWC file, you use the `include-classes`, `include-namespaces`, and `include-sources` component compiler options. For more information on building component libraries, see "Using compc, the component compiler" on page 2194.

Runtime Shared Libraries

You can use shared assets that can be separately downloaded and cached on the client in Flex. These shared assets are loaded by multiple applications at run time, but must be transferred only once to the client. These shared files are known as *Runtime Shared Libraries* or *RSLs*.

RSLs are the only kind of application asset that is dynamically linked into your Flex application. When you compile your application, the RSL source files must be available to the compiler so that it can perform proper link checking. The assets themselves are not included in the application SWF file, but are only referenced at run time.

To create an RSL SWC file, you add files to a library by using the `include-classes` and `include-namespaces` component compiler options. To use RSLs when compiling your application, you use the `external-library-path`, `externs`, `load-externs`, and `runtime-shared-libraries` application compiler options. The `external-library-path`, `externs`, and `load-externs` options provide the compile-time location of the libraries. The `runtime-shared-libraries` option provides the run-time location of the shared library. The compiler requires this for dynamic linking.

For more information, see "Runtime Shared Libraries" on page 253.

Themes

A *theme* defines the look and feel of a Flex application. A theme can define something as simple as the color scheme or common font for an application, or it can be a complete reskinning of all the components used by the application.

Themes usually take the form of a SWC file. However, themes can also be composed of a CSS file and embedded graphical resources, such as symbols from a SWF file.

Theme files must be available to the compiler at compile-time. You build a theme file by using the `include-file` and `include-classes` component compiler options to add skin files and style sheets to a SWC file. You then reference the theme SWC file when you compile the main Flex application by using the `theme` application compiler option.

For more information about themes, see "About themes" on page 1561.

Resource bundles

You can package libraries of localized properties files and ActionScript classes into a SWC file. The application compiler can then statically use this SWC file as a resource bundle. For more information about creating and using resource bundles, see "Localization" on page 2055.

Other assets

Other application assets include images, fonts, movies, and sound files. You can embed these assets at compile time or access them at run time.

When you embed an asset, you compile it into your application's SWF file. The advantage of embedding an asset is that it is included in the SWF file, and can be accessed faster than when the application has to load it from a remote location at run time. The disadvantage of embedding an asset is that your SWF file is larger than if you load the resource at run time.

The alternative to embedding an asset is to load the asset at run time. You can load an asset from the local file system in which the SWF file runs, or you can access a remote asset, typically though an HTTP request over a network.

Embedded assets load immediately, because they are already part of the Flex SWF file. However, they add to the size of your application and slow down the application initialization process. Embedded assets also require you to recompile your applications whenever your asset files change.

For more information, see "Embedding assets" on page 1699.

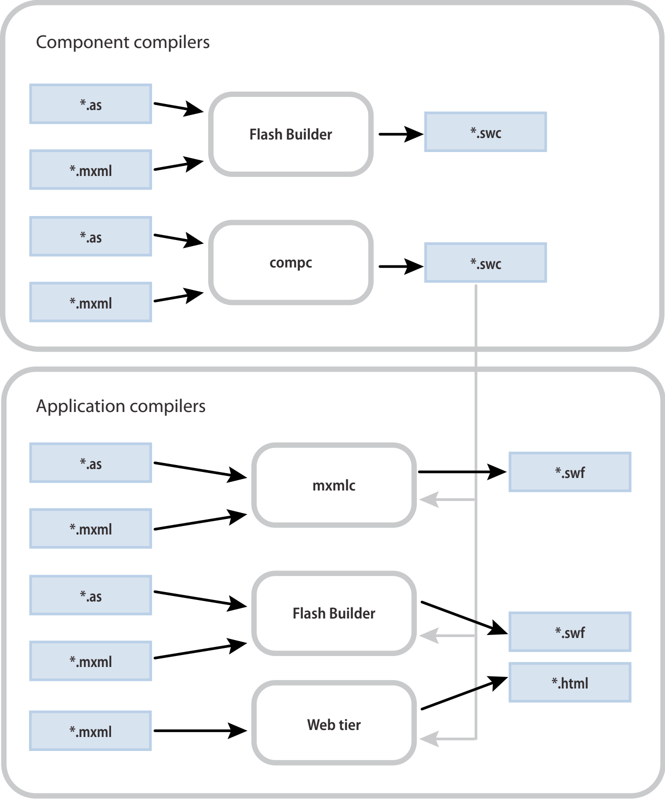
Flex compilers

About the Flex compilers

Flex includes the following application and component compilers:

- Application compilers. The application compilers create SWF files from MXML, ActionScript, and other assets such as images, SWF files, and SWC files.
- Component compilers. The component compilers create SWC files from the same kinds of files. The application compilers then use the SWC files as component libraries, themes, or RSLs.

The following example shows the input and output of the Flex compilers:



You open the application compiler with the mxmlc command-line tool or with the Flash Builder Build Project option. You open the component compiler with the Flash Builder Build Project option for a Library Project or with the compc command-line tool.

About the application compilers

The application compilers create SWF files that are run in an Adobe™ Flash® Player client or in an Adobe AIR™ application. The client can be a stand-alone Flash Player or a Flash Player in a browser, which takes the form of an ActiveX control for Microsoft Internet Explorer or a plug-in for Netscape-based browsers.

Flash Builder project compiler The Flash Builder application compiler is opened by Flash Builder for Flex Projects and ActionScript Projects. (The component compiler is used for Library Projects.) It is similar in functionality to the mxmlc command-line compiler, although the way you set options is different. You use this compiler to compile Flash Builder projects that you will later deploy. For more information, see "Using the Flash Builder application compiler" on page 2166.

The mxmlc command-line compiler You open the mxmlc compiler from the command line to create a SWF file that you then deploy to a website. Typically, you pass the name of the application's root MXML file to the compiler. The output is a SWF file. For more information, see "Using the mxmlc application compiler" on page 2166.

The Flash Builder compiler and mxmlc compiler have similar sets of options. These are described in "About the application compiler options" on page 2175.

You can compile applications that are written entirely in ActionScript and contain no MXML. You can compile these "ActionScript-only" applications with the Flash Builder and mxmlc compilers.

Using the Flash Builder application compiler

You use the Flash Builder application compiler to create SWF files from MXML, ActionScript, and other source files. You use this compiler to precompile SWF files that you deploy later.

To open the Flash Builder application compiler, you select Project > Build. The Flash Builder application compiler is opened by Flash Builder for Flex Projects and ActionScript Projects. (You use the component compiler for Library Projects.)

To edit the compiler settings, use the settings on the Project > Properties > Flex Compiler dialog box. For information on the compiler options, see "About the application compiler options" on page 2175.

The Flash Builder compiler has the same options as the mxmlc compiler. Some options are implemented with GUI controls in the Flex Compiler dialog box. To set the source path and library options, select Project > Properties > Flex Build Path and use the Flex Build Path dialog box.

You can set the values of most options in the Additional Compiler Arguments field by using the same syntax as on the command line. For information about the command-line syntax, see "About the command-line compilers" on page 2169.

In the Additional Compiler Arguments field, you can substitute a path to the SDK directory by using the `${flexlib}` token, as the following example shows:

```
-include-libraries "${flexlib}/libs/automation.swc" "${flexlib}/libs/automation_agent.swc"
```

By default, Flash Builder exposes the compilation options through the project properties. If you want to use a configuration file, you can create your own and pass it to the compiler by using the `load-config` option. For more information on setting compiler options with configuration files, see "About configuration files" on page 2171.

In addition to generating SWF files, the Flash Builder compiler also generates an HTML wrapper that you can use when you deploy the new application. The HTML wrapper includes the `<object>` and `<embed>` tags that reference the new SWF file, as well as scripts that support history management and player version detection. For more information about the HTML wrapper, see "Creating a wrapper" on page 2552.

The Flash Builder application compiler uses incremental compilation by default. For more information on incremental compilation, see "About incremental compilation" on page 2191.

Using the mxmlc application compiler

You use the mxmlc command-line compiler to create SWF files from MXML, AS, and other source files. You can open it as a shell script and executable file for use on Windows and UNIX systems. You use this compiler to precompile applications that you deploy later.

The command-line compiler is installed with Flex SDK. It is in the *flex_install_dir*/bin directory in Flex SDK. The compiler is also included in the default Flash Builder installation, in the *flash_builder_install_dir*/sdks/*sdk_version*/bin directory.

To use the mxmlc utility, you should understand its syntax and how to use configuration files. For more information, see "About the command-line compilers" on page 2169.

The basic syntax of the mxmlc utility is as follows:

```
mxmlc [options] target_file
```

The default option is the target file to compile into a SWF file, and it is required to have a value. If you use a space-separated list as part of the options, you can terminate the list with a double hyphen before adding the target file; for example:

```
mxmlc -option arg1 arg2 arg3 -- target_file.mxml
```

To see a list of options for mxmlc, you can use the `helplist` option, as the following example shows:

```
mxmlc -help list
```

To see a list of all options available for mxmlc, including advanced options, you use the following command:

```
mxmlc -help list advanced
```

The default output of mxmlc is *filename*.swf, where *filename* is the name of the root application file. The default output location is in the same directory as the target, unless you specify an output file and location with the `output` option.

The mxmlc command-line compiler does not generate an HTML wrapper. You must create your own wrapper to deploy a SWF file that the mxmlc compiler produced. The wrapper is used to embed the SWF object in the HTML tag. It includes the `<object>` and `<embed>` tags, as well as scripts that support Flash Player version detection and history management. For information about creating an HTML wrapper, see "Creating a wrapper" on page 2552.

The mxmlc utility uses the default compiler settings in the flex-config.xml file. This file is in the *flex_sdk_dir*/frameworks/ directory. You can change the settings in this file or use another custom configuration file. For more information on using configuration files, see "About configuration files" on page 2171.

The mxmlc compiler is highly customizable with a large set of options. For information on the compiler options, see "About the application compiler options" on page 2175.

You can also open the mxmlc compiler with the `java` command on the command line. For more information, see "Invoking the command-line compilers with Java" on page 2170.

About the component compiler

You use the component compiler to generate a SWC file from component source files and other asset files such as images and style sheets. A SWC file is an archive of components and other assets. For more information about SWC files, see "About SWC files" on page 2205.

In some ways, the component compiler is similar to the application compiler. The application compiler produces a SWF file from one or more MXML and ActionScript files; the component compiler produces a SWC file from its input files. SWC files are compressed files that contain a SWF file (library.swf), asset files, and a catalog.xml file.

You use the component compiler to create the following kinds of assets:

Component libraries Component libraries are SWC files that contain one or more components that are used by applications. SWC files also contain the namespace information that describe the contents of the SWC file. For more information about component libraries, see "About SWC files" on page 2205.

Runtime shared libraries (RSLs) RSLs are external shared assets that can be separately downloaded and cached on the client. These shared assets are loaded by any number of applications at run time. For more information on RSLs, see "Runtime Shared Libraries" on page 253.

Themes Themes are a combination of skins and Cascading Style Sheets (CSS). You use themes to define the look and feel of an application built with Flex. For more information on themes, see "Styles and themes" on page 1492.

You use the component compiler in the following ways:

Flash Builder Library Project compiler Flash Builder uses the component compiler when you create a Library Project. (The application compiler is used for Flex Projects and ActionScript Projects). For more information, see "Using the Flash Builder component compiler" on page 2168.

The compc command-line compiler You open the compc compiler from the command line to create a SWC file. For more information, see "Using the compc component compiler" on page 2168.

The component compiler has many of the same options as the application compilers, as described in "About the application compiler options" on page 2175. The component compiler has additional options as described in "About the component compiler options" on page 2194.

Like the application compiler, you can use the `load-config` option to point the component compiler to a configuration file, rather than specify command-line options or set the options in the Flex Compiler dialog box.

When you compile a SWC file, store the new file in a location that is not the same as the source files. If both sets of files are accessible by Flex when you compile your application, unexpected behavior can occur.

The SWC files that are produced by the component compilers do not require an HTML wrapper because they are used as themes, RSLs, or component libraries that are input to other compilers to create applications. You never deploy a SWC file that users can request directly.

Using the Flash Builder component compiler

You use the component compiler in Flash Builder to create SWC files. You do this by setting up a Flex Library Project using the New Library Project command. You add MXML and ActionScript components, style sheets, SWF files, and other assets to the project.

To open the Flash Builder component compiler, select Project > Build Project for your Flex Library Project.

You edit the compiler settings by using the settings on the Project > Properties > Flex Compiler dialog box. Using the Additional Compiler Arguments field in this dialog box, you can set compiler options as if you were using the command-line compiler. For information about the syntax for setting options in the Flex Compiler dialog box, see "About the command-line compilers" on page 2169.

You can set the value of some options using the GUI controls. To set the resource options in the Flex Library Build Path dialog box, select Project > Properties > Flex Library Build Path.

Flash Builder does not expose a default configuration file to set compiler options but you can create your own and pass it to the compiler with the `load-config` option. For more information on setting compiler options with configuration files, see "About configuration files" on page 2171.

Using the compc component compiler

You use the compc command-line compiler to compile SWC files from MXML, ActionScript, and other source files such as style sheets, images, and SWF files.

You can open the compc compiler as a shell script and executable file for use on Windows and UNIX systems. It is in the *flex_install_dir*/bin directory in Flex SDK

To use the compc compiler, you should understand how to pass options and use configuration files. For more information, see "About the command-line compilers" on page 2169.

The syntax of the compc compiler is as follows:

```
compc [options] -include-classes class [...]
```

The default option for compc is `include-classes`. At least one of the "include-" options is required.

To see a list of supported options for compc, you can use the `helplist` option, as the following example shows:

```
compc -help list
```

The compc compiler uses the default compiler settings in the flex-config.xml file. Like the application compiler, you can change these settings or use another custom configuration file. Unlike the application compiler, however, the component compiler does not support the use of default configuration files.

You cannot use the compc compiler to create a SWC file from a FLA file or other file created in the Adobe® Flash® authoring environment.

You can also open the compc compiler with the `java` command on the command line. For more information, see "Invoking the command-line compilers with Java" on page 2170.

About the command-line compilers

You use the mxmlc and compc command-line compilers to compile your MXML and AS files into SWF and SWC files. You can use the utilities to precompile applications that you want to deploy on another server or to automate compilation in a testing environment.

To use the command-line compilers, you must have a Java run-time environment in your system path.

For Flex SDK, the command-line compilers are located in the *flex_install_dir*/bin directory. For Flash Builder, the compilers are located in the *flash_builder_install_dir*/sdks/*sdk_version*/bin directory.

When using mxmlc and compc on the command line, you can also use a configuration file to store your options rather than list them on the command line. You can store command-line options as XML blocks in a configuration file. For more information, see "About configuration files" on page 2171.

Command-line syntax

The mxmlc and compc compilers take many options. The options are listed in the help which you can view with the `help` option, as the following example shows:

```
mxmlc -help
```

This displays a menu of choices for getting help. The most common choice is to list the basic configuration options:

```
mxmlc -help list
```

To see advanced options, use the `list advanced` option, as the following example shows:

```
mxmlc -help list advanced
```

To see a list of entries whose names or descriptions include a particular String, use the following syntax:

```
mxmlc -help pattern
```

The following example returns descriptions for the `external-library-path`, `library-path`, and `runtime-shared-libraries` options:

```
mxmlc -help list library
```

For a complete description of mxmlc options, see "About the application compiler options" on page 2175. For a complete description of compc options, see "About the component compiler options" on page 2194.

Many command-line options, such as `show-actionscript-warnings` and `accessible`, have `true` and `false` values. You specify these values by using the following syntax:

```
mxmlc -accessible=true -show-actionscript-warnings=true
```

Some options, such as `source-path`, take a list of one or more options. You can see which options take a list by examining the help output. Square brackets (`[ ]`) that surround options indicate that the option can take a list of one or more parameters.

You can separate each entry in a list with a space or a comma. The syntax is as follows:

```
-var val1 val2
```

or

```
-var=val1, val2
```

If you do not use commas to separate entries, you terminate a list by using a double hyphen, as the following example shows:

```
-var val1 val2 -- -next_option
```

If you use commas to separate entries, you terminate a list by not using a comma after the last entry, as the following example shows:

```
-var=val1, val2 -next_option
```

You can append values to an option using the += operator. This adds the new entry to the end of the list of existing entries rather than replacing the existing entries. The following example adds the c:/myfiles directory to the `library-path` option:

```
mxmlc -library-path+=c:/myfiles
```

Using abbreviated option names

In some cases, the command-line help shows an option with dot-notation syntax; for example, `source-path` is shown as `compiler.source-path`. This notation indicates how you would set this option in a configuration file. On the command line, you can specify the option with only the final node, `source-path`, as long as that node is unique, as the following example shows:

```
mxmlc -source-path . c:/myclasses/ -- foo.mxml
```

For more information about using configuration files to store command-line options, see “About configuration files” on page 2171.

Some compiler options have aliases. *Aliases* provide shortened variations of the option name to make command lines more readable and less verbose. For example, the alias for the `output` option is `o`. You can view a list of options by their aliases by using the following command:

```
mxmlc -help list aliases
```

or

```
mxmlc -help list advanced aliases
```

You can also see the aliases in the verbose help output by using the following command:

```
mxmlc -help list details
```

Invoking the command-line compilers with Java

Flex provides a simple interface to the command-line compilers. For UNIX users, there is a shell script. For Windows users, there is an executable file. These files are located in the bin directory. You can also invoke the compilers using Java. This lets you integrate the compilers into Java-based projects (such as Ant) or other utilities.

The shell scripts and executable files for the command-line compilers wrap calls to the mxmlc.jar and compc.jar JAR files. To invoke the compilers from Java, you call the JAR files directly. For Flex SDK, the JAR files are located in the *flex_install_dir*/lib directory. For Flash Builder, they are located in the *flash_builder_install_dir*/sdks/*sdk_version*/lib.

To invoke a command in a JAR file, use the `java` command from the command line and specify the JAR file you want to execute with the `jar` option. You must also specify the value of the `+flexlib` option. This advanced option lets you set the root directory that is used by the compiler to locate the flex-config.xml file, among other files. You typically point it to your frameworks directory. From there, the compiler can detect the location of other configuration files.

The following example compiles MyApp.mxml into a SWF file using the JAR file to invoke the mxmlc compiler:

```
java -jar ../lib/mxmlc.jar +flexlib c:/flex_4_sdk/frameworks c:/flex/MyApp.mxml
```

You pass all other options as you would when you open the command-line compilers. The following example sets the locale and source path when compiling MyApp:

```
java -jar ../lib/mxmlc.jar +flexlib c:/flex_4_sdk/frameworks -locale en_US -source-path
locale/{locale} c:/flex/MyApp.mxml
```

About configuration files

Configuration files can be used by the command-line utilities and Flash Builder compilers.

Flex includes a default configuration file named flex-config.xml. This configuration file contains most of the default compiler settings for the application and component compilers. You can customize this file or create your own custom configuration file.

Flex SDK includes the flex-config.xml file in the *flex_install_dir*/frameworks directory.

The Flash Builder compilers do not use a flex-config.xml file by default. The default settings are stored internally. You can, however, create a custom configuration file and pass it to the Flash Builder compilers by using the `load-config` option. Flash Builder includes a copy of the flex-config.xml file that you can use as a template for your custom configuration file. This file located in the *flash_builder_install_dir*/sdks/*sdk_version*/frameworks directory.

You can generate a configuration file with the current settings by using the `dump-config` option, as the following example shows:

```
mxmlc -dump-config myapp-config.xml
```

Locating configuration files

You can specify the location of a configuration file by using the `load-config` option. The target configuration file can be the default flex-config.xml file, or it can be a custom configuration file. The following example loads a custom configuration file:

```
compc -load-config=myconfig.xml
```

If you specify the filename with the `+=` operator, your loaded configuration file is used *in addition to* and not instead of the flex-config.xml file:

```
compc -load-config+=myconfig.xml
```

With the mxmlc compiler, you can also use a local configuration file. A *local configuration file* does not require you to point to it on the command line. Rather, Flex examines the same directory as the target MXML file for a configuration file with the same name (one that matches the *filename*-config.xml filename). If it finds a file, it uses it in conjunction with the flex-config.xml file. You can also specify a configuration file by using the `load-config` option with the `+=` operator.

For example, if your application’s top-level file is called MyApp.mxml, the compiler first checks for a MyApp-config.xml file for configuration settings. With this feature, you can easily compile multiple applications using different configuration options without changing your command-line options or your flex-config.xml file.

Options in the local configuration file take precedence over options set in the flex-config.xml file. Options set in a configuration file that the `load-config` option specify take precedence over the local configuration file. Command-line settings take precedence over all configuration file settings. For more information on the precedence of compiler options, see “About option precedence” on page 2174.

Configuration file syntax

You store values in a configuration file in XML blocks, which follow a specific syntax. In general, the tags you use match the command-line options.

About the root tag

The root tag of the default configuration file, flex-config.xml, is `<flex-config>`. If you write a custom configuration file, it must also have this root tag. Compiler configuration files must also have an XML declaration tag, as the following example shows:

```
<?xml version="1.0"?>
<flex-config>
```

You must close the `<flex-config>` tag as you would any other XML tag. All compiler configuration files must be closed with the following tag:

```
</flex-config>
```

In general, the second tag in a configuration file is the `<compiler>` tag. This tag wraps most compiler options. However, not all compiler options are set in the `<compiler>` block of the configuration file.

Tags that you must wrap in the compiler block are prefixed by `compiler` in the help output (for example, `compiler.services`). If the option uses no dot-notation in the help output (for example, `include-file`), it is a tag at the root level of the configuration file, and the entry appears as follows:

```
<compiler>
...
</compiler>
<include-file>
    <name>logo.gif</name>
    <path>c:/images/logo/logo1.gif</path>
</include-file>
```

In some cases, options have multiple parent tags, as with the fonts options, such as `compiler.fonts.managers` and `compiler.fonts.languages.language`. Other options that require parent tags when added to a configuration file include the `frames.frame` option and the metadata options. The following sections describe methods for determining the syntax.

Getting the configuration file tags

Use the `help list` option of the command-line compilers to get the configuration file syntax of the compiler options; for example:

```
mxmlc -help list advanced
```

The following is the entry for the `source-path` option:

```
-compiler.source-path [path-element][...]
```

This indicates that in the configuration file, you can have one or more `<path-element>` child tags of the `<source-path>` tag, and that `<source-path>` is a child of the `<compiler>` tag. The following example shows how this should appear in the configuration file:

```
<compiler>
    <source-path>
        <path-element>.</path-element>
        <path-element>c:/myclasses/</path-element>
    </source-path>
</compiler>
```

Understanding leaf nodes

The help output uses dot-notation to separate child tags from parent tags, with the right-most entry being known as the *leaf node*. For example, `-tag1.tag2` indicates that `<tag2>` should be a child tag of `<tag1>`.

Angle brackets (`< >`) or square brackets (`[ ]`) that surround an option indicate that the option is a leaf node.

Square brackets indicate that there can be a list of one or more parameters for that option.

If the leaf node of a tag in the angle bracket is unique, you do not have to specify the parent tags in the configuration file. For example, the help usage shows the following:

```
compiler.fonts.managers [manager-class][...]
```

You can specify the value of this option in the configuration file, as the following example shows:

```
<compiler>
    <fonts>
        <managers>
            <manager-class>flash.fonts.JREFontManager</manager-class>
        </managers>
    </fonts>
</compiler>
```

However, the `<manager-class>` leaf node is unique, so you can set the value without specifying the `<fonts>` and `<managers>` parent tags, as the following example shows:

```
<compiler>
    <manager-class>flash.fonts.JREFontManager</manager-class>
</compiler>
```

If the help output shows multiple options listed in angle brackets, you set the values of these options at the same level inside the configuration file and do not make them child tags of each other. For example, the usage for default-size (`default-size <width> <height>`) indicates that the default size of the application is set in a configuration file, as the following example shows:

```
<default-size>
    <height>height_value</height>
    <width>width_value</width>
</default-size>
```

Using tokens

You can pass custom token values to the compiler using the following syntax:

```
+token_name=value
```

In the configuration file, you reference that value using the following syntax:

```
${token_name}
```

You can use the `@Context` token in your configuration files to represent the context root of the application. You can also use the `${flexlib}` token to represent the frameworks directory. This is useful if you set up your own configuration and are not using the default `library-path` settings.

The default value of the `${flexlib}` token is *`application_home`*`\frameworks`.

Appending values

In a configuration file, you can specify the `append` attribute of any tag that takes a list of arguments. Set this attribute to `true` to indicate that the values should be appended to the option rather than replace it. The default value is `false`.

Setting the `append` attribute to `true` lets you compound the values of options with multiple configuration files. The following example appends two entries to the `library-path` option:

```
<library-path append="true">
    <path-element>/mylibs</path-element>
    <path-element>/myotherlibs</path-element>
</library-path>
```

About option precedence

You can set the same options in multiple places and the Flex compilers use the value from the source that has the highest precedence.

If you do not specify an option on the command line, the compilers check for a `load-config` option and get the value from that file.

When using the mxmlc compiler, Flex checks to see if there is an *app_name*-config.xml file in the same directory as the target MXML file. This is known as the local configuration file and is described in "Locating configuration files" on page 2171. The syntax and structure of local configuration files are the same as with the flex-config.xml file.

If no `load-config` option is specified, the compilers check for the flex-config.xml file. The compilers look for the flex-config.xml file in the /frameworks directory. The following location is the default:

```
{flex_root}/frameworks
```

Most options have a default value that the compilers use if the option is not set in any of the other ways.

The following table shows the possible sources of options for each compiler. The table also shows the order of precedence for each option. The options set using the method described in a lower row take precedence over the options set using the methods described in a higher row.

Compiler options	Flash Builder	mxmlc	compc
Default settings	Yes	No	No
flex-config.xml	No	Yes	Yes
Local configuration file	No	Yes	No
Configuration file specified by load-config option	Yes	Yes	Yes
Command-line option	No	Yes	Yes
Options panel	Yes	No	No

You can mix and match the source of the compiler options. For example, you can specify a custom configuration file with the `load-config` option, and also set additional options on the command line.

You can also use multiple configuration files. You can chain them by using the `+=` operator with the `load-config` option. If you specify a configuration file with this option, the compilers also look for the flex-config.xml and local (*appname*-config.xml) configuration files.

Using mxmlc, the application compiler

You use the application compiler to compile SWF files from your ActionScript and MXML source files.

The application compiler's options let you define settings such as the library path and whether to include debug information in the resulting SWF file. Also, you can set application-specific settings such as the frame rate at which the SWF file should play and its height and width.

To invoke the application compiler with Flex SDK, you use the mxmlc command-line utility. In Flash Builder, you use the application compiler by building a new Flex Project. Some of the Flex SDK command-line options have equivalents in the Flash Builder environment. For example, you can use the tabs in the Flex Build Path dialog box to add classes and libraries to your project.

The following set of examples use the application compiler.

About the application compiler options

The following table describes the application compiler options. You invoke the application compiler with the mxmlc command-line utility or when building a project in Flash Builder.

Option	Description
`accessible=true|false`	Enables accessibility features when compiling the application or SWC file. The default value is `false`. For more information on using the Flex accessibility features, see "Accessible applications" on page 2122.
`actionscript-file-encoding` *`string`*	Sets the file encoding for ActionScript files. For more information, see "Setting the file encoding" on page 2190.
`advanced`	Lists advanced help options when used with the help option, as the following example shows: `mxmlc -help advanced` This is an advanced option.
`allow-source-path-overlap=true|false`	Checks if a `source-path` entry is a subdirectory of another `source-path` entry. It helps make the package names of MXML components unambiguous. This is an advanced option.
`as3=true|false`	Use the ActionScript 3.0 class-based object model for greater performance and better error reporting. In the class-based object model, most built-in functions are implemented as fixed methods of classes. The default value is `true`. If you set this value to `false`, you must set the `es` option to `true`. This is an advanced option.
`benchmark=true|false`	Prints detailed compile times to the standard output. The default value is `true`.
`compress=true|false`	Enables or disables SWF file compression. The default value is `true` when debugging is disabled (so that release SWF files are compressed) and `false` when debugging is enabled (so that debug SWF files are not compressed).
`context-root` *`context-path`*	Sets the value of the `{context.root}` token, which is often used in channel definitions in the flex-services.xml file and other settings in the flex-config.xml file. The default value is null.
`contributor` *`name`*	Sets metadata in the resulting SWF file. For more information, see "Adding metadata to SWF files" on page 2189.
`creator` *`name`*	Sets metadata in the resulting SWF file. For more information, see "Adding metadata to SWF files" on page 2189.
`date` *`text`*	Sets metadata in the resulting SWF file. For more information, see "Adding metadata to SWF files" on page 2189.

Option	Description
`debug=true|false`	Generates a debug SWF file. This file includes line numbers and filenames of all the source files. When a run-time error occurs, the stacktrace shows these line numbers and filenames. This information is used by the command-line debugger and the Flex Builder debugger. Enabling the `debug` option generates larger SWF files and also disables compilation optimization. For the mxmlc compiler, the default value is `false`. For the compc compiler, the default value is `true`. For Flash Builder, the default value is `true`. If you export an application by using the Export Release Build feature, the Flash Builder compiler excludes the debugging information, which is the equivalent of setting the value of this option to `false`. When generating SWC files, if `debug` is set to `true`, then the library.swf file inside the SWC file contains debug information. If you are generating a SWC file for distribution, set this value to `false`. For information about the command-line debugger, see "Command-line debugger" on page 2209. If you set this option to `true`, Flex also sets the `verbose-stacktraces` option to `true`
`debug-password` *`string`*	Lets you engage in remote debugging sessions with the Flash IDE. This is an advanced option.
`default-frame-rate` *`int`*	Sets the application's frame rate. The default value is 24. This is an advanced option.
`default-script-limits` *`max-recursion-depth max-execution-time`*	Defines the application's script execution limits. The `max-recursion-depth` value specifies the maximum depth of Adobe Flash Player call stack before Flash Player stops. This is essentially the stack overflow limit. The default value is 1000. The `max-execution-time` value specifies the maximum duration, in seconds, that an ActionScript event handler can execute before Flash Player assumes that it is hung, and aborts it. The default value is 60 seconds. You cannot set this value above 60 seconds. You can override these settings in the application. This is an advanced option.
`default-size` *`width height`*	Defines the default application size, in pixels. This is an advanced option.
`defaults-css-files` *`filename`* `[, ...]`	Inserts CSS files into the output the same way that a per-SWC defaults.css file works, but without having to re-archive the SWC file to test each change. CSS files included in the output with this option have a higher precedence than default CSS files in existing SWCs. For example, a CSS file included with this option overrides definitions in framework.swc's defaults.css file, but it has the same overall precedence as other included CSS files inside the SWC file. This option does not actually insert the CSS file into the SWC file; it simulates it. When you finish developing the CSS file, you should rebuild the SWC file with the new integrated CSS file. This option takes one or more files. The precedence for multiple CSS files included with this option is from first to last. This is an advanced option.

Option	Description
`defaults-css-url` *`string`*	Defines the location of the default style sheet. Setting this option overrides the implicit use of the defaults.css style sheet in the framework.swc file. For more information on the defaults.css file, see "Styles and themes" on page 1492. This is an advanced option.

`define=`*`NAMESPACE::variable,value`*	Defines a global constant. The value is evaluated at compile time and exists as a constant within the application. A common use of inline constants is to set values that are used to include or exclude blocks of code, such as debugging or instrumentation code. This is known as conditional compilation.
	The following example defines the constant `debugging` in the `CONFIG` namespace:
	`-define=CONFIG::debugging,true`
	In ActionScript, you can use this value to conditionalize statements; for example:
	`CONFIG::debugging {// Execute debugging code here.}`
	To set multiple conditionals on the command-line, use the `define` option more than once.
	For more information, see "Using conditional compilation" on page 2191.

`description` *`text`*	Sets metadata in the resulting SWF file. For more information, see "Adding metadata to SWF files" on page 2189.
`dump-config` *`filename`*	Outputs the compiler options in the flex-config.xml file to the target path; for example: `mxmlc -dump-config myapp-config.xml` This is an advanced option.
`es=true|false`	Instructs the compiler to use the ECMAScript edition 3 prototype-based object model to allow dynamic overriding of prototype properties. In the prototype-based object model, built-in functions are implemented as dynamic properties of prototype objects. The default value is `false`. Using the ECMAScript edition 3 prototype-based object model lets you use untyped properties and functions in your application code. As a result, if you set the value of the `es` compiler option to `true`, you must set the `strict` compiler option to `false`. Otherwise, the compiler will throw errors. If you set this option to `true`, you must also set the value of the `as3` compiler option to `false`. This is an advanced option.
`externs` *`class_name [...]`*	Sets a list of classes to exclude from linking when compiling a SWF file. This option provides compile-time link checking for external references that are dynamically linked. For more information about dynamic linking, see "About linking" on page 254. This is an advanced option.

Option	**Description**
`external-library-path` *`path-element [...]`*	Specifies a list of SWC files or directories to exclude from linking when compiling a SWF file. This option provides compile-time link checking for external components that are dynamically linked. By default, the libs/player/playerglobal.swc file is linked as an external library. This library is built into Flash Player. For more information about dynamic linking, see “About linking” on page 254. You can use the += operator to append the new SWC file to the list of external libraries.
`fonts.advanced-anti-aliasing=true|false`	Sets the default value that determines whether embedded fonts use advanced anti-aliasing information when rendering the font. Setting the value of the `advanced-anti-aliasing` property in a style sheet overrides this value. The default value is `false`. For more information about using advanced anti-aliasing, see “Fonts” on page 1568.
`fonts.languages.language-range` *`lang range`*	Specifies the range of Unicode settings for that language. For more information, see “Fonts” on page 1568. This is an advanced option.
`fonts.local-fonts-snapshot` *`path_to_file`*	Sets the location of the local font snapshot file. The file contains system font data. This is an advanced option.
`fonts.managers` *`manager-class [...]`*	Defines the font manager. The default is flash.fonts.JREFontManager. You can also use the flash.fonts.BatikFontManager. For more information, see “Fonts” on page 1568. This is an advanced option.
`fonts.max-cached-fonts` *`string`*	Sets the maximum number of fonts to keep in the server cache.
`fonts.max-glyphs-per-face` *`string`*	Sets the maximum number of character glyph-outlines to keep in the server cache for each font face. This is an advanced option.
`frames.frame=`*`label,class_name`*`[,...]`	Specifies a SWF file frame label with a sequence of class names that are linked onto the frame; for example: `-frame=MyLabel,Class1,Class2` This option lets you add asset factories that stream in after the application that then publish their interfaces with the ModuleManager class. The advantage to doing this is that the application starts faster than it would have if the assets had been included in the code, but does not require moving the assets to an external SWF file. This is an advanced option.
`generate-frame-loader=true|false`	Toggles the generation of an IFlexBootstrap-derived loader class. This is an advanced option.

Option	**Description**
`headless-server=true|false`	Enables the headless implementation of the Flex compiler. This sets the following: `System.setProperty("java.awt.headless", "true")` The headless setting (java.awt.headless=true) is required to use fonts and SVG on UNIX systems without X Windows. This is an advanced option.
`help [-list [advanced]]`	Prints usage information to the standard output. For example: `help -list advanced` For more information, see “Command-line syntax” on page 2169.

`include-inheritance-dependencies-only=false|true`	Include only classes that are inheritance dependencies of classes that are included with the `include-classes` compiler option.
	The default value is `false`.
	This is an advanced option. You might use this compiler option if you are creating a custom RSL and want to externalize as many classes as possible. For example:
	`compc -include-classes mx.collections.ListCollectionView`
	`-include-inheritance-dependencies-only=true`
	`-source-path . -output lcv2 -directory`

`include-libraries` *`library`* `[...]`	Links all classes inside a SWC file to the resulting application SWF file, regardless of whether or not they are used. Contrast this option with the `library-path` option that includes only those classes that are referenced at compile time. To link one or more classes whether or not they are used and not an entire SWC file, use the `includes` option. This option is commonly used to specify resource bundles.
`include-resource-bundles` *`bundle [...]`*	Specifies the resource bundles to link into a resource module. All resource bundles specified with this option must be in the compiler’s source path. You specify this using the `source-path` compiler option. For more information on using resource bundles, see “Resource Bundles” on page 2091.
`includes` *`class`* `[...]`	Links one or more classes to the resulting application SWF file, whether or not those classes are required at compile time. To link an entire SWC file rather than individual classes, use the `include-libraries` option.
`incremental=true|false`	Enables incremental compilation. For more information, see “About incremental compilation” on page 2191. This option is `true` by default for the Flash Builder application compiler. For the command-line compiler, the default is `false`.
`isolate-styles=true|false`	Enables per-module styling. The default value is `true`. This is an advanced option. You typically only use this option if you want to set styles in a module that is loaded into your main application. For more information about modules, see “Modular applications” on page 138.

Option	**Description**
`keep-as3-metadata=class_name [...]`	Specifies custom metadata that you want to keep. By default, the compiler keeps the following metadata: • Bindable • Managed • ChangeEvent • NonCommittingChangeEvent • Transient If you want to preserve the default metadata, you should use the += operator to append your custom metadata, rather than the = operator which replaces the default metadata. This is an advanced option. For more information, see "About metadata tags" on page 2376.
`keep-all-type-selectors=true|false`	Instructs the compiler to keep a style sheet's type selector in a SWF file, even if that type (the class) is not used in the application. This is useful when you have a modular application that loads other applications. For example, the loading SWF file might define a type selector for a type used in the loaded (or, target) SWF file. If you set this option to `true` when compiling the loading SWF file, then the target SWF file will have access to that type selector when it is loaded. If you set this option to `false`, the compiler will not include that type selector in the loading SWF file at compile time. As a result, the styles will not be available to the target SWF file. This is an advanced option.
`keep-generated-actionscript=true|false`	Determines whether to keep the generated ActionScript class files. The generated class files include stubs and classes that are generated by the compiler and used to build the SWF file. When using the application compiler, the default location of the files is the /generated subdirectory, which is directly below the target MXML file. If the /generated directory does not exist, the compiler creates one. When using the compc component compiler, the default location of the /generated directory is relative to the output of the SWC file. When using Flash Builder, the default location of the generated files is the /bin/generated directory. The default names of the primary generated class files are filename-generated.as and filename-interface.as. The default value is `false`. This is an advanced option.
`language code`	Sets metadata in the resulting SWF file. For more information, see "Adding metadata to SWF files" on page 2189.

Option	Description
`library-path` *`path-element [...]`*	Links SWC files to the resulting application SWF file. The compiler only links in those classes for the SWC file that are required. You can specify a directory or individual SWC files. The default value of the `library-path` option includes all SWC files in the libs and libs/player directories, plus the current locale directory. These are required. To point to individual classes or packages rather than entire SWC files, use the `source-path` option. If you set the value of the `library-path` as an option of the command-line compiler, you must also explicitly add the framework.swc and locale SWC files. Your new entry is not appended to the `library-path` but replaces it, unless you use the += operator. On the command line, you use the += operator to append the new argument to the list of existing SWC files. In a configuration file, you can set the `append` attribute of the `library-path` tag to `true` to indicate that the values should be appended to the library path rather than replace existing default entries.
`license` *`product_name  license_key`*	Defines the license key to use when compiling.
`link-report` *`filename`*	Prints linking information to the specified output file. This file is an XML file that contains `<def>`, `<pre>`, and `<ext>` symbols showing linker dependencies in the final SWF file. The output of this command can be used as input to the `load-externs` option. For more information on the report, see "Examining linker dependencies" on page 2308. This is an advanced option.
`load-config` *`filename`*	Specifies the location of the configuration file that defines compiler options. If you specify a configuration file, you can override individual options by setting them on the command line. All relative paths in the configuration file are relative to the location of the configuration file itself. Use the `+=` operator to chain this configuration file to other configuration files. For more information on using configuration files to provide options to the command-line compilers, see "About configuration files" on page 2171.
`load-externs` *`filename [...]`*	Specifies the location of an XML file that contains `<def>`, `<pre>`, and `<ext>` symbols to omit from linking when compiling a SWF file. The XML file uses the same syntax as the one produced by the `link-report` option. For more information on the report, see "Examining linker dependencies" on page 2308. This option provides compile-time link checking for external components that are dynamically linked. For more information about dynamic linking, see "About linking" on page 254. This is an advanced option.

Option	Description
`locale locale[,...]`	Specifies one or more locales to be compiled into the SWF file. If you do not specify a locale, then the compiler uses the default locale from the flex-config.xml file. The default value is en_US. You can append additional locales to the default locale by using the += operator. If you remove the default locale from the flex-config.xml file, and do not specify one on the command line, then the compiler will use the machine's locale. For more information, see "Localization" on page 2055.
`localized-description text lang`	Sets metadata in the resulting SWF file. For more information, see "Adding metadata to SWF files" on page 2189.
`localized-title text lang`	Sets metadata in the resulting SWF file. For more information, see "Adding metadata to SWF files" on page 2189.
`mxml.compatibility-version=version`	Specifies the version of the Flex compiler that the output should be compatible with. This option affects some behavior such as the layout rules, padding and gaps, skins, and other style settings. In addition, it affects the rules for parsing properties files. The following example instructs the application to compile with the Flex 3 rules for these behaviors: `-compatibility-version=3.0.0` Possible values for this compiler option are defined as constants in the FlexVersion class. If you set this value to 3.0.0, you must also use a theme in your application that is compatible with version 3 of the SDK. For more information on using this option, see "Backward compatibility" on page 2239.

`mxml.minimum-supported-`
`version=`***`version_number`***
	Specifies the minimum version of the SDK that the application uses. This is typically used when generating SWC files.
	This is an advanced option.

`mxml.qualified-type-selectors=true|false`	Determines whether you want the compiler to ensure that type selectors have a qualified namespace in the CSS files. This is an advanced option. The default value is `true`.
`namespaces.namespace uri manifest`	Specifies a namespace for the MXML file. You must include a URI and the location of the manifest file that defines the contents of this namespace. This path is relative to the MXML file. For more information about manifest files, see "About manifest files" on page 2206.
`optimize=true|false`	Enables the ActionScript optimizer. This optimizer reduces file size and increases performance by optimizing the SWF file's bytecode. The default value is `true`.
`omit-trace-statements=false|true`	Enables `trace()` statements from being written to the flashlog.txt file. The default value is `false`, which means that by default, `trace()` statements are written to the flashlog.txt file.

Option	Description
`output` *`filename`*	Specifies the output path and filename for the resulting file. If you omit this option, the compiler saves the SWF file to the directory where the target file is located. The default SWF filename matches the target filename, but with a SWF file extension. If you use a relative path to define the filename, it is always relative to the current working directory, not the target MXML application root. The compiler creates extra directories based on the specified filename if those directories are not present. When using this option with the component compiler, the output is a SWC file rather than a SWF file, unless you set the `directory` option to `true`. In that case, the output is a directory with the contents of the SWC file. The name of the directory is that value of the `ouput` option.
`preloader` ***`class_name`***	Specify a download progress bar for your application. The value must be the name of a class that implements the IPreloaderDisplay interface. The default value is "mx.preloaders.SparkDownloadProgressBar" when `compatibility-version` is 4.0.0 or greater. When `compatibility-version` is less than 4.0.0, the default value is "mx.preloaders.DownloadProgressBar". For more information, see "Showing the download progress of an application" on page 408.
`publisher` *`name`*	Sets metadata in the resulting SWF file. For more information, see "Adding metadata to SWF files" on page 2189.
`raw-metadata` *`XML_string`*	Defines the metadata for the resulting SWF file. The value of this option overrides any metadata-related compiler options such as `contributor`, `creator`, `date`, and `description`. This is an advanced option.
`remove-unused-rsls=true|false`	Instructs the compiler to only include RSLs that are used by the application. The default value is `true`. For more information about RSLs, see "Runtime Shared Libraries" on page 253.
`resource-bundle-list` *`filename`*	Prints a list of resource bundles that are used by the current application to a file named with the ***`filename`*** argument. You then use this list as input that you specify with the `include-resource-bundles` option to create a resource module. For more information, see "Resource Bundles" on page 2091.
`runtime-shared-libraries` *`rsl-url [...]`*	Specifies a list of runtime shared libraries (RSLs) to use for this application. RSLs are dynamically-linked at run time. The compiler externalizes the contents of the application that you are compiling that overlap with the RSL. You specify the location of the SWF file relative to the deployment location of the application. For example, if you store a file named library.swf file in the *web_root*/libraries directory on the web server, and the application in the web root, you specify libraries/library.swf. This compiler argument is included for backwards compatibility with Flex 3 applications. For Flex 4 applications, use the `runtime-shared-library-path` option. For more information about RSLs, see "Runtime Shared Libraries" on page 253.

Option	Description
`runtime-shared-library-path=`*`path-element`*`,`*`rsl-url`*`[,`*`policy-file-url`*`,`*`failover-url`*`,...]`	Specifies the location of a runtime shared library (RSL). The compiler externalizes the contents of the application that you are compiling that overlap with the RSL. The `path-element` argument is the location of the SWC file or open directory to compile against. For example, c:\flexsdk\frameworks\libs\framework.swc. This is the equivalent of the using the `external-library-path` option when compiling against an RSL using the `runtime-shared-libraries` option. The `rsl-url` argument is the URL of the RSL that will be used to load the RSL at runtime. The compiler does not verify the existence of the SWF file at this location at compile time. It does store this string in the application, however, and uses it at run time. As a result, the SWF file must be available at run time but necessarily not at compile time. The `policy-file-url` is the location of the crossdomain.xml file that gives permission to read the RSL from the server. This might be necessary because the RSL can be on a separate server as the application. For example, http://www.mydomain.com/rsls/crossdomain.xml. The `failover-url` and second `policy-file-url` arguments specify the location of the secondary RSL and crossdomain.xml file if the first RSL cannot be loaded. This most commonly happens when the client Player version does not support cross-domain RSLs. You can add any number of failover RSLs, but must include a policy file URL for each one. Do not include spaces between the comma-separated values. The following example shows how to use this option: `mxmlc -o=../lib/app.swf -runtime-shared-library-path=../lib/mylib.swc,../bin/myrsl.swf Main.mxml` You can specify more than one library file to be used as an RSL. You do this by adding additional `runtime-shared-library-path` options. You can also use the `runtime-shared-libraries` command to use RSLs with your applications. However, the `runtime-shared-library-path` option lets you also specify the location of the policy file and failover RSL. For more information about RSLs, see "Runtime Shared Libraries" on page 253.
`runtime-shared-library-settings.application-domain=`***`path-element`***`,`***`application-domain-target`***	Controls which domain an RSL is loaded into at runtime. The `path-element` is the path of the SWC library. To specify an RSL with this option, you must also define it in the `runtime-shared-library-path` option. The `application-domain-target` is the domain that the RSL should be loaded into. Valid values for `application-domain-target` are `default`, `current`, `parent`, and `top-level`. The default value is `default`. For more information about modules, see "Modular applications" on page 138. For more information about sub-applications, see "Developing and loading sub-applications" on page 176. For more information about RSLs, see "Runtime Shared Libraries" on page 253.

Option	Description
`runtime-shared-library-settings.force-rsls=`***`path-element`***	Forces an RSL to be included, regardless of whether it is used by the application. This is useful if all the links to a particular class in an RSL are soft references, or if you anticipate a module or sub-application to need a class that is not used by the main application. The `path-element` is the path of the SWC library. You can specify more than one `path-element` by using a comma-delimited list of RSLs. To specify an RSL with this option, you must also define it in the `runtime-shared-library-path` option. For more information about RSLs, see "Runtime Shared Libraries" on page 253.
`services` *`filename`*	Specifies the location of the services-config.xml file. This file is used by LiveCycle Data Services ES.
`show-actionscript-warnings=true|false`	Shows warnings for ActionScript classes. The default value is `true`. For more information about viewing warnings and errors, see "Viewing warnings and errors" on page 2203.
`show-binding-warnings=true|false`	Shows a warning when Flash Player cannot detect changes to a bound property. The default value is `true`. For more information about viewing warnings and errors, see "Viewing warnings and errors" on page 2203.
`show-invalid-css-property-warnings=true|false`	Shows a warning when a style property is set in CSS on a component that does not support that property. The warning can be a result of the theme not supporting the style property, the component not declaring it, or the component excluding it. The default value is `true`. For more information about viewing warnings and errors, see "Viewing warnings and errors" on page 2203.
`show-shadowed-device-font-warnings=true|false`	Shows warnings when you try to embed a font with a family name that is the same as the operating system font name. The compiler normally warns you that you are shadowing a system font. Set this option to `false` to disable the warnings. The default value is `true`. For more information about viewing warnings and errors, see "Viewing warnings and errors" on page 2203.
`show-unused-type-selector-warnings=true|false`	Shows warnings when a type selector in a style sheet or `<fx:Style>` block is not used by any components in the application. The default value is `true`. This warning does not detect whether a condition is met for descendant selectors. For more information about viewing warnings and errors, see "Viewing warnings and errors" on page 2203.

Option	Description
`size-report=`***`filename`***	Creates a report that summarizes the size of each type of data within an application SWF file. Types of data include media files, fonts, shapes, and ActionScript. For example: `mxmlc -size-report=myreport.xml MyApp.mxml` The file format of the output is XML. While the format has some similarities to the output of the `link-report` option, the size report cannot be used as input to the `load-externs` option. This option is useful if you are optimizing your application and want to see how big areas of your application are. For more information about the size report, see "Using the size report" on page 2305.
`source-path` *`path-element [...]`*	Adds directories or files to the source path. The Flex compiler searches directories in the source path for MXML, AS, or CSS source files that are used in your applications and includes those that are required at compile time. You can use wildcards to include all files and subdirectories of a directory. To link an entire library SWC file and not individual classes or directories, use the `library-path` option. The source path is also used as the search path for the component compiler's `include-classes` and `include-resource-bundles` options. You can also use the += operator to append the new argument to the list of existing source path entries. This option has the following default behavior: • If `source-path` is empty, the target file's directory will be added to source-path. • If `source-path` is not empty and if the target file's directory is a subdirectory of one of the directories in `source-path`, `source-path` remains unchanged. • If `source-path` is not empty and if the target file's directory is not a subdirectory of any one of the directories in `source-path`, the target file's directory is prepended to `source-path`.
`static-link-runtime-shared-libraries=true|false`	Determines whether to compile against libraries statically or use RSLs. Set this option to `true` to ignore the RSLs specified by the `runtime-shared-library-path` option. Set this option to `false` to use the RSLs. The default value is `true`. This option is useful so that you can quickly switch between a statically and dynamically linked application without having to change the `runtime-shared-library-path` option, which can be verbose, or edit the configuration files. For more information about RSLs, see "Runtime Shared Libraries" on page 253.
`strict=true|false`	Prints undefined property and function calls; also performs compile-time type checking on assignments and options supplied to method calls.\ The default value is `true`. For more information about viewing warnings and errors, see "Viewing warnings and errors" on page 2203.

Option	**Description**
`swf-version=`***`int`***	Specifies the SWF file format version of the output SWF file. Features requiring a later version of the SWF file format are not compiled into the application. This is different from the Player version in that it refers to the SWF specification versioning scheme. For Flex 4.6, the default value of `swf-version` is 14 (and the default Player version is 11.1). This is an advanced option. For more information, see "Targeting Flash Player versions" on page 2240.
`target-player=`*`major_version[.minor_version.revision]`*	Specifies the version of Flash Player that you want to target with the application. Features requiring a later version of Flash Player are not compiled into the application. The ***`player_version`*** parameter has the following format: *`major_version.minor_version.revision`* The ***`major_version`*** is required while ***`minor_version`*** and ***`revision`*** are optional. For Flex 4.0 and 4.1, the minimum value is 10.0.0. If you do not specify the ***`minor_version`*** or ***`revision`***, then the compiler uses zeros. For Flex 4.5, the default value is 10.2.0. For Flex 4.6, the default value is 11.1. If you do not explicitly set the value of this option, the compiler uses the default from the flex-config.xml file. The value in flex-config.xml is the version of Flash Player that shipped with the SDK. This option is useful if your application's audience has a specific Player and cannot upgrade. You can use this option to "downgrade" your application for that audience. For more information, see "Targeting Flash Player versions" on page 2240
`theme` *`filename [...]`*	Specifies a list of theme files to use with this application. Theme files can be SWC files with CSS files inside them or CSS files. For information on compiling a SWC theme file, see "Styles and themes" on page 1492.
`title` *`text`*	Sets metadata in the resulting SWF file. For more information, see "Adding metadata to SWF files" on page 2189.
`tools-locale=`***`locale`***	Specifies the locale to use when reporting compiler errors and warnings. Valid values are the language code (such as "ja" or "en") or the language code plus country code (such as "ja_JP" or "en_US"), depending on your system's configuration.
`use-direct-blit=false|true`	Specifies whether hardware acceleration is used to copy graphics to the screen (if such acceleration is available). This option only applies to applications running in the standalone Flash Player. For applications running in a browser, setting `use-direct-blit` to `true` is equivalent to setting `wmode` to `"direct"` in the HTML wrapper. For AIR applications, use the `renderMode` application descriptor tag. The default value is `false`. This is an advanced option.

Option	Description
`use-gpu=false|true`	Specifies whether GPU (Graphics Processing Unit) acceleration is used when drawing graphics (if such acceleration is available). This option only applies to applications running in the standalone Flash Player. For applications running in a browser, setting `use-gpu` to `true` is equivalent to setting `wmode` to `"gpu"` in the HTML wrapper. For AIR applications, use the `renderMode` application descriptor tag. The default value is `false`. This is an advanced option.
`use-network=true|false`	Specifies that the current application uses network services. The default value is `true`. When the `use-network` property is set to `false`, the application can access the local filesystem (for example, use the `XML.load()` method with file: URLs) but not network services. In most circumstances, the value of this property should be `true`. For more information about the `use-network` property, see "Security" on page 117.
`use-resource-bundle-metadata=true|false`	Enables resource bundles. Set to `true` to instruct the compiler to process the contents of the `[ResourceBundle]` metadata tag. The default value is `true`. For more information, see "Resource Bundles" on page 2091. This is an advanced option.
`verbose-stacktraces=true|false`	Generates source code that includes line numbers. When a run-time error occurs, the stacktrace shows these line numbers. Enabling this option generates larger SWF files. Enabling this option does not generate a debug SWF file. To do that, you must set the `debug` option to `true`. The default value is `false`.
`verify-digests=true|false`	Instructs the application to check the digest of the RSL SWF file against the digest that was compiled into the application at compile time. This is a security measure that lets you load RSLs from remote domains or different sub-domains. It also lets you enforce versioning of your RSLs by forcing an application's digest to match the RSL's digest. If the digests are out of sync, you must recompile your application or load a different RSL SWF file. For more information about RSLs, see "Runtime Shared Libraries" on page 253.
`version`	Returns the version number of the MXML compiler. If you are using a trial or Beta version of Flex, the version option also returns the number of days remaining in the trial period and the expiration date.
`warn-warning_type=true|false`	Enables specified warnings. For more information, see "Viewing warnings and errors" on page 2203.
`warnings=true|false`	Enables all warnings. Set to `false` to disable all warnings. This option overrides the `warn-`***`warning_type`*** options. The default value is `true`.

The following sections provide examples of using the mxmlc application compiler options on the command line. You can also use these techniques with the application compiler in Flash Builder.

Basic example of using mxmlc

The most basic example is one in which the MXML file has no external dependencies (such as components in a SWC file or ActionScript classes) and no special options. In this case, you invoke the mxmlc compiler and point it to your MXML file as the following example shows:

```
mxmlc c:/myfiles/app.mxml
```

The default option is the target file to compile into a SWF file, and it is required to have a value. If you use a space-separated list as part of the options, you can terminate the list with a double hyphen before adding the target file; for example:

```
mxmlc -option arg1 arg2 arg3 -- target_file.mxml
```

Adding metadata to SWF files

The application compilers support adding metadata to SWF files. This metadata can be used by search engines and other utilities to gather information about the SWF file. This metadata represents a subset of the Dublin Core schema.

You can set the following values:

- `contributor`
- `creator`
- `date`
- `description`
- `language`
- `localized-description`
- `localized-title`
- `publisher`
- `title`

For the mxmlc command-line compiler, the default metadata settings in the flex-config.xml file are as follows:

```
<metadata>
    <title>Adobe Flex 4 Application</title>
    <description>http://www.adobe.com/products/flex</description>
    <publisher>unknown</publisher>
    <creator>unknown</creator>
    <language>EN</language>
</metadata>
```

You can also set the metadata values as command-line options. The following example sets some of the metadata values:

```
mxmlc -language+=klingon -title "checkintest!"
    -localized-description "it r0x0rs" en-us
    -localized-description "c'est magnifique!" fr-fr
    -creator "Flexy Frank" -publisher "Franks Beans" flexstore.mxml
```

In this example, the following values are compiled into the resulting SWF file:

```
<rdf:RDF xmlns:rdf='http://www.w3.org/1999/02/22-rdf-syntax-ns#'>
    <rdf:Description rdf:about='' xmlns:dc='http://purl.org/dc/elements/1.1'>
        <dc:format>application/x-shockwave-flash</dc:format>
        <dc:title>checkintest!</dc:title>
        <dc:description>
            <rdf:Alt>
                <rdf:li xml:lang='fr-fr'>c'est magnifique!</rdf:li>
                <rdf:li xml:lang='x-default'>http://www.adobe.com/products/flex</rdf:li>
                <rdf:li xml:lang='en-us'>it r0x0rs</rdf:li>
            </rdf:Alt>
        </dc:description>
        <dc:publisher>Franks Beans</dc:publisher>
        <dc:creator>Flexy Frank</dc:creator>
        <dc:language>EN</dc:language>
        <dc:language>klingon</dc:language>
        <dc:date>Mar 16, 2010</dc:date>
    </rdf:Description>
</rdf:RDF>
```

For information on the SWF file format, see the Flash File Format Specification, which is available through the Player Licensing program.

Setting the file encoding

You use the `actionscript-file-encoding` option to set the file encoding so that the application compiler correctly interprets ActionScript files. This tag does not affect MXML files because they are XML files that contain an encoding specification in the `xml` tag.

You use the `actionscript-file-encoding` option when your ActionScript files do not contain a Byte Order Mark (BOM), and the files use an encoding that is different from the default encoding of your computer. If your ActionScript files contain a BOM, the compiler uses the information in the BOM to determine the file encoding.

For example, if your ActionScript files use Shift_JIS encoding, have no BOM, and your computer uses ISO-8859-1 as the default encoding, you use the `actionscript-file-encoding` option, as the following example shows:

```
actionscript-file-encoding=Shift_JIS
```

Editing application settings

The mxmlc compiler includes options to set the application's frame rate, size, and script limits. By setting them when you compile your application, you do not need to edit the HTML wrapper or the application's MXML file. You can override these settings by using properties of the `<s:Application>` tag or properties of the `<object>` and `<embed>` tags in the HTML wrapper.

The following command-line example sets default application properties:

```
mxmlc -default-size 240 240 -default-frame-rate=24 -default-script-limits 5000 10 --
c:/myfiles/flex/misc/MainApp.mxml
```

For more information about the Application class, see "Application containers" on page 393.

For more information about the HTML wrapper, see "Creating a wrapper" on page 2552.

Using SWC files

Often, you use SWC files when compiling MXML files. SWC files can provide themes, components, or other helper files. You typically specify SWC files used by the application by using the `library-path` option.

The following example compiles the RotationApplication.mxml file into the RotationApplication.swf file:

```
mxmlc -library-path+=c:/mylibraries/MyButtonSwc.swc c:/myfiles/comptest/testRotation.mxml
```

In a configuration file, this appears as follows:

```
<compiler>
    <library-path>
        <path-element>libs</path-element>
        <path-element>libs/player</path-element>
        <path-
element>libs/player/{targetPlayerMajorVersion}.{targetPlayerMinorVersion}</path-element>
        <path-element>locale/{locale}</path-element>
        <path-element>c:/mylibraries/MyButtonSwc.swc</path-element>
    </library-path>
</compiler>
```

About incremental compilation

You can use incremental compilation to decrease the time it takes to compile an application or component library with the application compilers. When incremental compilation is enabled, the compiler inspects changes to the bytecode between revisions and only recompiles the section of bytecode that has changed. These sections of bytecode are also referred to as *compilation units*.

You enable incremental compilation by setting the `incremental` option to `true`, as the following example shows:

```
mxmlc -incremental=true MyApp.mxml
```

Incremental compilation means that the compiler inspects your code, determines which parts of the application are affected by your changes, and only recompiles the newer classes and assets. The Flex compilers generate many compilation units that do not change between compilation cycles. It is possible that when you change one part of your application, the change might not have any effect on the bytecode of another.

As part of the incremental compilation process, the compiler generates a cache file that lists the compilation units of your application and information on your application's structure. This file is located in the same directory as the file that you are compiling. For example, if my application is called MyApp.mxml, the cache file is called MyApp.mxml.cache. This file helps the compiler determine which parts of your application must be recompiled. One way to force a complete recompile is to delete the cache file from the directory.

Incremental compilation can help reduce compile time on small applications, but you achieve the biggest gains on larger applications.

The default value of the `incremental` compiler option is `true` for the Flash Builder application compiler. For the mxmlc command-line compiler, the default is `false`.

Using conditional compilation

To include or exclude blocks of code for certain builds, you can use conditional compilation. The mxmlc compiler lets you pass the values of constants to the application at compile time. Commonly, you pass a Boolean that is used to include or exclude a block of code such as debugging or instrumentation code. The following example conditionalizes a block of code by using an inline constant Boolean:

```
CONFIG::debugging {
    // Execute debugging code here.
}
```

To pass constants, you use the `compiler.define` compiler option. The constant can be a Boolean, String, or Number, or an expression that can be evaluated in ActionScript at compile time. This constant is then accessible within the application source code as a global constant.

To use the `define` option, you define a configuration namespace for the constant, a variable name, and a value using the following syntax:

```
-define=namespace::variable_name,value
```

The configuration namespace can be anything you want. The following example defines the constant `debugging` with a value of `true` in the `CONFIG` namespace:

```
-define=CONFIG::debugging,true
```

You use the `+=` operator rather than the `=` operator to append definitions on the command line to the definitions set in the configuration file. Use the `=` operator to replace the definitions in the configuration file with the definitions on the command line.

To set the values of multiple constants on the command-line, use the `define` option more than once; for example:

```
mxmlc -define+=CONFIG::debugging,true -define+=CONFIG::release,false MyApp.mxml
```

To set the value of these constants in the flex-config.xml file, rather than on the command line, you write this as the following example shows:

```
<compiler>
    <define append="true">
        <name>CONFIG::debugging</name>
        <value>true</value>
    </define>
    <define append="true">
        <name>CONFIG::release</name>
        <value>false</value>
    </define>
</compiler>
```

If you set the same definition in a configuration file and on the command line, the value on the command line takes precedence.

In a Flex Ant task, you can set constants with a `define` element, as the following example shows:

```
<mxmlc ... >
    <define name="CONFIG::debugging" value="true"/>
    <define name="CONFIG::release" value="false"/>
</mxmlc>
```

Using inline constants

You can use inline constants in ActionScript. Boolean values can be used to conditionalize top-level definitions of functions, classes, and variables, in much the same way you would use an `#IFDEF` preprocessor command in C or C++. You cannot use constant Boolean values to conditionalize metadata or `import` statements.

The following example conditionalizes which class definition the compiler uses when compiling the application:

```
// compilers/MyButton.as
package  {
    import mx.controls.Button;
    CONFIG::debugging
    public class MyButton extends Button {
        public function MyButton() {
            super();
            // Set the label text to blue.
            setStyle("color", 0x0000FF);
        }
    }
    CONFIG::release
    public class MyButton extends Button {
        public function MyButton() {
            super();
            // Set the label text to red.
            setStyle("color", 0xFF0000);
        }
    }
}
```

You can also pass Strings and Numbers to the application and use them as inline constants, in the same way you might use a `#define` directive in C or C++. For example, if you pass a value named `NAMES::Company`, you replace it with a constant in your application by using an ActionScript statement like the following example shows:

```
private static const companyName:String = NAMES::Company;
```

Passing expressions

You can pass expressions that can be evaluated at compile time as the value of the constant. The following example evaluates to false:

```
-define+=CONFIG::myConst,"1 > 2"
```

The following example evaluates to 3:

```
-define+=CONFIG::myConst,"4 - 1"
```

Expressions can contain constants and other configuration values; for example:

```
-define+=CONFIG::bool2,false -define+=CONFIG::and1,"CONFIG::bool2 && false"
```

In general, you should wrap all constants with double quotes, so that the mxmlc compiler correctly parses them as a single argument.

Passing Strings

When passing Strings, you must add extra quotes to ensure that the compiler parses them correctly.

To define Strings on the command-line, you must surround them with double-quotes, *and* either escape-quote them (`"\"Adobe Systems\""` or `"\\x\\x`) or single-quote them (`"'Adobe Systems'"`).

The following example shows both methods of including Strings on the command line:

```
-define+=NAMES::Company,"'Adobe Systems'" -define+=NAMES::Ticker,"\"ADBE\""
```

To define Strings in configuration files, you must surround them with single or double quotes; for example:

```
<define>
    <name>NAMES::Company</name>
    <value>'Adobe Systems'</value>
</define>
<define>
    <name>NAMES::Ticker</name>
    <value>"ADBE"</value>
</define>
```

To pass empty Strings on the command line, use single quotes surrounded by double quotes, as the following example shows:

```
-define+=CONFIG::debugging,"''"
```

To pass empty Strings in configuration files, use double quotes (`""`) or single quotes (`' '`).

Using compc, the component compiler

You use the component compiler to generate a SWC file from component source files and other asset files such as images and style sheets.

To use the component compiler with Flex SDK, you use the compc command-line utility. In Flash Builder, you use the compc component compiler by building a new Flex Library Project. Some of the Flex SDK command-line options have equivalents in the Flash Builder environment. You use the tabs in the Flex Library Build Path dialog box to add classes, libraries, and other resources to the SWC file.

Xavi Beumala has an excellent blog entry on creating libraries with compc.

About the component compiler options

The component compiler options let you define settings such as the classes, resources, and namespaces to include in the resulting SWC file.

The component compiler can take most of the application compiler options, and the options described in this section. For a description of the application compiler options, see “About the application compiler options” on page 2175. Application compiler options that do not apply to the component compiler include the metadata options (such as `contributor`, `title`, and `date`), default application options (such as `default-frame-rate`), `locale`, `debug-password`, and `theme`.

The component compiler has compiler options that the application compilers do not have. The following table describes the component compiler options that are not used by the application compilers:

Option	Description
`compute-digest=true|false`	Writes a digest to the catalog.xml of a library. Use this when the library will be used as a cross-domain RSL or when you want to enforce the versioning of RSLs. The default value is true. For more information about RSLs, see "Runtime Shared Libraries" on page 253.
`directory=false|true`	Outputs the SWC file in an open directory format rather than a SWC file. You use this option with the `output` option to specify a destination directory, as the following example shows: `compc -directory=true -output=destination_directory` You typically use this option when you create RSLs because you must extract the library.swf file from the SWC file before deployment. For more information, see "Runtime Shared Libraries" on page 253. The default value is false.
`include-classes` *`class [...]`*	Specifies classes to include in the SWC file. You provide the class name (for example, MyClass) rather than the file name (for example, MyClass.as) to the file for this option. As a result, all classes specified with this option must be in the compiler's source path. You specify this by using the `source-path` compiler option. You can use packaged and unpackaged classes. To use components in namespaces, use the `include-namespaces` option. If the components are in packages, ensure that you use dot-notation rather than slashes to separate package levels. This is the default option for the component compiler.
`include-file` *`name path [...]`*	Adds the file to the SWC file. This option does not embed files inside the library.swf file. This is useful for adding graphics files, where you want to add non-compiled files that can be referenced in a style sheet or embedded as assets in MXML files. If you add a stylesheet that references compiled resources such as programmatic skins, use the `include-stylesheet` option. If you use the `[Embed]` syntax to add a resource to your application, you are not required to use this option to also link it into the SWC file. For more information, see "Adding nonsource classes" on page 2202.
`include-lookup-only=false|true`	If `true`, only manifest entries with `lookupOnly=true` are included in the SWC catalog. The default value is `false`. This is an advanced option.

Option	**Description**
`include-namespaces` *`uri [...]`*	Specifies namespace-style components in the SWC file. You specify a list of URIs to include in the SWC file. The uri argument must already be defined with the `namespace` option. To use components in packages, use the `include-classes` option.
`include-sources` *`path-element`*	Specifies classes or directories to add to the SWC file. When specifying classes, you specify the path to the class file (for example, MyClass.as) rather than the class name itself (for example, MyClass). This lets you add classes to the SWC file that are not in the source path. In general, though, use the `include-classes` option, which lets you add classes that are in the source path. If you specify a directory, this option includes all files with an MXML or AS extension, and ignores all other files. If you use this option to include MXML components that are in a non-default package, you must include the source folder in the source path.
`include-stylesheet` *`namepath [...]`*	Specifies stylesheets to add to the SWC file. This option compiles classes that are referenced by the stylesheet before including the stylesheet in the SWC file. You do not need to use this option for all stylesheets; only stylesheets that reference assets that need to be compiled such as programmatic skins or other class files. If your stylesheet does not reference compiled assets, you can use the `include-file` option. This option does not compile the stylesheet into a SWF file before including it in the SWC file. You compile a CSS file into a SWF file when you want to load it at run time.

On the command line, you cannot point the compc utility to a single directory and have it compile all components and source files in that directory. You must specify each source file to compile.

If you have a large set of components in a namespace to include in a SWC file, you can use a manifest file to avoid having to type an unwieldy compc command. For information on creating manifest files, see “About manifest files” on page 2206.

The following sections describe common scenarios where you could use the compc command-line compiler. You can apply the techniques described here to compiling SWC files in Flash Builder with the Flex Compiler.

Compiling stand-alone components and classes

In many cases, you have one or more components that you use in your applications, but you do not have them in a package structure. You want to be able to use them in the generic namespace (“*”) inside your applications. In these cases, you use the `include-classes` option to add the components to your SWC file.

The following command-line example compiles two MXML components, Rotation.as and RotationInstance.as, into a single SWC file:

```
compc -source-path .
    -output c:/jrun4/servers/flex/WEB-INF/flex/user_classes/RotationClasses.swc
    -include-classes rotationClasses.Rotation rotationClasses.RotationInstance
```

The rotationClasses directory is a subdirectory of the current directory, which is in the source path. The SWC file is output to the user_classes directory, so the new components require no additional configuration to be used in a server environment.

You use the `include-classes` option to add components to the SWC file. You use just the class name of the component and not the full filename (for example, MyComponent rather than MyComponent.as). Use dot-notation to specify the location of the component in the package structure.

You also set the `source-path` to the current directory or a directory from which the component directory can be determined.

You can also add the framework.swc and framework_rb.swc files to the `library-path` option. This addition is not always required if the compiler can determine the location of these SWC files on its own. However, if you move the compiler utility out of the default location relative to the frameworks files, you must add it to the library path.

The previous command-line example appears in a configuration file as follows:

```
<compiler>
    <source-path>
        <path-element>.</path-element>
    </source-path>
    <output>
        c:/jrun4/servers/flex/WEB-INF/flex/user_classes/RotationClasses.swc
    </output>
</compiler>
<include-classes>
    <class>rotationClasses.Rotation</class>
    <class>rotationClasses.RotationInstance</class>
</include-classes>
```

To use components that are not in a package in an application, you must declare a namespace that includes the directory structure of the components. The following example declares a namespace for the components compiled in the previous example:

```
<?xml version="1.0"?>
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmln:local="rotationclasses.*">
    ...
    <local:Rotation id="Rotate75" angleFrom="0" angleTo="75" duration="100"/>
    ...
</s:Application>
```

To use the generic namespace of "*" rather than a namespace that includes a component's directory structure, you can include the directory in the `source-path` as the following command-line example shows:

```
compc -source-path . c:/flexdeploy/comps/rotationClasses
    -output c:/jrun4/servers/flex/WEB-INF/flex/user_classes/RotationComps.swc
    -include-classes Rotation RotationInstance
```

Then, you can specify the namespace in your application as:

```
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmln:local="*">
```

You are not required to use the directory name in the `include-classes` option if you add the directory to the source path.

These options appear in a configuration file, as the following example shows:

```
<compiler>
    <source-path>
        <path-element>.</path-element>
        <path-element>c:/flexdeploy/comps/rotationClasses</path-element>
    </source-path>
    <output>c:/jrun4/servers/flex/WEB-INF/flex/user_classes/RotationComps.swc</output>
</compiler>
<include-classes>
    <class>Rotation</class>
    <class>RotationInstance</class>
<include-classes>
```

This example assumes that the components are not in a named package. For information about compiling packaged components, see “Compiling components in packages” on page 2198.

Compiling components in packages

Some components are created inside packages or directory structures so that they can be logically grouped and separated from application code. As a result, packaged components can have a namespace declaration that includes the package name or a unique namespace identifier that references their location within a package.

You compile packaged components similarly to how you compile components that are not in packages. The only difference is that you must use the package name in the namespace declaration, regardless of how you compiled the SWC file, and that package name uses dot-notation instead of slashes. You must be sure to specify the location of the classes in the `source-path`.

In the following command-line example, the MyButton component is in the mypackage package:

```
compc -source-path . c:/flexdeploy/comps/mypackage/
    -output c:/jrun4/servers/flex/WEB-INF/flex/user_classes/MyButtonComp.swc
    -include-classes mypackage.MyButton
```

These options appear in a configuration file, as the following example shows:

```
<compiler>
    <source-path>
        <path-element>.</path-element>
        <path-element>c:/flexdeploy/comps/mypackage/</path-element>
    </source-path>
    <output>
        c:/jrun4/servers/flex/WEB-INF/flex/user_classes/MyButtonComp.swc
    </output>
</compiler>
<include-classes>
    <class>mypackage.MyButton</class>
<include-classes>
```

To access the MyButton class in your application, you must declare a namespace that includes its package; for example:

```
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:mine="mypackage.*">
```

You can use the compc compiler to compile components from multiple packages into a single SWC file. In the following command-line example, the MyButton control is in the mypackage package, and the CustomComboBox control is in the acme package:

```
compc -source-path .
    -output c:/jrun4/servers/flex/WEB-INF/flex/user_classes/CustomComps.swc
    -include-classes mypackage.MyButton
    acme.CustomComboBox
```

You then define each package as a separate namespace in your MXML application:

```
<?xml version="1.0"?>
<s:Application <s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:mine="mypackage.*"
    xmlns:acme="acme.*">
    <mine:MyButton/>
    <acme:CustomComboBox/>
</s:Application>
```

Compiling components using namespaces

When you have many components in one or more packages that you want to add to a SWC file and want to reference from an MXML file through a custom namespace, you can list them in a manifest file, then reference that manifest file on the command line. Also, you can specify a namespace for that component or define multiple manifest files and, therefore, specify multiple namespaces to compile into a single SWC file.

When you use manifest files to define the components in your SWC file, you specify the namespace that the components use in your applications. You can compile all the components from one or more packages into a single SWC file. If you have more than one package, you can set it up so that all packages use a single namespace or so that each package has an individual namespace.

Components in a single namespace

In the manifest file, you define which components are in a namespace. The following sample manifest file defines two components to be included in the namespace:

```
<?xml version="1.0"?>
<!-- SimpleManifest.xml -->
<componentPackage>
    <component id="MyButton" class="MyButton"/>
    <component id="MyOtherButton" class="MyOtherButton"/>
</componentPackage>
```

The manifest file can contain references to any number of components in a namespace. The `class` option is the full class name (including package) of the class. The `id` property is optional, but you can use it to define the MXML tag interface that you use in your applications. If the compiler cannot find one or more files listed in the manifest, it throws an error. For more information on using manifest files, see “About manifest files” on page 2206.

On the command line, you define the namespace with the `namespace` option; for example:

```
-namespace http://mynamespace SimpleManifest.xml
```

Next, you target the defined namespace for inclusion in the SWC file with the `include-namespaces` option; for example:

```
-include-namespaces http://mynamespace
```

The `namespace` option matches a namespace (such as “http://ns.adobe.com/mxml/2009”) with a manifest file. The `include-namespaces` option instructs compc to include all the components listed in that namespace’s manifest file in the SWC file.

After you define the manifest file, you can compile the SWC file. The following command-line example compiles the components into the “http://mynamespace” namespace:

```
compc -source-path .
    -output c:/jrun4/servers/flex/WEB-INF/flex/user_classes/MyButtons.swc
    -namespace http://mynamespace SimpleManifest.xml
    -include-namespaces http://mynamespace
```

In a configuration file, these options appear as the following example shows:

```
<compiler>
    <source-path>
        <path-element>.</path-element>
    </source-path>
    <output>c:/jrun4/servers/flex/WEB-INF/flex/user_classes/MyButtons.swc</output>
    <namespaces>
        <namespace>
            <uri>http://mynamespace</uri>
            <manifest>SimpleManifest.xml</manifest>
        </namespace>
    </namespaces>
</compiler>
<include-namespaces>
    <uri>http://mynamespace</uri>
<include-namespaces>
```

In your application, you can access the components by defining the new namespace in the `<s:Application>` tag, as the following example shows:

```
<?xml version="1.0"?>
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:a="http://mynamespace">
    <a:MyButton/>
    <a:MyOtherButton/>
</s:Application>
```

Components in multiple namespaces

You can use the compc compiler to compile components that use multiple namespaces into a SWC file. Each namespace must have its own manifest file.

The following command-line example compiles components defined in the AcmeManifest.xml and SimpleManifest.xml manifest files:

```
compc -source-path .
    -output c:/jrun4/servers/flex/WEB-INF/flex/user_classes/MyButtons.swc
    -namespace http://acme2009 AcmeManifest.xml
    -namespace http://mynamespace SimpleManifest.xml
    -include-namespaces http://acme2009 http://mynamespace
```

In this case, all components in both the http://mynamespace and http://acme2009 namespaces are targeted and included in the output SWC file.

In a configuration file, these options appear as the following example shows:

```
<compiler>
    <source-path>
        <path-element>.</path-element>
    </source-path>
    <output>c:/jrun4/servers/flex/flex/WEB-INF/flex/user_classes/MyButtons.swc</output>
    <namespaces>
        <namespace>
            <uri>http://acme2009</uri>
            <manifest>AcmeManifest.xml</manifest>
        </namespace>
        <namespace>
            <uri>http://mynamespace</uri>
            <manifest>SimpleManifest.xml</manifest>
        </namespace>
    </namespaces>
</compiler>
<include-namespaces>
    <uri>http://acme2009</uri>
    <uri>http://mynamespace</uri>
<include-namespaces>
```

In your MXML application, you define both namespaces separately:

```
<?xml version="1.0"?>
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:simple="http://mynamespace"
    xmlns:acme="http://acme2009">
    <simple:SimpleComponent/>
    <acme:AcmeComponent/>
</s:Application>
```

You are not required to include all namespaces that you define as target namespaces. You can define multiple namespaces, but use only one target namespace. You might do this if some components use other components that are not directly exposed as MXML tags. You cannot then directly access the components in the unused namespace, however.

The following command line example defines two namespaces, http://acme2009 and http://mynamespace, but only includes one as a namespace target:

```
compc -source-path .
    -output c:/jrun4/servers/flex/flex/WEB-INF/flex/user_classes/MyButtons.swc
    -namespace http://acme2009 AcmeManifest.xml
    -namespace http://mynamespace SimpleManifest.xml
    -include-namespaces http://mynamespace
```

Adding utility classes

You can add any classes that you want to use in your applications to a SWC file. These classes do not have to be components, but are often files that components use. They are classes that might be used at run time and, therefore, are not checked by the compiler. For example, your components might use a library of classes that perform mathematical functions, or use a custom logging utility. This documentation refers to these classes as *utility classes*. Utility classes are not exposed as MXML tags.

To add utility classes to a SWC file, you use the `include-sources` option. This option lets you specify a path to a class file rather than the class name, or specify an entire directory of classes.

The following command-line example adds the FV_calc.as and FV_format.as utility classes to the SWC file:

```
compc -source-path .
    -output c:/jrun4/servers/flex/WEB-INF/flex/user_classes/MySwc.swc
    -include-sources FV_classes/FV_format.as FV_classes/FV_calc.as
    -include-classes asbutton.MyButton
```

In a configuration file, these options appear as the following example shows:

```
<compiler>
    <source-path>
        <path-element>.</path-element>
    </source-path>
    <output>c:/jrun4/servers/flex/flex/WEB-INF/flex/user_classes/MySwc.swc</output>
</compiler>
<include-classes>
    <class>asbutton.MyButton</class>
</include-classes>
<include-sources>
    <path-element>FV_classes/FV_format.as</path-element>
    <path-element>FV_classes/FV_calc.as</path-element>
<include-sources>
```

When specifying files with the `include-sources` option, you must give the full filename (for example, FV_calc.as instead of FV_calc) because the file is not a component. If you use this option to include MXML components that are in a non-default package, you must include the source folder in the source path.

You can also provide a directory name to the `include-sources` option. In this case, the compiler includes all files with an MXML or AS extension, and ignores all other files.

Classes that you add with the `include-sources` option can be accessed from the generic namespace in your applications. To use them, you need to add the following code in your application tag:

```
xmlns:local="*"
```

You can then use them as tags; for example:

```
<local:FV_calc id="calc" rate=".0125" nper="12" pmt="100" pv="0" type="1"/>
```

Adding nonsource classes

You often include noncompiled (or nonsource) files with your applications. A *nonsource* file is a class or resource (such as a style sheet or graphic) that is not compiled but is included in the SWC file for other classes to use. For example, a font file that you embed or a set of images that you use as graphical skins in a component's style sheet should not be compiled but should be included in the SWC file. These are classes that you typically do not use the `[Embed]` syntax to link in to your application.

Use the `include-file` option to define nonsource files in a SWC file.

The syntax for the `include-file` option is as follows:

```
-include-file name path
```

The *name* argument is the name used to reference the embedded file in your applications. The *path* argument is the current path to the file in the file system.

When you use the `include-file` option, you specify both a name and a filepath, as the following example shows:

```
compc -include-file logo.gif c:/images/logo/logo1.gif ...
```

In a configuration file, these options appear as the following example shows:

```
<compiler>
    <output>c:/jrun4/servers/flex/flex/WEB-INF/flex/user_classes/Combo.swc</output>
</compiler>
<include-file>
    <name>logo.gif</name>
    <path>c:/images/logo/logo1.gif</path>
</include-file>
<include-classes>
    <class>asbutton.MyButton</class>
<include-classes>
```

Each name that you assign to a resource must be unique because the name becomes a global variable.

You cannot specify a list of files with the `include-file` option. So, you must add a separate `include-file` option for each file that you include, as the following command-line example shows:

```
compc -include-file file1.jpg ../images/file1.jpg -include-file file2.jpg ../images/file2.jpg
-- -output MyFile.swc
```

If you want to add many resources to the SWC file, consider using a configuration file rather than listing all the resources on the command line. For an example of a configuration file that includes multiple resources in a SWC file, see “Styles and themes” on page 1492.

In general, specify a file extension for files that you include with the `include-file` option. In some cases, omitting the file extension can lead to a loss of functionality. For example, if you include a CSS file in a theme SWC file, you must set the name to be *.css. When Flex examines the SWC file, it applies all CSS files in that SWC file to the application. CSS files without the CSS extension are ignored.

Creating themes

You can use the `include-file` and `include-classes` options to add skin files and style sheets to a SWC file. The SWC file can then be used as a theme. For more information about using themes in applications, see “Styles and themes” on page 1492.

Viewing errors and warnings

You can use the compiler options to specify what level of warnings and errors to view. Also, you can set levels of logging with the compiler options.

Viewing warnings and errors

There are several options that let you customize the level of warnings and errors that are displayed by the Flex compilers, including the following:

- `show-actionscript-warnings`
- `show-binding-warnings`
- `show-invalid-css-property-warnings`
- `show-shadowed-device-font-warnings`
- `show-unused-type-selector-warnings`
- `strict`
- `warnings`

To disable all warnings, set the `warnings` option to `false`.

The `show-actionscript-warnings` option displays compiler warnings for the following situations:

1. Situations that are probably not what the developer intended, but are still legal; for example:

   ```
   if (a = 10)                 // Did you really want '==' instead of '='?
   if (b == NaN)               // Any comparison with NaN is always false.
   var b;                      // Missing type declaration.
   ```

2. Usage of deprecated or removed ActionScript 2.0 APIs.
3. Situations where APIs behave differently in ActionScript 2.0 than in ActionScript 3.0.

You can customize the types of warnings displayed by using options that begin with *warn* (for example, `warn-constructor-return-values` and `warn-bad-type-cast`). A complete list of warnings are available in the advanced command-line help or in the flex-config.xml file.

The `strict` option enforces typing and reports run-time verifier errors at compile time. This option assumes that definitions are not dynamically redefined at run time, so these checks can be made at compile time. It displays errors for conditions such as undefined references, const and private violations, argument mismatches, and type checking.

The `show-binding-warnings` option displays warnings when Flash Player cannot detect changes to bound properties.

About deprecation

In some cases, Flex functionality has been deprecated. Deprecated features and properties have the following characteristics:

- Generate compiler warnings.
- Continue to work in Flex 4.x.
- Will be removed from the product in a future major release.

The command-line compilers report deprecation warnings by default. You can suppress deprecation warnings by setting the `show-deprecation-warnings` option to `false`.

In some cases, deprecated functionality does not work as expected unless you instruct the compiler to use an earlier version of the compiler with the `compatibility-version` compiler argument. For example, to use functionality that was deprecated since Flex 3, you could use the following command-line compiler argument:

```
-compatibility-version=3.0.0
```

Possible values for this compiler argument are defined as constants in the FlexVersion class. For more information on using this compiler argument, see “Backward compatibility” on page 2239.

You can use the `[Deprecated]` metadata tag to deprecate your own classes and class elements. For more information, see “Deprecated metadata tag” on page 2383.

About logging

Errors and warnings are reported differently, depending on which compiler you are using.

The mxmlc and compc command-line compilers send error and warning messages to the standard output. You can redirect this output by using the redirector (>).

Flash Builder displays error and warning messages in the Problems tab.

About SWC files

A *SWC* file is an archive file, sometimes also referred to as a class library, for components and other assets. SWC files contain a SWF file and a catalog.xml file, in addition to properties files and other uncompiled assets such as CSS files. The SWF file implements the compiled component or group of components and includes embedded resources as symbols. An application extracts the SWF file from a SWC file. It uses the SWF file's contents when the application refers to resources in that SWC file. The catalog.xml file lists of the contents of the component package and its individual components.

In most cases, the symbols defined in the SWF file that are referenced by the application are embedded in the application at compile-time. This is known as static linking. The application compiler only includes those classes that are used by your application, and dependent classes, in the final SWF file.

You can also dynamically link the contents of SWC files. Dynamic linking is when the entire SWF file is loaded at run time. To achieve dynamic linking of the SWF file, you must use the SWC file as a Runtime Shared Library, or RSL. For more information, see "Runtime Shared Libraries" on page 253.

SWC files make it easy to exchange components and other assets among Flex developers. You need only exchange a single file, rather than the MXML or ActionScript files and images and other resource files. The SWF file in a SWC file is compiled, which means that the code is loaded efficiently and it is hidden from casual view. Also, compiling a component as a SWC file can make namespace allocation an easier process.

You can package and expand SWC files with tools that support the PKZip archive format, such as WinZip or jar. However, do not manually change the contents of a SWC file, and do not try to run the SWF file that is in a SWC file in Flash Player.

You typically create SWC files by using compc, the command-line component compiler.

You can also save SWC files as open directories rather than archived files. This gives you easier access to the contents of the SWC file. You create an open directory SWC by setting the `directory` option to `true`. This is typically only used when you create a custom RSL because RSLs require that you deploy the SWF file with your application.

The properties files inside SWC files are uncompiled text files in UTF-8 format. They are used as resource bundles for localization of applications. Within the SWC file, they are stored in the /locale/*locale_string* directory, where `locale_string` is something like en_US or fr_FR. For more information, see "Localization" on page 2055.

Distributing SWC files

After you generate a SWC file, you can use it in your applications.

You can also copy SWC files to a directory specified by the `library-path` compiler option. You must store SWC files at the top level of the user_classes directory or the directory specified by the `library-path`. You cannot store SWC files in subdirectories.

To use a SWC file when compiling components or applications from the command line or from within Flash Builder, you specify the location of the SWC file with the `library-path` compiler option.

***Note:** Do not store custom components or classes in the flex_root/WEB-INF/flex/libs directory. This directory is for Adobe classes and components.*

Using components in SWC files

If a component in a SWC file does not have a namespace, you can add a generic namespace identifier in your `<s:Application>` tag to use the component, as the following example shows:

```
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:a="*">
```

If the component has a package name as part of its namespace, you must do one of the following:

1 Add the package name to the namespace declaration in the `<s:Application>` tag; for example:

```
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:but="mycomponents.*">
```

2 Create a manifest file and recompile the SWC file. You pass the manifest file to the compc compiler by using the `namespace` option. In the `<s:Application>` tag, you specify only the unique namespace URI that you used with compc. For more information on specifying a namespace for the component, see “Compiling components using namespaces” on page 2199.

About manifest files

Manifest files map a component namespace to class names. They define the package names that the components used before being compiled into a SWC file. They are not required when compiling SWC files, but they can help keep your source files organized.

Manifest files use the following syntax:

```
<?xml version="1.0"?>
<componentPackage>
    <component id="component_name" class="component_class"/>
    [...]
</componentPackage>
```

For example:

```
<?xml version="1.0"?>
<componentPackage>
    <component id="MyButton" class="package1.MyButton"/>
    <component id="MyOtherButton" class="package2.MyOtherButton"/>
</componentPackage>
```

In a manifest file, the `id` property of each `<component>` tag must be unique. It is the name you use for the tag in your applications. For example, you define the `id` as `MyButton` in the manifest file:

```
<component id="MyButton" class="asbutton.MyButton"/>
```

In your application, you use `MyButton` as the tag name:

```
<local:MyButton label="Click Me"/>
```

The `id` property in the manifest file entry is optional. If you omit it, you can use the class name as the tag. This is useful if you have two classes with the same name in different packages. In this case, you use the manifest to define the tags, as the following example shows:

```
<?xml version="1.0"?>
<componentPackage>
    <component id="BoringButton" class="boring.MyButton"/>
    <component id="GreatButton" class="great.MyButton"/>
</componentPackage>
```

Some SWC files consist of multiple components from different packages, so compc includes a manifest file with your SWC file in those cases to prevent compiler errors.

When compiling the SWC file, you specify the manifest file by using the `namespace` and the `include-namespaces` options. You define the namespace and its contents with the namespace option:

```
-namespace http://mynamespace mymanifest.xml
```

Then you identify that namespace's contents for inclusion in the SWC file:

```
-include-namespaces http://mynamespace
```

Using fcsh, the Flex compiler shell

The fcsh (Flex Compiler Shell) utility provides a shell environment that you use to compile applications, modules, and component libraries. It works very similarly to the mxmlc and compc command line compilers, but it compiles faster than the mxmlc and compc command-line compilers. One reason is that by keeping everything in memory, fcsh eliminates the overhead of launching the JVM and loading the compiler classes. Another reason is that compilation results (for example, type information) can be kept in memory for subsequent compilations.

This utility is intended to improve the experience of users of the command-line compilers. If you are using Flash Builder, you do not need to use fcsh. The Flash Builder tool already uses the optimizations provided by fcsh.

For simple applications, fcsh might not be necessary. But for more complex applications that you compile frequently, you should experience a significant performance improvement over using the mxmlc and compc command-line compilers.

When you first compile an application with fcsh, you will not typically notice any difference in speed between the fcsh and the command-line compilers. This is because fcsh must load the application model and custom libraries into memory, just as the command-line compilers would. After that, however, each subsequent compilation uses the libraries in memory to compile. This reduces the amount of disk access that the compilers need to perform and should result in shorter compile times.

The fcsh tool is in the bin directory. For Unix and Mac OS, it is a shell script called fcsh. For Windows, it is fcsh.exe. You invoke it only from the command line. The Java settings are managed by the jvm.config file in the bin directory.

Using fcsh

You invoke fcsh from the command line. You can launch the utility either as an executable (Windows) or shell command (Unix/Linux/Mac).

1 Open a command prompt.

2 Navigate to the {*SDK_root*}/bin directory.

3 Enter `fcsh` at the command line. Your commands will now be executed within the fcsh environment. You will know this if your command prompt becomes `(fcsh)`.

Typically, you compile a simple application when you first launch fcsh; for example:

```
(fcsh) mxmlc c:/myfiles/MyApp.mxml
```

The fcsh utility returns a target id:

```
fcsh: Assigned 1 as the compile target id.
```

You can then refer to the target ids when using subsequent commands inside the fcsh utility. For example, to compile the previous application with incremental compilation:

```
(fcsh) compile 1
```

You can enter `help` in the fcsh shell to see a list of available options; for example:

```
(fcsh) help
```

You can enter `quit` in the fcsh shell to exit fcsh and return to the command prompt; for example:

```
(fcsh) quit
```

The following example shows that fcsh dramatically reduces compilation time when compiling the same application multiple times. The first compilation takes 8885 milliseconds. The second takes only 5140 milliseconds:

```
(fcsh) mxmlc -benchmark=true flexstore.mxml
    Total time: 8885ms
    Peak memory usage: 84 MB (Heap: 58, Non-Heap: 26)
(fcsh) mxmlc -benchmark=true flexstore.mxml
    Total time: 5140ms
    Peak memory usage: 84 MB (Heap: 57, Non-Heap: 27)
```

In addition, subsequent *full* compilations of the same application are much faster, as the following example shows:

```
> touch flexstore.mxml

(fcsh) compile 1
    Files changed: 1 Files affected: 0
    Total time: 933ms
    Peak memory usage: 88 MB (Heap: 62, Non-Heap: 26)
    flexstore.swf (522456 bytes)
    Total time: 1102ms
    Peak memory usage: 77 MB (Heap: 51, Non-Heap: 26)
(fcsh)
```

About fcsh commands

The following table describes the available fcsh commands:

Option	Description
`clear [`*id*`]`	Removes the target id(s) from memory but saves the target's *.cache file. If you enter this command without specifying an id argument, fcsh clears all target ids. For information about cache files, see “About incremental compilation” on page 2191.
`compile` *id*	Uses incremental compilation (without linking) to compile the specified id. This command uses the same arguments used in previous compilations. If you try to compile a target that has not changed, fcsh skips that target.
`compc` *arg1* `[...]`	Compiles SWC files from the specified sources. This command returns a target id that you can then pass to other fcsh options. The target ids are incremented by 1 for each new compilation. If you quit fcsh and then relaunch it, all targets are cleared and the ids start at 1 again. This command takes all the same arguments as the compc command-line compiler. For information about using compc, see “Using compc, the component compiler” on page 2194.
`help`	Lists commands. Commands not listed but also supported include `cp`, `mv`, `rm`, and `touch`.

Option	Description
`info [id]`	Displays compiler target information such as the source files and cache file name. If you do not specify a target id, fcsh prints information for all targets in reverse id order.
`mxmlc arg1 [...]`	Compiles and optimizes the target application or module using the mxmlc command-line compiler. This command returns a target id that you can then pass to other fcsh options. The target ids are incremented by 1 for each new compilation. If you quit fcsh and then relaunch it, all targets are cleared and the ids start at 1 again. This command takes all the same arguments as the mxmlc command-line compiler. For information about using mxmlc, see "Using mxmlc, the application compiler" on page 2174.
`quit`	Exits the fcsh utility. All data stored in memory is destroyed. When you relaunch fcsh, you cannot access targets that you created in a previous session.

The fcsh tool also supports the following commands:

- `cp`
- `mv`
- `rm`
- `touch`

Command-line debugger

If you encounter errors in your applications, you can use the debugging tools to set and manage breakpoints in your code; control application execution by suspending, resuming, and terminating the application; step into and over the code statements; select critical variables to watch; evaluate watch expressions while the application is running, and so on.

About debugging

Debugging Adobe® Flex® applications can be as simple as enabling `trace()` statements or as complex as stepping into an application's source files and running the code, one line at a time. The Adobe® Flash® Builder™ debugger and the command-line debugger, fdb, let you step through and debug the files used by your Flex applications.

To debug a Flex application, you must generate a debug SWF file. This is a SWF file with debug information in it. You then connect fdb to the debugger version of Adobe® Flash® Player that is running the debug SWF file.

The debugger is an agent that communicates with the application that is running in Flash Player. It connects to your application with a local socket connection. As a result, you might have to disable anti-virus software to use it if your anti-virus software prevents socket communication. The debugger uses this connection to transfer information from the SWF file to the command line so that you can add breakpoints, inspect variables, and do other common debugging tasks. The port through which the debugger connects to your application is 7935. You cannot change this port.

This topic describes how to use the fdb command-line debugger. To use the Flash Builder debugger, see Debugging Tools in Flash Builder.

To use either debugger, you must install and configure the debugger version of Flash Player. To determine if you are running the debugger version or the standard version of Flash Player, open any Flex application in the player and right-click the mouse button. If you see the Show Redraw Regions option, you are running the debugger version of Flash Player. For more information about the debugger version of Flash Player, and how to detect which player you are running, see "Using the debugger version of Flash Player" on page 2223.

Using the command-line debugger

The fdb command-line debugger is located in the *flex_install_dir*/bin directory. To start fdb, open a command prompt, change to that directory, and enter **fdb**.

For a description of available commands, use the following command:

```
(fdb) help
```

For an overview of the fdb debugger, use the following command:

```
(fdb) tutorial
```

Generating debug SWF files

To debug a Flex application, you first generate a debug SWF file. Debug SWF files are similar to other application SWF files except that they contain debugging-specific information that the debugger and the debugger version of Flash Player use during debugging sessions. Debug SWF files are larger than non-debug SWF files, so generate them only when you are going to debug with them.

To generate the debug SWF file using the mxmlc command-line compiler, you set the `debug` option to `true`, either on the command line or in the flex-config.xml file. The following example sets the `debug` option to `true` on the command line:

```
mxmlc -debug=true myApp.mxml
```

Flash Builder generates debug SWF files by default in the project's /bin-debug directory. To generate a non-debug SWF file in Flash Builder, you use the Export Release Build feature. This generates a non-debug SWF file in the project's /bin-release directory. You can also manually set the `debug` compiler option to `false` in the Additional Compiler Arguments field of the project's properties.

You can use fdb in any gdb-compatible debugging environment. For example, you can use M-x gdb inside Emacs and specify fdb.exe as the gdb command.

Command-line debugger limitations

The command-line debugger supports debugging only at the ActionScript level and does not support the Flash timeline concept. The debugger also does not support adding breakpoints inside script snippets in MXML tags. You can set breakpoints on event handlers defined for MXML tags.

Flash Player may interact with a server. The debugger does not assist in debugging the server-side portion of the application, nor does it offer support for inspecting any of the IP transactions that take place from Flash Player to the server, and vice versa.

Command-line debugger shortcuts

You can open commands within the fdb debugger by using the fewest number of nonambiguous keystrokes. For example, to use the `print` command, you can type **p**, because no other command begins with that letter.

Using the default browser

When you debug an application in a web browser, fdb opens the player in the default browser. The *default browser* is the browser that opens when you open a web-specific file without specifying an application. You must also have the debugger version of Flash Player installed with this browser. If you do not have the debugger version of Flash Player, Flash displays an error indicating that your Flash Player does not support all fdb commands.

Your default browser might not be the first browser that you installed on your computer. For example, if you installed another web browser *after* installing Microsoft Internet Explorer, Internet Explorer might not be your default browser.

Determine your default browser

1 From the Windows toolbar, select Start.

2 Select Run and enter a URL in the Run dialog box. For example:

```
http://www.adobe.com
```

3 Click OK.

Windows opens the default browser or displays an error message indicating that there is no application configured to handle your request.

Set Internet Explorer 6.x as your default browser

1 Open the Internet Explorer application.

2 Select Tools > Internet Options.

3 Select the Programs tab.

4 Select the "Internet Explorer should check to see whether it is the default browser" option, and click OK.

The next time you start Internet Explorer, Internet Explorer prompts you to make it the default browser. If you are not prompted, Internet Explorer is already your default browser.

Set Firefox as your default browser

1 Open the Firefox application.

2 Select Tools > Options.

3 Select the General icon to view general settings.

4 Select the "Firefox should check to see if it is the default browser when starting" option, and click OK.

The next time you start FireFox, FireFox prompts you to make it the default browser. If you are not prompted, FireFox is already your default browser.

About the source files

Each application can have any number of ActionScript files. Some of the files that fdb steps into are external class files, and some are generated by the Flex compilers.

In general, Flex generates a single file that contains ActionScript statements used in `<fx:Script>` blocks in the root MXML file, and an additional file for each ActionScript class that the application uses. Flex generates many source files so that you can navigate the application from within the debugger.

To view a list of files that are used by the application you are debugging, use the `info files` command. For more information, see "Getting status" on page 2220.

The generated ActionScript class files are sometimes referred to as compilation units. For more information about compilation units, see "About incremental compilation" on page 2191.

Using RSLs when debugging

By default, you compile applications against the signed framework RSLs. The signed framework RSLs are optimized, which means that they do not include debugging information. Flash Builder automatically uses unoptimized debug RSLs when you launch the debugger. If you compile on the command line, however, and use the command line debugger, you must either disable RSLs or specify non-optimized RSLs to use. Otherwise, you will not be able to set break points or take advantage of other debugging functionality.

For more information, see "Example of using the framework RSLs on the command line" on page 266

Starting a debugging session

You start a debugging session by using the fdb command-line debugger. After you start a session, you typically type **continue** once before you set break points and perform other debugging tasks. This is because the first frame that suspends debugging occurs before the application has finished initialization.

For more information about which commands are available after you start a debugging session, see “Using the command-line debugger commands” on page 2213.

Starting a session with the stand-alone Flash Player

You can start a debugging session with the stand-alone debugger version of Flash Player. You do this by compiling the application into a SWF file, and then invoking the SWF file with the fdb command-line debugger. The fdb debugger opens the debugger version of the stand-alone Flash Player.

The debugger version of the stand-alone Flash Player runs as an independent application. It does not run within a web browser or other shell. The debugger version of the stand-alone Flash Player does not support any server requests, such as web services and dynamic SWF loading, so not all applications can be properly debugged inside the debugger version of the stand-alone Flash Player.

Debug with the stand-alone Flash Player

1 Compile the Flex application’s debug SWF file and set the `debug` option to `true`.

The following example compiles an application with the mxmlc command-line compiler:

```
mxmlc -debug=true myApp.mxml
```

You can also compile an application SWF file by using the Flash Builder compiler. For more information on Flex compilers, see “About the Flex compilers” on page 2164.

2 Find the *flex_install_dir*/bin directory. You installed the Flex application files to this directory.

3 Type **fdb** from the command line. The fdb prompt appears.

You can also open fdb with the JAR file, as the following example shows:

```
 java -jar ../lib/fdb.jar
```

4 Type **run** at the fdb prompt, followed by the path to the SWF file, as shown in the following example:

```
(fdb) run c:/myfiles/fonts/EmbedMyFont.swf
```

The fdb debugger starts the Flex application in the debugger version of the stand-alone Flash Player, and the `(fdb)` command prompt appears. You can also start a session by typing **fdb** *filename***.swf** at the command prompt, rather than by using the `run` command.

Starting a session in a browser

You can start a debugging session in a browser. This requires that you pre-compile the SWF file and are able to request it from a web server.

Debug in a browser

1 Compile the Flex application’s debug SWF file and set the `debug` option to `true`. The following example compiles an application with the mxmlc command-line compiler:

```
mxmlc -debug=true myApp.mxml
```

You can also compile an application SWF file by using the Flash Builder compiler. For more information on Flex compilers, see “About the Flex compilers” on page 2164.

2 Create an HTML wrapper that embeds this SWF file, if you have not already done so. For more information on creating a wrapper, see "Creating a wrapper" on page 2552.

3 Copy the SWF file and its wrapper files to your web server.

4 Find the *flex_install_dir*/bin directory. You installed the Flex application files to this directory.

5 Type **fdb** in the command line. The fdb prompt appears.

You can also open fdb with the JAR file, as the following example shows:

```
java -jar ../lib/fdb.jar
```

6 Type **run** at the fdb prompt:

```
(fdb) run
```

This instructs fdb to wait for a player to connect to it.

7 In your browser, request a wrapper that embeds the debug SWF file. Do not request the SWF file directly in a browser because some browsers do not allow you to run a SWF file directly.

Alternatively, you can type **run** *filename*.**html** at the command line, and fdb launches the browser for you. The filename should include the entire URL; for example:

```
(fdb) run http://localhost:8100/flexapps/index.html
```

Configuring the command-line debugger

You can configure the current session of the fdb command-line debugger using variables that exist entirely within fdb; they are not part of your application. The configuration variables are prefixed with $.

The following table describes the most common configuration variables used by fdb:

Variable	Description
`$invokegetters`	Set to 0 to prevent fdb from firing getter functions. The default value is `1` (enabled).
`$listsize`	Sets the number of lines to display with the list command. The default value is `10`.

To set the value of a configuration variable, you use the `set` command, as the following example shows:

```
(fdb) set $invokegetters = 0
```

For more information on using the `set` command, see "Changing data values" on page 2218.

Using the command-line debugger commands

The fdb command-line debugger includes commands that you use to debug and navigate your Flex application.

Running the debugger

The fdb debugger provides several commands for stepping through the debugged application's files. The following table summarizes those commands:

Command	**Description**
`continue`	Continues running the application.
`file [`*`file`*`]`	Specifies an application to be debugged, without starting it. This command does not cause the application to start; use the `run` command without an argument to start debugging the application.
`finish`	Continues until the function exits.
`next [`*`N`*`]`	Continues to the next source line in the application. The optional argument ***N*** means do this ***N*** times or until the program stops for some other reason.
`quit`	Exits from the debug session.
`run [`*`file`*`]`	Starts a debugging session by running the specified file. To run the application that the file command previously specified, execute the `run` command without any options. The `run` command starts the application in a browser or stand-alone Flash Player.
`step [`*`N`*`]`	Steps into the application. The optional argument ***N*** means do this ***N*** times or until the program stops for some other reason. These commands are nonblocking, which means that when they return, the client has at least begun the operation, but it has not necessarily finished it.

When you start a session, fdb stops execution before Flex renders the application on the screen. Use the `continue` command to get to the application's starting screen.

The following example shows a sample application after it starts:

```
(fdb) continue
[trace] ComboBase: y = undefined text_mc.bl = undefined
[trace] ComboBase: y = undefined text_mc.bl = undefined
[trace] ComboBase: y = undefined text_mc.bl = undefined
[trace] ComboBase: y = undefined text_mc.bl = undefined
[trace] ComboBase: y = undefined text_mc.bl = undefined
[trace] ComboBase: y = undefined text_mc.bl = undefined
[trace] ComboBase: y = undefined text_mc.bl = undefined
[trace] RadioButtonGroup.addInstance: instance = _level0._VBox0._Accordion0._For
m2._FormItem3._RadioButton1 data = undefined label = 2005
[trace] RadioButtonGroup.addInstance: instance = _level0._VBox0._Accordion0._For
m2._FormItem3._RadioButton2 data = undefined label = 2004
[trace] RadioButtonGroup.addInstance: instance = _level0._VBox0._Accordion0._For
m2._FormItem3._RadioButton3 data = undefined label = 2005
[trace] RadioButtonGroup.addInstance: instance = _level0._VBox0._Accordion0._For
m2._FormItem3._RadioButton4 data = undefined label = 2006
[trace] ComboBase: y = 0 text_mc.bl = 12
[trace] ComboBase: y = 0 text_mc.bl = 12
[trace] ComboBase: y = 0 text_mc.bl = 12
[trace] ComboBase: y = 0 text_mc.bl = 14
```

During the debugging session, you interact with the application in the debugger version of Flash Player. For example, if you select an item from the drop-down list, the debugger continues to output information to the command window:

```
[trace] SSL : ConfigureScrolling
[trace] SSP : 5 51 true 47
[trace] ComboBase: y = 0 text_mc.bl = 14
[trace] layoutChildren : bRowHeightChanged
[trace] >>SSL:layoutChildren
[trace] deltaRows 5
[trace] rowCount 5
[trace] <<SSL:layoutChildren
[trace] >>SSL:draw
[trace] bScrollChanged
[trace] SSL : ConfigureScrolling
[trace] SSP : 5 51 false 46
[trace] SSL Drawing Rows in UpdateControl 5
[trace] <<SSL:draw
```

You can store commonly used commands in a source file, and then load that file by using the `source` command. For more information, see “Accessing commands from a file” on page 2217.

Setting breakpoints

Setting breakpoints is a critical aspect of debugging any application. You can set breakpoints on any ActionScript code in your Flex application. You can set breakpoints on statements in any external ActionScript file, on ActionScript statements in an `<fx:Script>` tag, or on MXML tags that have event handler properties. In the following MXML code, `click` is an event handler property:

```
<s:Button click="ws.getWeather.send();"/>
```

Breakpoints are maintained from session to session. However, when you change the target file or quit fdb, breakpoints are lost.

The following table summarizes the commands for manipulating breakpoints with the ActionScript debugger:

Command	Description
`break [`***`args`***`]`	Sets a breakpoint at the specified line or function. The argument can be a line number or function name. With no arguments, the `break` command sets a breakpoint at the currently stopped line (not the currently listed line). If you specify a line number, fdb breaks at the start of code for that line. If you specify a function name, fdb breaks at the start of code for that function.
`clear [`***`args`***`]`	Clears a breakpoint at the specified line or function. The argument can be a line number or function name. If you specify a line number, fdb clears a breakpoint in that line. If you specify a function name, fdb clears a breakpoint at the beginning of that function. With no argument, fdb clears a breakpoint in the line that the selected frame is executing in. Compare the `delete` command, which clears breakpoints by number.
`commands [`*`breakpoint`*`]`	Sets commands to execute when the specified breakpoint is encountered. If you do not specify a breakpoint, the commands are applied to the last breakpoint.

Command	Description

`condition` *bp_num* [*expression*]	Specifies a condition that must be met to stop at the given breakpoint (identified by the breakpoint number). The fdb debugger evaluates expression when the breakpoint is reached. If the value is `true` or nonzero, fdb stops at the breakpoint. Otherwise, fdb ignores the breakpoint and continues execution.
	To remove the condition from the breakpoint, do not specify an expression.
	You can use conditional breakpoints to stop on all events of a particular type. For example, to stop on every `initialize` event, use the following commands:
	`(fdb) ` **`break UIEvent:dispatch`**
	`Breakpoint 18 at 0x16cb3: file UIEventDispatcher.as, line 190(fdb)`
	`condition 18 (eventObj.type == 'initialize')`

`delete` [***args***]	Deletes breakpoints. Specify one or more comma- or space-separated breakpoint numbers to delete those breakpoints. To delete all breakpoints, do not provide an argument.
`disable breakpoints` [*bp_num*]	Disables breakpoints. Specify one or more space-separated numbers as options to disable only those breakpoints.
`enable breakpoints` [*bp_num*]	Enables breakpoints that were previously disabled. Specify one or more space-separated numbers as options to enable only those breakpoints.

The following example sets a breakpoint on the `myFunc()` method, which is triggered when the user clicks a button:

```
(fdb) break myFunc
Breakpoint 1 at 0x401ef: file file1.mxml, line 5
(fdb) continue
Breakpoint 1, myFunc() at file1.mxml:5
    5ta1.text = "Clicked";
(fdb)
```

To see all breakpoints and their numbers, use the `info breakpoints` command. This will also tell you if a breakpoint is unresolved.

You can use the `commands` command to periodically print out values of objects and variables whenever fdb encounters a particular breakpoint. The following example prints out the value of ta1.text (referred to as `$1`), executes the `where` command, and then continues when it encounters the button's click handler breakpoint:

```
(fdb) commands 1
Type commands for when breakpoint 1 is hit, one per line.
End with a line saying just 'end'.
>print ta1.text
>where
>continue
>end
(fdb) cont
Breakpoint 1, myFunc() at file1.mxml:5
    5ta1.text = "Clicked";
$1 = ""
#0  [MovieClip 1].myFunc(event=undefined) at file1.mxml:5
#1  [MovieClip 1].handler(event=[Object 18127]) at file1.mxml:15
```

Breakpoints are not specific to a single SWF file. If you set a breakpoint in a file that is common to multiple SWF files, fdb applies the breakpoint to all SWF files.

For example, suppose you have four SWF files loaded and each of those SWF files contains the same version of an ActionScript file, view.as. To set a breakpoint in the `init()` function of the view.as file, you need to set only a single breakpoint in one of the view.as files. When fdb encounters any of the `init()` functions, it triggers the break.

By using the `watch` command, you can set watchpoints on variables. When that variable changes, the debugger halts. Watched variables can be any member variable, but cannot be dynamic, getters, or local variables. The `watch` command has the following syntax:

```
(fdb) watch variable_name
```

Accessing commands from a file

You can use the `source` command to read fdb commands from a file and execute them. This lets you write commands such as breakpoints once and use them repeatedly when debugging the same application in different sessions or across different applications.

The `source` command has the following syntax:

```
(fdb) source file
```

The value of file can be a filename for a file in the current working directory or an absolute path to a remote file. To determine the current working directory, use the `pwd` command.

The following examples read in the mycommands.txt file from different locations:

```
(fdb) source mycommands.txt
(fdb) source mydir\mycommands.txt
(fdb) source c:\mydir\mycommands.txt
```

Examining data values

The `print` command displays values of members such as variables, objects, and properties. This command excludes functions, static variables, constants, and inaccessible member variables (such as the members of an Array).

The `print` command uses the following syntax:

```
print [variable_name | object_name[.] | property]
```

The `print` command prints the value of the specified variable, object, or property. You can specify the `name` or `name.property` to narrow the results. If fdb can determine the type of the entity, fdb displays the type.

If you specify the `print` command on an object, fdb displays a numeric identifier for the object.

To list all the properties of an object, use trailing dot-notation syntax. The following example prints all the properties of the object myButton:

```
(fdb) print myButton.
```

To print the value of a single variable, use dot-notation syntax, as the following example shows:

```
(fdb) print myButton.label
```

Use the `what` command to view the context of a variable. The `what` command has the following syntax:

```
(fdb) what variable
```

Use the `display` command to add an expression to the autodisplay list. Every time debugging stops, fdb prints the list of expressions in the autodisplay list. The `display` command has the following syntax:

```
(fdb) display [expression]
```

The expression is the same as the arguments for the `print` command, as the following example shows:

```
(fdb) display myButton.color
```

To view all expressions on the autodisplay list, use the `infodisplay` command.

To remove an expression from the autodisplay list, use the `undisplay` command. The `undisplay` command has the following syntax:

```
(fdb) undisplay [list_num]
```

Use the `undisplay` command without an argument to remove all entries on the autodisplay list. Specify one or more `list_num` options separated by spaces to remove numbered entries from the autodisplay list.

You can temporarily disable autodisplay expressions by using the `disabledisplay` command. The `disable display` command has the following syntax:

```
(fdb) disable display [display_num]
```

Specify one or more space-separated numbers as options to disable only those entries in the autodisplay list.

To re-enable the display list, use the `enabledisplay` command, which has the same syntax as the `disable display` command.

Changing data values

You can use the `set` command to assign the value of a variable or a configuration variable. The `set` command has the following syntax:

```
set [expression]
```

Depending on the variable type, you use different syntax for the *expression*. The following example sets the variable `i` to the number 3:

```
(fdb) set i = 3
```

The following example sets the variable `employee.name` to the string `Reiner`:

```
(fdb) set employee.name = "Reiner"
```

The following example sets the convenience variable `$myVar` to the number `20`:

```
(fdb) set $myVar = 20
```

You use the `set` command to set the values of fdb configuration variables. For more information, see “Configuring the command-line debugger” on page 2213.

Viewing file contents

You use the `list` command to view lines of code in the ActionScript files. The `list` command uses the following syntax:

```
list [- | line_num[,line_num] | [file_name:]line_num | file_name[:line_num] |
[file_name:]function_name]
```

You use the `list` command to print the lines around the specified function or line of the current file. If you do not specify an argument, `list` prints 10 lines after or around the previous listing. If you specify a filename, but not a line number, `list` assumes line 1.

If you specify a single numeric argument, the `list` command lists 10 lines around that line. If you specify more than one comma-separated numeric argument, the `list` command displays lines between and including those line numbers.

To set the list location to where the execution is currently stopped, use the `home` command.

The following example lists code from line 10 to line 15:

```
(fdb) list 10, 15
```

If you specify a hyphen (-) in the previous example, the `list` command displays the 10 lines before a previous 10-line listing.

Specify a line number to list the lines around that line in the current file, as in the following example:

```
(fdb) list 10
```

Specify a filename followed by a line number to list the lines around that line in that file, as in the following example:

```
(fdb) list effects.mxml:10
```

Specify a function name to list the lines around the beginning of that function, as in the following example:

```
(fdb) list myFunction
```

Specify a filename followed by a function name to list the lines around the beginning of that function. This lets you distinguish among like-named static functions, as follows:

```
(fdb) list effects.mxml:myFunction
```

You can resolve ambiguous matches by extending the value of the function name or filename, as the following examples show:

Filenames:

```
(fdb) list UIOb
Ambiguous matching file names:
UIComponent.as#66
UIComponentDescriptor.as#67
UIComponentExtensions.as#68
(fdb) list UIComponent.
```

Function names:

```
(fdb) list init
Ambiguous matching function names:
init
initFromClipParameters
(fdb) list init(
```

Viewing and changing the current file

The `list` command acts on the current file by default. To change to a different file, use the `cf` command. The `cf` command has the following syntax:

```
(fdb) cf [file_name|file_number]
```

For example, to change the file to MyApp.mxml, use the following command:

```
(fdb) cf MyApp.mxml
```

If you do not specify a filename, the `cf` command lists the name and file number of the current file.

To view a list of all files used by the current application, use the `infofiles` command. For more information, see “Getting status” on page 2220.

Viewing the current working directory

Use the `pwd` command to view the file system’s current working directory, as the following example shows. This is the directory from which fdb was run.

```
(fdb) pwd
c:/Flex2SDK/bin/
```

Locating source files

Usually, fdb can find the source files for your application to display them with the `list` command. In some situations, however, you need to add a directory to the search path so that fdb can find the source files. This can be necessary, for example, when the application was compiled on a different computer than you are using to debug the application.

You use the `directory` command to add a directory to the search path. This command adds the specified directory or directories to the beginning of the list of directories that fdb searches for source files. The syntax for the `directory` command is as follows:

```
(fdb) directory path
```

For example:

```
(fdb) directory C:\MySource;C:\MyOtherSource
```

On Windows, use the semicolon character as a separator. On Macintosh and UNIX, use the colon character as a separator.

To see the current list of directories in the search path, use the `show directories` command.

Using truncated file and function names

The fdb debugger supports truncated file and function names. You can specify *`file_name`* and *`function_name`* arguments with partial names, as long as the names are unambiguous.

If you use truncated file and function names, fdb tries to map the argument to an unambiguous function name first, and then a filename. For example, `listfoo` first tries to find a function unambiguously starting with *foo* in the current file. If this fails, it tries to find a file unambiguously starting with *foo*.

Printing stack traces

Use the `bt` command to display a back trace of all stack frames. The `bt` command has the following syntax:

```
(fdb) bt
```

Getting status

Use the `info` command to get general information about the application. The `info` command has the following syntax:

```
info [options] [args]
```

The `info` command displays general information about the application being debugged. The following table describes the options of the `info` command:

Option	Description
`arguments`	Displays the argument variables of the current stack frame.
`breakpoints`	Displays the status of user-settable breakpoints.
`display`	Displays the list of autodisplay expressions.

Option	**Description**

`files [arg]`	Displays the names of all files used by the target application. This includes authored files and system files, plus generated files. Also indicates the file number for each file.
	You can use wildcards and literals to select and sort the output. The `infofiles` command supports the following:
	`info files character` Alphabetically lists files with names that start with the specified character. The following example lists all files starting with the letter V:
	`info files V`
	`info files *.extension` Alphabetically lists all files with the given extension. The following example lists all files with the as extension:
	`info files *.as`
	`info files *string*` Alphabetically lists all files with names that include string.

`functions [arg]`	Displays all function names used in this application. The `info functions` command optionally takes an argument; for example: `infofunctions` Lists all functions in all files. `infofunctions` Lists all functions in the current file. `infofunctions MyApp.mxml` Lists all functions in the MyApp.mxml file.
`handle`	Displays settings for fault handling in the debugger.
`locals`	Displays the local variables of the current stack frame.
`sources`	Displays authored source files used by the target application.
`stack`	Displays the backtrace of the stack.
`swfs`	Displays all current SWF files.
`targets`	Displays the HTTP or file URL of the target application.
`variables`	Displays all global and static variable names.

For additional information about these options, use the `help` command, as the following example shows:

```
(fdb) help info targets
```

Handling faults and catching exceptions

Use the `handle` command to specify how fdb reacts to Flash Player exceptions during execution. To view the current settings, use the `info` command, as the following example shows:

```
(fdb) info handle
```

The `handle` command has the following syntax:

```
(fdb) handle exception [action]
```

The *fault_type* is the category of fault that fdb handles. The *action* is what fdb does in response to that fault. The possible actions are `print`, `noprint`, `stop`, and `nostop`. The following table describes these actions:

Action	**Description**
`print`	Prints a message if this type of fault occurs.

Action	Description
`noprint`	Does not print a message if this type of fault occurs.
`stop`	Stops execution of the debugger if this type of fault occurs.
`nostop`	Does not stop execution of the debugger if this type of fault occurs.

You can also use the `catch` command to halt the debugger when an exception of a specified type is encountered. The debugger halts even if there is a `catch` statement that catches the exception. The syntax of the `catch` command is as follows:

```
(fdb) catch exception_type
```

The *exception_type* argument is the type of exception that stops the debugger. For example, TypeError:

```
(fdb) catch TypeError
```

To halt the debugger on any exception, you can use a wildcard (“*”), as the following example shows:

```
(fdb) catch *
```

Getting help

Use the `help` command to get information on particular topics. The `help` command has the following syntax:

```
help [topic]
```

The `help` command provides a relatively terse description of each command and its usage. The following example opens the `help` command:

```
(fdb) help
```

Type **help** followed by the command name to get the full help information, as the following example shows:

```
(fdb) help delete
```

Terminating the session

You use the `kill` and `exit` commands to end the current debugging session and exit from the fdb application. The `kill` and `exit` commands do not take any arguments. If fdb opened the default browser, you can also terminate the fdb session by closing the browser window.

To stop the current session, use the `kill` command, as the following example shows:

```
(fdb) kill
```

Using the `kill` command does not quit the fdb application. You can immediately start another session. To exit from fdb, use the `exit` command, as follows:

```
(fdb) exit
```

Logging

You can log messages at several different points in an Adobe® Flex® application’s life cycle. You can log messages when you compile the application, when you deploy it to a web application server, or when a client runs it. You can log messages on the server or on the client. These messages are useful for informational, diagnostic, and debugging activities.

About logging

When you encounter a problem with your application, whether during compilation or at run time, the first step is to gather diagnostic information to locate the cause of the problem. The source of a problem typically is in one of two places: the server web application, or the client application.

***Note:** For detailed information on debugging Adobe® AIR™ applications, see Debugging Tools in Flash Builder.*

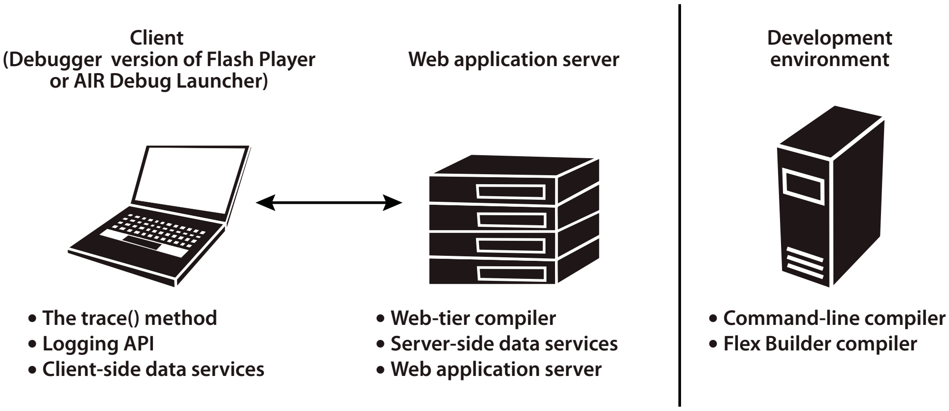
Flex includes several different logging and error reporting mechanisms that you can use to track down failures:

Client-side logging and debugging With the debugger version of Adobe® Flash® Player, or with an AIR application that you debug using ADL, you can use the global trace() method to write out messages or configure a TraceTarget to customize log levels of applications for data services-based applications. For more information, see "Client-side logging and debugging" on page 2227.

Compiler logging When compiling your Flex applications from the command line and in Adobe® Flash® Builder®, you can view deprecation and warning messages, and sources of fatal errors. For more information, see "Compiler logging" on page 2237.

Policy file logging You can log messages for all policy file interactions between a running SWF and Flash Player. For more information, see "Policy file logging" on page 2237.

The following example shows the types of logging you can do in the appropriate environment:



To use client-side debugging utilities such as the `trace()` global method and client-side data services logging, you must install and configure the debugger version of Flash Player. This is described in "Using the debugger version of Flash Player" on page 2223. The debugger version of Flash Player is not required to log compiler messages.

Using the debugger version of Flash Player

The debugger version of Flash Player is a tool for development and testing. Like the standard version of Adobe Flash Player, it runs SWF files in a browser or on the desktop in a stand-alone player. Unlike Flash Player, the debugger version of Flash Player enables you to do the following:

- Output statements and application errors to the debugger version of the Flash Player local log file by using the trace() method.
- Write data services log messages to the local log file of the debugger version of Flash Player.
- View run-time errors (RTEs).
- Use the fdb command-line debugger.
- Use the Flash Builder debugging tool.

- Use the Flash Builder profiling tool.

***Note:** Any client running the debugger version of Flash Player can view your application's `trace()` statements and other log messages unless you disable them. For more information, see "Suppressing debug output" on page 134.*

The debugger version of Flash Player lets you take advantage of the client-side logging utilities such as the `trace()` method and the logging API. You are not required to run the debugger version of Flash Player to log compiler messages because compiling does not require a player.

***Note:** ADL logs `trace()` output from AIR applications, based on the setting in mm.cfg (the same setting used by the debug version of Flash Player).*

In nearly all respects, the debugger version of Flash Player appears to be the same as the standard version of Flash Player. To determine whether or not you are running the debugger version of Flash Player, use the instructions in "Determining Flash Player version in Flex" on page 2227.

The debugger version of Flash Player comes in ActiveX, Plug-in, and stand-alone versions for Microsoft Internet Explorer, Netscape-based browsers, and desktop applications, respectively. You can find the debugger version of Flash Player installers in the following locations:

- Flash Builder: *install_dir*/Player/*os_version*
- Flex SDK: *install_dir*/runtimes/player/*os_version*/

Uninstall your current Flash Player before you install the debugger version of Flash Player. For information on installing the debugger version of Flash Player, see the Flex installation instructions.

You can enable or disable trace logging and perform other configuration tasks for the debugger version of Flash Player. For more information, see "Editing the mm.cfg file" on page 2224.

Editing the mm.cfg file

You use the settings in the mm.cfg text file to configure the debugger version of Flash Player. These settings also affect logging of `trace()` output in AIR applications running in the ADL debugger. If this file does not exist, you can create it when you first configure the debugger version of Flash Player. The location of this file depends on your operating system.

The following table shows where to create the mm.cfg file for Flash Player 10.1 and later on several operating systems:

Operating system	**Create file in ...**
Macintosh OS X	Flash Player first checks the user's home directory (~). If none is found, then Flash Player looks in /Library/Application Support/Macromedia
Windows 2000/XP	`%HOMEDRIVE%\%HOMEPATH%` The default value is "c:\Documents and settings\username". Your system administrator might map the home directory to a shared network drive. In that case, check with your system administrator to determine how to configure your debugger Player.
Windows Vista Windows 7	`%HOMEDRIVE%\%HOMEPATH%` The default value is "c:\Users\username". Your system administrator might map the home directory to a shared network drive. In that case, check with your system administrator to determine how to configure your debugger Player.
Linux	`/home/`*`username`*

On Microsoft Windows 2000, the default location of the mm.cfg file for earlier versions of Flash Player was \.

The following table lists the properties that you can set in the mm.cfg file:

Property	**Description**
`ErrorReportingEnable`	Enables the logging of error messages. Set the `ErrorReportingEnable` property to 1 to enable the debugger version of Flash Player to write error messages to the log file. To disable logging of error messages, set the `ErrorReportingEnable` property to 0. The default value is 0.
`MaxWarnings`	Sets the number of warnings to log before stopping. The default value of the `MaxWarnings` property is 100. After 100 messages, the debugger version of Flash Player writes a message to the file stating that further error messages will be suppressed. Set the `MaxWarnings` property to override the default message limit. For example, you can set it to 500 to capture 500 error messages. Set the `MaxWarnings` property to 0 to remove the limit so that all error messages are recorded.
`PolicyFileLog`	Enables the logging of policy file messages. Set `PolicyFileLog` to 1 to log policy file messages. The default value is 0. For more information on using policy file logs, see “Log file location” on page 2226.

Property	Description
`PolicyFileLogAppend`	Lets you save the contents of the policy file log file. Set the `PolicyFileLogAppend` property to 1 to save previous policy file log entries. The default value is 0. If `PolicyFileLogAppend` is not enabled, each new root-level SWF clears the log file. If PolicyFileLogAppend is enabled, the previous contents of the log file will always be kept, and the log file will grow at the end. If many different root-level SWF files are loaded during your testing, you will probably want to enable `PolicyFileLogAppend`. However, if you enable `PolicyFileLogAppend`, you will probably need to manually rename or delete the log file from time to time, since otherwise it will grow to a large size, and it will be difficult to determine where previous output ends and new output begins. For more information on using policy file logs, see "Policy file logging" on page 2237.
`TraceOutputFileEnable`	Enables trace logging. Set `TraceOutputFileEnable` to 1 to enable the debugger version of Flash Player to write trace messages to the log file. Disable trace logging by setting the `TraceOutputFileEnable` property to 0. The default value is 0.
`TraceOutputFileName`	**Note**: Beginning with the Flash Player 9 Update, Flash Player ignores the `TraceOutputFileName` property and stores the flashlog.txt file in a hard-coded location based on operating system. For more information, see "Log file location" on page 2226. Sets the location of the log file. By default, the debugger version of Flash Player writes error messages to a file named flashlog.txt, located in the same directory in which the mm.cfg file is located. Set `TraceOutputFileName` to override the default name and location of the log file by specifying a new location and name in the following form: On Macintosh OS X, you should use colons to separate directories in the TraceOutputFileName path rather than slashes. `TraceOutputFileName=<fully qualified path/filename>`

The following sample mm.cfg file enables error reporting and trace logging:

```
ErrorReportingEnable=1
```

Log file location

Beginning with the Flash Player 9 Update, you cannot modify the log file location or name. The filename is flashlog.txt, and its location is hard-coded, depending on your operating system. The following table shows the flashlog.txt file location:

Operating System	Log file location
Windows 95/98/ME/2000/XP	`C:\Documents and Settings\`*`username`*`\Application Data\Macromedia\Flash Player\Logs`
Windows Vista/Windows 7	`C:\Users\`*`username`*`\AppData\Roaming\Macromedia\Flash Player\Logs`
Macintosh OS X	`/Users/`*`username`*`/Library/Preferences/Macromedia/Flash Player/Logs/`
Linux	`/home/`*`username`*`/.macromedia/Flash_Player/Logs/`

The default log file location changed between the initial Flash Player 9 release and the Flash Player 9 Update. In the initial Flash Player 9 release, the default location was the same directory as the mm.cfg file and you could update the log file location and name through the `TraceOutputFileName` property.

Determining Flash Player version in Flex

To determine which version of Flash Player you are currently using—the standard version or the debugger version—you can use the Capabilities class. This class contains information about Flash Player and the system that it is currently operating on. To determine if you are using the debugger version of Flash Player, you can use the `isDebugger` property of that class. This property returns a Boolean value: the value is `true` if the current player is the debugger version of Flash Player and `false` if it is not.

The following example uses the `playerType`, `version`, and `isDebugger` properties of the Capabilities class to display information about the Player:

```
<?xml version="1.0"?>
<!-- logging/CheckDebugger.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
        import flash.system.Capabilities;
        private function reportVersion():String {
            if (Capabilities.isDebugger) {
                return "Debugger version of Flash Player";
            } else {
                return "Flash Player";
            }
        }
        private function reportType():String {
            return Capabilities.playerType + " (" + Capabilities.version + ")";
        }
        ]]>
    </fx:Script>

    <s:Label text="{reportVersion()}"/>
    <s:Label text="{reportType()}"/>
</s:Application>
```

Other properties of the Capabilities class include `hasPrinting`, `os`, and `language`.

Client-side logging and debugging

Often, you use the `trace()` method when you debug applications to write a checkpoint message on the client, which signals that your application reached a specific line of code, or to output the value of a variable.

The debugger version of Flash Player has two primary methods of writing messages that use `trace()`:

- The global `trace()` method. The global trace() method prints Strings to a specified output log file. For more information, see “Using the global trace() method” on page 2228.

- Logging API. The logging API provides a layer of functionality on top of the `trace()` method that you can use with your custom classes or with the data service APIs. For more information, see “Using the logging API” on page 2229.

Configuring the debugger version of Flash Player to record trace() output

To record messages on the client, you must use the debugger version of Flash Player. You must also set `TraceOutputFileEnable` to 1 in your mm.cfg file. For more information on editing the mm.cfg file, see “Editing the mm.cfg file” on page 2224.

The debugger version of Flash Player sends output from the trace() method to the flashlog.txt file. The location of this file is determined by the operating system. For more information, see “Log file location” on page 2226.

You can suppress trace output by setting the `omit-trace-statements` compiler argument to `true`.

Using the global trace() method

You can use the debugger version of Flash Player to capture output from the global `trace()` method and write that output to the client log file. You can use trace() statements in any ActionScript or MXML file in your application. Because it is a global function, you are not required to import any ActionScript classes packages to use the `trace()` method.

Only debug SWF files will write out `trace()` statements. To create a debug SWF file, set the `debug` compiler argument to true.

The following example defines a function that logs the various stages of the Button control’s startup life cycle:

```
<?xml version="1.0"?>
<!-- logging/ButtonLifeCycle.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
        private function traceEvent(event:Event):void {
            trace(event.currentTarget + ":" + event.type);
        }
        ]]>
    </fx:Script>
    <s:Button id="b1" label="Click Me"
        preinitialize="traceEvent(event)"
        initialize="traceEvent(event)"
        creationComplete="traceEvent(event)"
        updateComplete="traceEvent(event)"
    />
</s:Application>
```

The following example shows the output of this simple application:

```
TraceLifecycle_3.b1:Button:preinitialize
TraceLifecycle_3.b1:Button:initialize
TraceLifecycle_3.b1:Button:creationComplete
TraceLifecycle_3.b1:Button:updateComplete
TraceLifecycle_3.b1:Button:updateComplete
TraceLifecycle_3.b1:Button:updateComplete
```

Messages that you log by using the `trace()` method should be Strings. If the output is not a String, use the `String(...)` conversion function, or use the object's `toString()` method, if one is available, before you call the `trace()` method.

To enable tracing, you must configure the debugger version of Flash Player as described in "Configuring the debugger version of Flash Player to record trace() output" on page 2228.

Using the logging API

The logging API lets an application capture and write messages to a target's configured output. Typically the output is equivalent to the global `trace()` method, but it can be anything that an active target supports.

The logging API consists of the following parts:

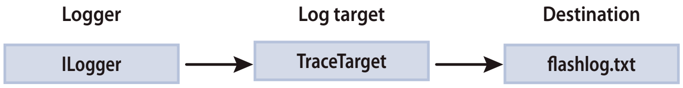
Logger The logger provides an interface for sending a message to an active target. Loggers implement the ILogger interface and call methods on the Log class. The two classes of information used to filter a message are category and level. Each logger operates under a category. A *category* is a string used to filter all messages sent from that logger. For example, a logger can be acquired with the category "orange". Any message sent using the "orange" logger only reaches those targets that are listening for the "orange" category. In contrast to the category that is applied to all messages sent with a logger, the *level* provides additional filtering on a per-message basis. For example, to indicate that an error occurred within the "orange" subsystem, you can use the error level when logging the message. The supported levels are defined by the LogEventLevel class. The Flex framework classes that use the logging API set the category to the fully qualified class name as a convention.

Log target The log target defines where log messages are written. Flex predefines a single log target: TraceTarget, which is the most commonly used log target. This log target connects the logging API to the trace system so that log messages are sent to the same location as the output of the trace() method. For more information on the `trace()` method, see "Using the global trace() method" on page 2228.

You can also write your own custom log target. For more information, see "Implementing a custom logger with the logging API" on page 2233.

Destination The destination is where the log message is written. Typically, this is a file, but it can also be a console or something else, such as an in-memory object. The default destination for TraceTarget is the flashlog.txt file. You configure this destination on the client.

The following example shows a sample relationship between a logger, a log target, and a destination:



You can also use the logging API to send messages from custom code you write. You can do this when you create a set of custom APIs or components or when you extend the Flex framework classes and you want users to be able to customize their logging. For more information, see "Implementing a custom logger with the logging API" on page 2233.

The following packages within the Flex framework are the only ones that use the logging API:

- mx.rpc.*
- mx.messaging.*
- mx.data.*

To configure client-side logging in MXML or ActionScript, create a TraceTarget object to log messages. The TraceTarget object logs messages to the same location as the output of the `trace()` statements. You can also use the TraceTarget to specify which classes to log messages for, and what level of messages to log.

The levels of logging messages are defined as constants of the LogEventLevel class. The following table lists the log level constants and their numeric equivalents, and describes each message level:

Logging level constant (int)	Description
`ALL (0)`	Designates that messages of all logging levels should be logged.
`DEBUG (2)`	Logs internal Flex activities. This is most useful when debugging an application. Select the `DEBUG` logging level to include `DEBUG`, `INFO`, `WARN`, `ERROR`, and `FATAL` messages in your log files.
`INFO (4)`	Logs general information. Select the `INFO` logging level to include `INFO`, `WARN`, `ERROR`, and `FATAL` messages in your log files.
`WARN (6)`	Logs a message when the application encounters a problem. These problems do not cause the application to stop running, but could lead to further errors. Select the `WARN` logging level to include `WARN`, `ERROR`, and `FATAL` messages in your log files.
`ERROR (8)`	Logs a message when a critical service is not available or a situation has occurred that restricts the use of the application. Select the `ERROR` logging level to include `ERROR` and `FATAL` messages in your log files.
`FATAL (1000)`	Logs a message when an event occurs that results in the failure of the application. Select the `FATAL` logging level to include only `FATAL` messages in your log files.

The log level lets you restrict the amount of messages sent to any running targets. Whatever log level you specify, all “lower” levels of messages are written to the log. For example, if you set the log level to `DEBUG`, all log levels are included. If you set the log level to `WARNING`, only `WARNING`, `ERROR`, and `FATAL` messages are logged. If you set the log level to the lowest level of message, `FATAL`, only `FATAL` messages are logged.

Using the logging API with data services

The data services classes are designed to use the logging API to log client-side and server-side messages.

Enable the logging API with data services

1 Create a TraceTarget logging target and set the value of one or more filter properties to include the classes whose messages you want to log. You can filter the log messages to a specific class or package. You can use wildcards (*) when defining a filter.

2 Set the log level by using the `level` property of the log target. You can also add detail to the log file output, such as the date and time that the event occurred, by using properties of the log target.

3 When you create a target within ActionScript, call the Log class’s `addTarget()` method to add the new target to the logging system. Calling the `addTarget()` method is not required when you create a target in MXML. As long as the client is using the debugger version of Flash Player and meets the requirements described in “Configuring the debugger version of Flash Player to record trace() output” on page 2228, the messages are logged.

The following example configures a TraceTarget logging target in ActionScript:

```
<?xml version="1.0"?>
<!-- logging/ActionScriptTraceTarget.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    creationComplete="initLogging();"
    height="600">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
        import mx.collections.ArrayCollection;
        import mx.logging.targets.*;
        import mx.logging.*;
        [Bindable]
        public var myData:ArrayCollection;
        private function initLogging():void {
            /* Create a target. */
            var logTarget:TraceTarget = new TraceTarget();
            /* Log only messages for the classes in the mx.rpc.* and
               mx.messaging packages. */
            logTarget.filters=["mx.rpc.*","mx.messaging.*"];
            /* Log all log levels. */
            logTarget.level = LogEventLevel.ALL;
            /* Add date, time, category, and log level to the output. */
            logTarget.includeDate = true;
            logTarget.includeTime = true;
            logTarget.includeCategory = true;
            logTarget.includeLevel = true;
            /* Begin logging. */
            Log.addTarget(logTarget);
        }
        ]]>
    </fx:Script>
    <fx:Declarations>
        <!-- HTTPService is in the mx.rpc.http.* package -->
        <mx:HTTPService id="srv"
            url="../assets/trace_example_data.xml"
            useProxy="false"
            result="myData=ArrayCollection(srv.lastResult.data.result)"/>
    </fx:Declarations>
    <mx:LineChart id="chart" dataProvider="{myData}" showDataTips="true">
        <mx:horizontalAxis>
            <mx:CategoryAxis categoryField="month"/>
        </mx:horizontalAxis>
        <mx:series>
            <mx:LineSeries yField="apple" name="Apple"/>
            <mx:LineSeries yField="orange" name="Orange"/>
            <mx:LineSeries yField="banana" name="Banana"/>
        </mx:series>
    </mx:LineChart>
    <s:Button id="b1" click="srv.send();" label="Load Data"/>
</s:Application>
```

In the preceding example, the `filters` property is set to log messages for all classes in the mx.rpc and mx.messaging packages. In this case, it logs messages for the HTTPService class, which is in the mx.rpc.http.* package.

You can also configure a log target in MXML. When you do this, though, you must be sure to use an appropriate number (such as 2) rather than a constant (such as `DEBUG`) for the log level.

The following example sets the values of the filters for a TraceTarget logging target by using MXML syntax:

```
<?xml version="1.0"?>
<!-- charts/MXMLTraceTarget.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    creationComplete="initApp();"
    height="600">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Declarations>
        <!-- HTTPService is in the mx.rpc.http.* package -->
        <mx:HTTPService id="srv"
            url="../assets/trace_example_data.xml"
            useProxy="false"
            result="myData=ArrayCollection(srv.lastResult.data.result)"/>
        <mx:TraceTarget id="logTarget"
            includeDate="true"
            includeTime="true"
            includeCategory="true"
            includeLevel="true">
            <mx:filters>
                <fx:Array>
                    <fx:String>mx.rpc.*</fx:String>
                    <fx:String>mx.messaging.*</fx:String>
                </fx:Array>
            </mx:filters>
            <!-- 0 is represents the LogEventLevel.ALL constant. -->
            <mx:level>0</mx:level>
        </mx:TraceTarget>
    </fx:Declarations>

    <fx:Script>
        <![CDATA[
        import mx.collections.ArrayCollection;
        import mx.logging.Log;
        [Bindable]
        public var myData:ArrayCollection;

        private function initApp():void {
            Log.addTarget(logTarget);
        }
        ]]>
    </fx:Script>
    <mx:LineChart id="chart" dataProvider="{myData}" showDataTips="true">
        <mx:horizontalAxis>
            <mx:CategoryAxis categoryField="month"/>
        </mx:horizontalAxis>
        <mx:series>
            <mx:LineSeries yField="apple" name="Apple"/>
            <mx:LineSeries yField="orange" name="Orange"/>
            <mx:LineSeries yField="banana" name="Banana"/>
        </mx:series>
    </mx:LineChart>
    <s:Button id="b1" click="srv.send();" label="Load Data"/>
</s:Application>
```

Implementing a custom logger with the logging API

If you write custom components or an ActionScript API, you can use the logging API to access the trace system in the debugger version of Flash Player. You do this by defining your log target as a TraceTarget, and then calling methods on your logger when you log messages.

The following example extends a Button control. It writes log messages for the startup life cycle events, such as `initialize` and `creationComplete`, and the common UI events, such as `click` and `mouseOver`.

```
// logging/MyCustomLogger.as
package { // The empty package.
    import mx.controls.Button;
    import flash.events.*;
    import mx.logging.*;
    import mx.logging.targets.*;

    public class MyCustomLogger extends Button {
        private var myLogger:ILogger;
        public function MyCustomLogger() {
            super();
            initListeners();
            initLogger();
        }
        private function initListeners():void {
            // Add event listeners life cycle events.
            addEventListener("preinitialize", logLifeCycleEvent);
            addEventListener("initialize", logLifeCycleEvent);
            addEventListener("creationComplete", logLifeCycleEvent);
            addEventListener("updateComplete", logLifeCycleEvent);

            // Add event listeners for other common events.
            addEventListener("click", logUIEvent);
            addEventListener("mouseUp", logUIEvent);
            addEventListener("mouseDown", logUIEvent);
            addEventListener("mouseOver", logUIEvent);
            addEventListener("mouseOut", logUIEvent);
        }
        private function initLogger():void {
            myLogger = Log.getLogger("MyCustomClass");
        }
        private function logLifeCycleEvent(e:Event):void {
            if (Log.isInfo()) {
                myLogger.info(" STARTUP: " + e.target + ":" + e.type);
            }
        }
        private function logUIEvent(e:MouseEvent):void {
            if (Log.isDebug()) {
                myLogger.debug(" EVENT:   " + e.target + ":" + e.type);
            }
        }
    }
}
```

Within the application that uses the MyCustomLogger class, define a TraceTarget, as the following example shows:

```
<?xml version="1.0"?>
<!-- logging/LoadCustomLogger.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns="*" >
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Declarations>
        <mx:TraceTarget level="0"
            includeDate="true"
            includeTime="true"
            includeCategory="true"
            includeLevel="true">
            <mx:filters>
                <fx:Array>
                    <fx:String>*</fx:String>
                </fx:Array>
            </mx:filters>
        </mx:TraceTarget>
    </fx:Declarations>
    <MyCustomLogger label="Click Me"/>
</s:Application>
```

After running this application, the flashlog.txt file looks similar to the following:

```
3/9/2009 18:58:05.042 [INFO] MyCustomLogger STARTUP: Main_3.mcc:MyCustomLogger:preinitialize
3/9/2009 18:58:05.487 [INFO] MyCustomLogger STARTUP:
Main_3.mcc:MyCustomLogger:initialize
3/9/2009 18:58:05.557 [INFO] MyCustomLogger STARTUP:
Main_3.mcc:MyCustomLogger:creationComplete
3/9/2009 18:58:05.567 [INFO] MyCustomLogger STARTUP: Main_3.mcc:MyCustomLogger:updateComplete
3/9/2009 18:58:05.577 [INFO] MyCustomLogger STARTUP: Main_3.mcc:MyCustomLogger:updateComplete
3/9/2009 18:58:05.577 [INFO] MyCustomLogger STARTUP: Main_3.mcc:MyCustomLogger:updateComplete
3/9/2009 18:58:06.849 [DEBUG] MyCustomLogger EVENT: Main_3.mcc:MyCustomLogger:mouseOver
3/9/2009 18:58:07.109 [DEBUG] MyCustomLogger EVENT: Main_3.mcc:MyCustomLogger:mouseDown
3/9/2009 18:58:07.340 [DEBUG] MyCustomLogger EVENT: Main_3.mcc:MyCustomLogger:mouseUp
3/9/2009 18:58:07.360 [DEBUG] MyCustomLogger EVENT: Main_3.mcc:MyCustomLogger:click
3/9/2009 18:58:07.610 [DEBUG] MyCustomLogger EVENT: Main_3.mcc:MyCustomLogger:mouseOut
```

To log a message, you call the appropriate method of the ILogger interface. The ILogger interface defines a method for each log level: `debug()`, `info()`, `warn()`, `error()`, and `fatal()`. The logger logs messages from these calls if their levels are at or under the log target's logging level. If the target's logging level is set to `all`, the logger records messages when any of these methods are called.

To improve performance, a static method corresponding to each level exists on the Log class, which indicates if any targets are listening for a specific level. Before you log a message, you can use one of these methods in an `if` statement to avoid running the code. The previous example uses the `Log.isDebug()` and `Log.isInfo()` static methods to ensure that the messages are of level `INFO` or `DEBUG` before logging them.

The previous example logs messages dispatched from any category because the TraceTarget's `filters` property is set to the wildcard character (*). The framework code sets the category of the logger to the fully qualified class name of the class in which logging is being performed. This is by convention only; any String specified when calling `Log.getLogger(x)` is the category required in a `filters` property to receive the message.

When you set the `filters` property for logging within the Flex framework, you can restrict this to a certain package or packages, or to other classes. To restrict the logging to your custom class only, add the category specified when the logger was acquired ("MyCustomLogger") to the `filters` Array, as the following example shows:

```
<mx:filters>
    <mx:Array>
        <mx:String>MyCustomLogger</mx:String>
    </mx:Array>
</mx:filters>
```

In ActionScript, you can set the `filters` property by using the following syntax:

```
traceTarget.filters = ["p1.*", "p2.*", "otherPackage*"];
```

The wildcard character can appear only at the end of a value in the Array.

The `Log.getLogger()` method sets the category of the logger. You pass this method a String that defines the category.

Note: *The Flex packages that use the logging API set the category to the current class name by convention, but it can be any String that falls within the filters definitions.*

The value of the category must fall within the definition of at least one of the filters for the log message to be logged. For example, if you set the `filters` property to something other than "*" and you use `Log.getLogger("MyCustomLogger")`, the filter Array must include an entry that matches MyCustomLogger, such as "MyCustomLogger" or "My*".

You can include the logger's category in your log message, if you set the logger's `includeCategory` property to `true`.

You can also use the ILogger interface's `log()` method to customize the log message, and you can specify the logging level in that method. The following example logs messages that use the log level that is passed into the method:

```
package { // The empty package.
    // logging/MyCustomLogger2.as
    import mx.controls.Button;
    import flash.events.*;
    import flash.events.MouseEvent;
    import mx.logging.*;
    import mx.logging.targets.*;

    public class MyCustomLogger2 extends Button {
        private var myLogger:ILogger;
        public function MyCustomLogger2() {
            super();
            initListeners();
            initLogger();
        }
        private function initListeners():void {
            // Add event listeners life cycle events.
            addEventListener("preinitialize", logLifeCycleEvent);
            addEventListener("initialize", logLifeCycleEvent);
            addEventListener("creationComplete", logLifeCycleEvent);
            addEventListener("updateComplete", logLifeCycleEvent);

            // Add event listeners for other common events.
            addEventListener("click", logUIEvent);
            addEventListener("mouseUp", logUIEvent);
            addEventListener("mouseDown", logUIEvent);
            addEventListener("mouseOver", logUIEvent);
            addEventListener("mouseOut", logUIEvent);
        }
        private function initLogger():void {
            myLogger = Log.getLogger("MyCustomClass");
        }
        private function logLifeCycleEvent(e:Event):void {
            if (Log.isInfo()) {
                dynamicLogger(LogEventLevel.INFO, e, "STARTUP");
            }
        }
        private function logUIEvent(e:MouseEvent):void {
            if (Log.isDebug()) {
                dynamicLogger(LogEventLevel.DEBUG, e, "EVENT");
            }
        }

        private function dynamicLogger(
                level:int,
                e:Event, prefix:String):void {
            var s:String = "__" + prefix + "__" + e.currentTarget +
                ":" + e.type;
            myLogger.log(level, s);
        }
    }
}
```

Compiler logging

Flex provides you with control over the output of warning and debug messages for the application and component compilers. When you compile, you can enable the message output to help you to locate and fix problems in your application.

For the command-line compiler, the settings that you use to control messages are defined in the flex-config.xml file or as command-line compiler options.

You have a high level of control over what compiler messages are displayed. For example, you can enable or disable messages such as binding-related warnings in the flex-config.xml file by using the `show-binding-warnings` option. The following example disables these messages in the flex-config.xml file:

```
<show-binding-warnings>false</show-binding-warnings>
```

You can also set this option on the command line.

For Flash Builder, you set error and warning options in the Compiler Properties dialog box. To open the Compiler Properties dialog box, select Project > Properties > Flex Compiler. You can enable or disable warnings in this dialog box. In addition, you can enter more specific options such as `show-binding-warnings` in the Additional Compiler Arguments field.

If you enable compiler messages, they are written to the console window (or System.out) by default.

Also in Flash Builder is a separate Eclipse Error Log file. This file stores messages from the Eclipse environment. The default location of this log file on Windows XP is c:\Documents and Settings*user_name*\workspace\.metadata\.log. For MacOS and Linux, the default location is also in the workspace directory, but files and directories that begin with a dot are hidden by default. As a result, you must make those files visible before you can view the log file.

For more information on the compiler logging settings, see “Viewing warnings and errors” on page 2203.

Policy file logging

Flash Player 9 and later support policy file logging. The policy file log shows messages for every event relating to policy files like the crossdomain.xml file. This includes attempts to retrieve them, successes and failures in processing them, and the fate of the requests that depend on them.

The policy file log file is named policyfiles.txt. It is in the same location as the trace log (flashlog.txt). For information on where to find these log files, see “Log file location” on page 2226.

To use policy file logging, you must use the debug version of Flash Player. In addition, you must add the following to your mm.cfg file:

```
PolicyFileLog=1    # Enables policy file logging
PolicyFileLogAppend=1  # Optional; do not clear log at startup
```

For more information about editing the mm.cfg file, see “Editing the mm.cfg file” on page 2224.

To test if you are logging policy file log messages, open any SWF file with your debug player. The application does not need to use a policy file, or even be running on the network. In the log file, you should see at least one message indicating that the root-level SWF was loaded.

For information about the meaning of the policy file log messages, see http://www.adobe.com/devnet/flashplayer/articles/fplayer9_security.html.

Versioning

You might encounter some versioning issues when working on Adobe® Flex® applications. When compiling, you can choose the version of the SDK to use and you can target specific versions of Adobe® Flash® Player. You can replicate behavior of previous SDK versions. Also, you can design applications that can load modules and other SWF files that were compiled with different SDKs.

Overview of versioning

When a new version of Flex is released, it usually includes changes to the APIs, compiler, and the user interface for Adobe® Flash® Builder™. As a result, if you were working on a project but then upgraded your version of the SDK, you might have to refactor some part of your code to be compatible with the new version. In addition, if the audience for your application is restricted in which version of Flash Player it can use, you might have to make certain concessions to ensure that your application runs without errors.

Use a different SDK

Flash Builder lets you choose any SDK, based on your needs. This lets you maintain projects in Flash Builder that have not been updated to be compatible with the latest version of the SDK, or lets you use new Flash Builder features without having to refactor older Flex projects. For more information, see "Using multiple SDKs" on page 2238.

Maintain older look and feel

The differences between some versions of Flex go beyond new features. The layout schemes and the styles of many components might have changed from one version to the next. If you want to use new Flex features but have your application look and feel the same as an older version of Flex, you can specify the version whose styles you want to use with the `compatibility-version` compiler option. For more information, see "Backward compatibility" on page 2239.

Target specific Player versions

With current Flex tools, you can target your application toward a specific version of Flash Player. To do this, you use the `target-player` compiler option. This is not the same as targeting an application to a specific *SWF version*. For more information, see "Targeting Flash Player versions" on page 2240.

Ensure sub-applications and applications work together

If you want to load a sub-application into a main application that was compiled with a different version of the compiler, you can use the `loadForCompatibility` property of the SWFLoader control. Setting this property ensures that each SWF file contains its own definitions of the linked classes, removing reliance on particular APIs that might have changed between versions. You can only use this property when the main application and sub-application were compiled with version 3.2 of the Flex framework or later. In addition, the main application must be compiled with a more recent or the same version of the compiler as the sub-applications. For more information, see "Developing multi-versioned applications" on page 213.

Using multiple SDKs

Flash Builder lets you change the version of the SDK that you use to compile your projects. You can select the SDK when you first create a project, or at any time you are working on a project. You can change the SDK for any type of Flex project, including library projects and ActionScript-only projects.

You can determine the current SDK's version by using the `-version` option on the command line. For example:

```
mxmlc -version
```

To change the SDK in Flash Builder:

1 With your project open in Flash Builder, select Project > Properties.

2 Select ActionScript Compiler in the left-hand pane.

3 Select the “Use a specific SDK” option.

4 Select the SDK you want to compile with from the drop-down list. If an SDK is not in the list, click “Configure Flex SDKs” and add the definition of the new SDK.

5 Click OK to save your changes.

When you change the SDK, Flash Builder rebuilds your application and flags any code that is no longer compatible with the selected SDK.

Flash Builder includes the Flex 4.6.0 and Flex 3.6.0 SDKs. You can also add any SDK you want by adding it to the list of available SDKs in Flash Builder..

Backward compatibility

To specify the version of the Flex compiler and framework that the output should be compatible with, use the `compatibility-version` compiler option. Possible values for this compiler option are defined as constants in the FlexVersion class. This option affects some behavior such as the theme, layout rules, padding and gaps, skins, and other style settings. In addition, it affects the rules for parsing properties files.

If you do not explicitly set the value of the `compatibility-version` option, the compiler defaults to the current SDK’s version.

In Flash Builder, you add the `compatibility-version` compiler option to the Additional Compiler Arguments field on the Flex Compiler properties panel. The following example sets the compatibility version to 3.0.0:

```
-compatibility-version=3.0.0
```

For the command-line compilers, you can either pass the `compatibility-version` compiler option on the command line or set the value in the configuration file. The following example sets the compatibility version to 4.0 in the flex-config.xml file:

```
<compiler>
    <mxml>
        <compatibility-version>4.0</compatibility-version>
    <mxml>
<compiler>
```

When you set the `compatibility-version` option, you must be sure that the configuration files that you use are compatible with the version you select.

You can programmatically access the version of the application that you are running by using the FlexVersion class. To get the current compatibility version in your application, use the `compatibilityVersionString` property of that class. This lets you conditionalize the logic in your application based on the compatibility version.

Using themes with compatibility-version

When you set the compatibility version, you should also be sure to use the appropriate theme file that matches that version. Themes are located in the frameworks/themes directory. For Flex 4.x, you do not have to specify a theme file. The default Spark theme file is designed for Flex 4.x compatibility. However, if you want the Flex 3 look and feel, you must specify the Halo theme or another theme that is compatible with the Flex 3 SDK.

The following command-line example uses the Halo theme and sets `compatibility-version` to 3.0.0:

```
mxmlc -compatibility-version=3.0.0 -theme=..\frameworks\themes\Halo\halo.swc MyApp.mxml
```

For more information on using themes, see “About themes” on page 1561.

The default style sheets for several versions of Flex are available in the framework.swc file. This SWC file contains the current default style sheet (defaults.css) and the Flex 3 default style sheet (defaults-3.0.0.css). The compiler uses the style sheet that is appropriate for the compatibility version you set. For example, if you set the `compatibility-version` option to 3.0, then the compiler uses the Flex 3 default style sheet.

Differences between SDK 3 and SDK 4.x

The differences between SDK 3 and SDK 4.x that result from setting the `compatibility-version` option include fonts, skins, and styles.

If you set `compatibility-version` to 3.0.0, differences include:

- The value of `embedAsCFF` defaults to `false`. This means that non-CFF fonts are embedded, rather than CFF fonts. For more information, see “Embedding fonts with MX components” on page 1592.
- The Halo theme should be used to define the look and feel of your application. This includes styles and skins.
- Bi-directional binding will not work.

For a list of differences when using the `compatibility-version` compiler option, see Flex 4: Backward Compatibility.

Targeting Flash Player versions

Use the `target-player` compiler option to specify the version of Flash Player that you want to target with the application. Features requiring a later version of Flash Player are not compiled into the application.

One reason for setting the target Player version is if you are unsure of Player usage penetration rates and want to choose a Player version that is lower than the most recent one. Another reason is if your users are locked in to a particular Player version, such as when they are on an intranet and cannot upgrade.

The `target-player` option has the following syntax:

```
-target-player=major_version.minor_version.revision
```

The *major_version* is required while *minor_version* and *revision* are optional. If you do not specify the *minor_version* or *revision*, the compiler uses zero.

For Flex 4.0, the only supported value of the `target-player` option is 10.0.0. For Flex 4.1, the default value is 10.1.0. For Flex 4.5, the default value is 10.2.0. For Flex 4.6, the default value is 11.1.

The minimum value for Flex 4.6 is 11.1. The minimum value for Flex 4.5 is 10.2.0. For Flex 4.0 and 4.1, the minimum value is 10.0.0 (although Flex 4.1 included Player 10.1).

If you do not explicitly set the value of this option, the compiler uses the default from the flex-config.xml file.

SWF version (advanced)

The `swf-version` compiler option specifies the SWF file format version of the output SWF file. Features requiring a later version of the SWF file format are not compiled into the application. This is different from the Player version in that it refers to the SWF specification versioning scheme.

For example, to compile an application to version 10 of the SWF specification, use the following:

```
-swf-version=10
```

This is an advanced option that you should only use if you have an understanding of the SWF specification that you are targeting. For information about the SWF specifications, visit the SWF Technology Center.

ASDoc

ASDoc is a command-line tool that you can use to create API language reference documentation as HTML pages from the ActionScript classes and MXML files in your Adobe® Flex™ application. The Adobe Flex team uses the ASDoc tool to generate the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

About the ASDoc tool

The ASDoc tool parses one or more ActionScript class definitions and MXML files, and generates API language reference documentation for all public and protected methods and properties. The ASDoc tool also recognizes many types of metadata, such as the `[Bindable]`, `[Event]`, `[Style]`, and `[Effect]` metadata tags.

You specify a single class, multiple classes, an entire namespace, or any combination as inputs to the ASDoc tool.

ASDoc generates its output as a directory structure of HTML files that matches the package structure of the input class files. Also, ASDoc generates an index of all public and protected methods and properties. To view the ASDoc output, open the index.html file in the top-level directory of the output.

Using ASDoc

To use ASDoc, run the `asdoc` command from the bin directory of your Flex installation. For example, from the bin directory, enter the following command to create output for the Flex Button class:

```
asdoc -source-path C:\flex\frameworks\projects\framework\src
    -doc-classes mx.controls.Button
    -main-title "Flex API Documentation"
    -window-title "Flex API Documentation"
    -output framework-asdoc
```

In this example, the source code for the Button class is in the directory C:\flex\frameworks\projects\framework\src\mx\controls. Use the `source-path` option to specify where the ASDoc tool looks for the source code, and the `doc-classes` option to specify the name of the class to process.

The ASDoc tool writes the output to C:\flex\bin\framework-asdoc directory, as defined by the `output` option.

The ASDoc tool supports many options for specifying the files to process. For example, instead of explicitly specifying the list of files to process, you can use the `doc-sources` option to specify a directory name. The following example runs the ASDoc tool on all files in the C:\flex\frameworks\projects\framework\src\mx\controls directory:

```
asdoc
    -doc-sources C:\a\flex\flex\sdk\frameworks\projects\framework\src\mx\controls
    -main-title "Flex API Documentation"
    -window-title "Flex API Documentation"
    -output framework-asdoc
```

To view the output, open the file C:\flex\bin\framework-asdoc\index.html. For more information on running the `asdoc` command, see "Using the ASDoc tool" on page 2261.

Creating ASDoc comments in ActionScript

A standard programming practice is to include comments in source code. The ASDoc tool recognizes a specific type of comment in your source code and copies that comment to the generated output.

Writing an ASDoc comment

An ASDoc comment consists of the text between the characters `/**` that mark the beginning of the ASDoc comment, and the characters `*/` that mark the end of it. The text in a comment can continue onto multiple lines.

Use the following format for an ASDoc comment:

```
/**
* Main comment text.
*
* @tag Tag text.
*/
```

As a best practice, prefix each line of an ASDoc comment with an asterisk (*) character, followed by a single white space to make the comment more readable, and to ensure correct parsing of comments. When the ASDoc tool parses a comment, the leading asterisk and white-space characters on each line are discarded; blanks and tabs preceding the initial asterisk are also discarded.

The ASDoc comment in the previous example creates a single-paragraph description in the output. To add additional comment paragraphs, enclose each subsequent paragraph in HTML paragraph tags, `<p></p>`. You must close the `<p>` tag, in accordance with XHTML standards, as the following example shows:

```
/**
* First paragraph of a multiparagraph description.
*
* <p>Second paragraph of the description.</p>
*/
```

All the classes that ship with Flex contain the ASDoc comments that appear in the *ActionScript 3.0 Reference for the Adobe Flash Platform*. For example, view the mx.controls.Button class for examples of ASDoc comments.

Placing ASDoc comments

Place an ASDoc comment immediately before the declaration for a class, interface, constructor, method, property, or metadata tag that you want to document, as the following example shows for the `myMethod()` method:

```
/**
* This is the typical format of a simple
* multiline (single paragraph) main description
* for the myMethod() method, which is declared in
* the ActionScript code below.
* Notice the leading asterisks and single white space
* following each asterisk.
*/
public function myMethod(param1:String, param2:Number):Boolean {}
```

The ASDoc tool ignores comments placed in the body of a method and recognizes only one comment per ActionScript statement.

A common mistake is to put an `import` statement, or other code line or metadata tag, between the ASDoc comment for a class and the `class` declaration. Because an ASDoc comment is associated with the next ActionScript statement in the file after the comment, this example associates the comment with the import statement, not the `class` declaration:

```
/**
* This is the class comment for the class MyClass.
*/
import flash.display.*; // MISTAKE - Do not to put import statement here.
class MyClass {
}
```

Formatting ASDoc comments

The main body of an ASDoc comment begins immediately after the starting characters, `/**`, and continues until the tag section, as the following example shows:

```
/**
* Main comment text continues until the first tag.
*
* @tag Tag text.
*/
```

The first sentence of the main description of the ASDoc comment should contain a concise but complete description of the declared entity. The first sentence ends at the first period followed by a space, tab, or line terminator.

ASDoc uses the first sentence to populate the summary table at the top of the HTML page for the class. Each type of class element (method, property, event, effect, and style) has a separate summary table in the ASDoc output.

The tag section begins with the first ASDoc tag in the comment, defined by the first @ character that begins a line, ignoring leading asterisks, white space, and the leading separator characters, `/**`. The main description cannot continue after the tag section begins.

The text following an ASDoc tag can span multiple lines. You can have any number of tags, where some tags can be repeated, such as the `@param` and `@see` tags, while others cannot.

The following example shows an ASDoc comment that includes a main description and a tag section. Notice the use of white space and leading asterisks to make the comment more readable:

```
/**
* Typical format of a simple multiline comment.
* This text describes the myMethod() method, which is declared below.
*
* @param param1 Describe param1 here.
* @param param2 Describe param2 here.
*
* @return Describe return value here.
*
* @see someOtherMethod
*/
public function myMethod(param1:String, param2:Number):Boolean {}
```

For a complete list of the ASDoc tags, see “ASDoc tags” on page 2256.

Using the @private tag

By default, the ASDoc tool generates output for all public and protected elements in an ActionScript class, even if you omit the ASDoc comment for the element. The ASDoc tool ignores all elements defined as private.

To make ASDoc ignore a public or protected element, insert an ASDoc comment that contains the `@private` tag anywhere in the comment. The ASDoc comment can contain additional text along with the `@private` tag, which is also excluded from the output.

ASDoc generates output for all public classes in the list of input classes. You can specify to ignore an entire class by inserting an ASDoc comment that contains the `@private` tag before the class definition. The ASDoc comment can contain additional text along with the `@private` tag, which is also excluded from the output, as the following example shows:

```
/**
* This class is omitted from the output.
*
* @private
*/
public class MyClass {
}
```

Excluding an inherited element

By default, the ASDoc tool copies information and a link for all elements inherited by a subclass from a superclass. In some cases, a subclass might not support an inherited element. You can use the `[Exclude]` metadata tag to cause ASDoc to omit the inherited element from the list of inherited elements.

The `[Exclude]` metadata tag has the following syntax:

```
[Exclude(name="elementName", kind="property|method|event|style|effect")]
```

For example, to exclude documentation on the `click` event in the MyButton subclass of the Button class, insert the following `[Exclude]` metadata tag in the MyButton.as file:

```
[Exclude(name="click", kind="event")]
```

Using HTML tags

You can use selected HTML entities and HTML tags to define paragraphs, format text, create lists, and add anchors. For a list of the supported HTML tags, see "Summary of commonly used HTML elements" on page 2260.

Write the text of an ASDoc comment in XHTML-compliant HTML. That means your HTML syntax has to conform to XML syntax rules. For example, close all HTML tags, such as `<p>` and `<code>` tags, by inserting the closing `</p>` or `</code>` tag.

The following example comment contains HTML tags to format the output:

```
/**
* This is the typical format of a simple multiline comment
* for the myMethod() method.
*
* <p>This is the second paragraph of the main description
* of the <code>myMethod</code> method.
* Notice that you do not use the paragraph tag in the
* first paragraph of the description.</p>
*
* @param param1 Describe param1 here.
* @param param2 Describe param2 here.
*
* @return A value of <code>true</code> means this;
* <code>false</code> means that.
*
* @see someOtherMethod
*/
public function myMethod(param1:String, param2:Number):Boolean {}
```

Using special characters

The ASDoc tool can fail if your source files contain non-UTF-8 characters such as curly quotes. If it does fail, the error messages it displays refers to a line number in the class. That message helps you track down the location of the special character.

ASDoc passes all HTML tags and tag entities in a comment to the output. Therefore, if you want to use special characters in a comment, enter them using HTML code equivalents. For example, to use a less-than (<) or greater-than (>) symbols in a comment, use `&lt;` and `&gt;`. To use the at-sign (@) in a comment, use `&#64;`. Otherwise, these characters are interpreted as literal HTML characters in the output.

For a list of common HTML tags and their entity equivalents, see "Summary of commonly used HTML elements" on page 2260.

Because asterisks (*) are used to delimit comments, ASDoc does not support asterisks within a comment. To use an asterisk in an ASDoc comment, use the double tilde (~~).

Hiding text in ASDoc comments

The ASDoc style sheet contains a class called `hide`, which you use to hide text in an ASDoc comment by setting the class attribute to `hide`. Hidden text does not appear in the ASDoc HTML output, but does appear in the generated HTML file. Therefore, do not use it for confidential information. The following example uses the `hide` class:

```
/**
* Dispatched when the user presses the Button control.
* If the <code>autoRepeat</code> property is <code>true</code>,
* this event is dispatched repeatedly as long as the button stays down.
*
* <span class="hide">This text is hidden.</span>
* @eventType mx.events.FlexEvent.BUTTON_DOWN
*/
```

Rules for parsing ASDoc comments

The following rules summarize how ASDoc processes an ActionScript file:

- If an ASDoc comment precedes an ActionScript element, ASDoc copies the comment and code element to the output file.
- If an ActionScript element is not preceded by an ASDoc comment, ASDoc copies the code element to the output file with an empty description.
- If an ASDoc comment contains the `@private` ASDoc tag, the associated ActionScript element and the ASDoc comment are ignored.
- The comment text must precede any @ tags, otherwise the comment text is interpreted as an argument to an @ tag. The only exception is the `@private` tag, which can appear anywhere in an ASDoc comment.
- HTML tags, such as `<p></p>`, and `<ul></ul>`, in ASDoc comments are passed through to the output.
- HTML tags must use XML style conventions, which means there must be a beginning and ending tag. For example, close an `<li>` tag with a `</li>` tag.

Documenting ActionScript elements

You can add ASDoc comments to class, property, method, and metadata elements to document ActionScript classes. For more information on documenting MXML files, see "Documenting MXML files" on page 2251.

Documenting classes

The ASDoc tool automatically includes all public classes in its output. Place the ASDoc comment for a class just before the `class` declaration, as the following example shows:

```
/**
* The MyButton control is a commonly used rectangular button.
* MyButton controls look like they can be pressed.
* They can have a text label, an icon, or both on their face.
*/
public class MyButton extends UIComponent {
}
```

This comment appears at the top of the HTML page for the associated class.

To configure ASDoc to omit the class from the output, insert an `@private` tag anywhere in the ASDoc comment, as the following example shows:

```
/**
* @private
* The MyHiddenButton control is for internal use only.
*/
public class MyHiddenButton extends UIComponent {
}
```

Documenting properties

The ASDoc tool automatically includes all public and protected properties in its output. You can document properties that are defined as variables or defined as setter and getter methods.

Documenting properties defined as variables

Place the ASDoc comment for a public or protected property that is defined as a variable just before the `var` declaration, as the following example shows:

```
/**
* The default label for MyButton.
*
* @default null
*/
public var myButtonLabel:String;
```

A best practice for a property is to include the `@default` tag to specify the default value of the property. The `@default` tag has the following format:

```
@default value
```

This tag generates the following text in the output for the property:

```
The default value is value.
```

For properties that have a calculated default value, or a complex description, omit the `@default` tag and describe the default value in text.

ActionScript lets you declare multiple properties in a single statement. However, this does not allow for unique documentation for each property. Such a statement can have only one ASDoc comment, which is copied for all properties in the statement. For example, the following documentation comment does not make sense when written as a single declaration and would be better handled as two declarations:

```
/**
* The horizontal and vertical distances of point (x,y)
*/
public var x, y;// Avoid this
```

ASDoc generates the following documentation from the preceding code:

```
public var x
    The horizontal and vertical distances of point (x,y)

public var y
    The horizontal and vertical distances of point (x,y)
```

Documenting properties defined by setter and getter methods

Properties defined by setter and getter methods are handled in a special way by the ASDoc tool because these elements are used as if they were properties rather than methods. Therefore, ASDoc creates a property definition for an item that is defined by a setter or a getter method.

If you define a setter method and a getter method, insert a single ASDoc comment before the getter, and mark the setter as `@private`. Adobe recommends this practice because usually the getter comes first in the ActionScript file, as the following example shows:

```
/**
* Indicates whether or not the text field is enabled.
*/
public function get html():Boolean {};

/**
* @private
*/
public function set html(value:Boolean):void {};
```

The following rules define how ASDoc handles properties defined by setter and getter methods:

- If you precede a setter or getter method with an ASDoc comment, the comment is included in the output.
- If you define both a setter and a getter method, only a single ASDoc comment is needed – either before the setter or before the getter.
- If you define a setter method and a getter method, insert a single ASDoc comment before the getter, and mark the setter as `@private`.
- You do not have to define the setter method and getter method in any particular order, and they do not have to be consecutive in the source-code file.
- If you define just a getter method, the property is marked as read-only.
- If you define just a setter method, the property is marked as write only.
- If you define both a public setter and public getter method in a class, and you want to hide them by using the `@private` tag, they both must be marked `@private`.
- If you have only one public setter or getter method in a class, and it is marked `@private`, ASDoc applies normal `@private` rules and omits it from the output.
- A subclass always inherits its visible superclass setter and getter method definitions.

Documenting methods

The ASDoc tool automatically includes all public and protected methods in its output. Place the ASDoc comment for a public or protected method just before the `function` declaration, as the following example shows:

```
/**
* This is the typical format of a simple multiline documentation comment
* for the myMethod() method.
*
* <p>This is the second paragraph of the main description
* of the <code>myMethod</code> method.
* Notice that you do not use the paragraph tag in the
* first paragraph of the description.</p>
*
* @param param1 Describe param1 here.
* @param param2 Describe param2 here.
*
* @return A value of <code>true</code> means this;
* <code>false</code> means that.
*
* @see someOtherMethod
*/
public function myMethod(param1:String, param2:Number):Boolean {}
```

If the method takes an argument, include an `@param` tag for each argument to describe the argument. The order of the `@param` tags in the ASDoc comment must match the order of the arguments to the method. The `@param` tag has the following syntax:

```
@param paramName  description
```

Where *paramName* is the name of the argument and *description* is a description of the argument.

If the method returns a value, use the `@return` tag to describe the return value. The `@return` tag has the following syntax:

```
@return description
```

Where *description* describes the return value.

Documenting metadata

Flex uses metadata tags to define certain characteristics of a class. ASDoc recognizes some of these metadata tags to generate output. The metadata tags recognized by ASDoc include the following:

- `[Bindable]`
- `[DefaultProperty]`
- `[Deprecated]`
- `[Effect]`
- `[Event]`
- `[Exclude]`
- `[SkinPart]`
- `[SkinState]`
- `[Style]`

Some metadata tags take an ASDoc comment, such as `[Effect]` and `[Event]`. Other metadata tags, such as `[Bindable]` and `[DefaultProperty]` do not. If you put an ASDoc comment before a metadata tag that does not accept a comment, the comment is passed through to the next element in the class. If the next element in the class already has an ASDoc comment, the comment on the metadata tag is ignored.

For more information on the `[Exclude]` tag, see “Excluding an inherited element” on page 2244.

For more information on using these metadata tags in an application, see “Metadata tags in custom components” on page 2376.

Documenting bindable properties

A bindable property is any property that can be used as the source of a data binding expression. To mark a property as bindable, you insert the `[Bindable]` metadata tag before the property definition, or before the class definition to make all properties defined within the class bindable. The `[Bindable]` metadata tag does not take an ASDoc comment.

When a property is defined as bindable, ASDoc automatically adds the following line to the output for the property:

```
This property can be used as the source for data binding.
```

For more information on the `[Bindable]` metadata tag, see “Metadata tags in custom components” on page 2376.

Documenting default properties

The `[DefaultProperty]` metadata tag defines the name of the default property of the component when you use the component in an MXML file. The `[DefaultProperty]` metadata tag does not take an ASDoc comment.

When ASDoc encounters the `[DefaultProperty]` metadata tag, it automatically adds a line to the class description that specifies the default property. For example, see the List control in *ActionScript 3.0 Reference for the Adobe Flash Platform*.

For more information on the `[DefaultProperty]` metadata tag, see “Metadata tags in custom components” on page 2376.

Documenting deprecated properties

A class or class elements marked as deprecated is one which is considered obsolete, and whose use is discouraged. While the class or class element still works, its use can generate compiler warnings.

Insert the `[Deprecated]` metadata tag before a property, method, or class definition to mark that element as deprecated. The `[Deprecated]` metadata tag does not take an ASDoc comment.

The following example uses the `[Deprecated]` metadata tag to mark the dataProvider property as obsolete:

```
[Deprecated(replacement="MenuBarItem.data")]
public function set dataProvider(value:Object):void
{}
```

When ASDoc encounters the `[Deprecated]` metadata tag, it adds a line to the output marking the item as deprecated, and inserts a link to the replacement item.

The mxmlc command-line compiler supports the `show-deprecation-warnings` compiler option, which, when `true`, configures the compiler to issue deprecation warnings when your application uses deprecated elements. The default value is `true`.

For more information on the `[Deprecated]` metadata tag, see “Deprecated metadata tag” on page 2383.

Documenting skin states and skin parts

You use metadata tags to add information about skin parts and skin states to a class definition. Put the `[SkinPart]` metadata tag before a property definition in the source code file, and put the `[SkinState]` metadata tag at the top of the class definition.

The `[SkinPart]` metadata tag does not take an ASDoc comment. It is used to identify that a property corresponds to a skin part, as the following example shows:

```
[SkinPart(required="false")]
/**
*  A skin part that defines the  label of the button.
*/
public var labelElement:TextGraphicElement;
```

A property identified as a skin part appears in the ASDoc output in the Skin Part section, not in the Properties section. The ASDoc comment for the property appears in the Skin Part section.

The `[SkinState]` metadata tag takes an ASDoc comment describing the skin state, as the following example shows:

```
/**
*  Up State of the Button
*/
[SkinState("up")]
```

The ASDoc comment for the skin state appears in the Skin States section of the ASDoc output.

Documenting effects, events, and styles

You use metadata tags to add information about effects, events, and styles in a class definition. The `[Effect]`, `[Event]`, and `[Style]` metadata tags typically appear at the top of the class definition file. To document the metadata tags, insert an ASDoc comment before the metadata tag, as the following example shows:

```
/**
* Defines the name style.
*/
[Style "name"]
```

For events and effects, the metadata tag includes the name of the event class associated with the event or effect. The following example shows an event definition from the Flex mx.controls.Button class:

```
/**
* Dispatched when the user presses the Button control.
* If the <code>autoRepeat</code> property is <code>true</code>,
* this event is dispatched repeatedly as long as the button stays down.
*
* @eventType mx.events.FlexEvent.BUTTON_DOWN
*/
[Event(name="buttonDown", type="mx.events.FlexEvent")]
```

In the ASDoc comment for the `mx.events.FlexEvent.BUTTON_DOWN` constant, you insert a table that defines the values of the `bubbles`, `cancelable`, `target`, and `currentTarget` properties of the Event class, and any additional properties added by a subclass of Event. At the end of the ASDoc comment, you insert the `@eventType` tag so that ASDoc can find the comment, as the following example shows:

```
/**
* The FlexEvent.BUTTON_DOWN constant defines the value of the
* <code>type</code> property of the event object
* for a <code>buttonDown</code> event.
*
* <p>The properties of the event object have the following values:</p>
* <table class="innertable">
* <tr><th>Property</th><th>Value</th></tr>
* ...
* </table>
*
* @eventType buttonDown
*/
public static const BUTTON_DOWN:String = "buttonDown"
```

The ASDoc tool does several things for this event:

- In the output for the mx.controls.Button class, ASDoc creates a link to the event class specified by the `type` argument of the `[Event]` metadata tag.
- ASDoc copies the description of the `mx.events.FlexEvent.BUTTON_DOWN` constant to the description of the `buttonDown` event in the Button class.

  For a complete example, see the mx.controls.Button and mx.events.FlexEvent classes.

  For more information on the `[Effect]`, `[Event]`, and `[Style]` metadata tags, see “Metadata tags in custom components” on page 2376.

Documenting MXML files

An MXML file contains several types of elements, including MXML code, ActionScript code in `<fx:Script>` blocks, and metadata tags. The ASDoc tool supports all these element types so that you can generate ASDoc content for MXML files just as you can for ActionScript classes.

MXML files correspond to ActionScript classes where the superclass corresponds to the first tag in the MXML file. For an application file, that tag is the `<s:Application>` tag and therefore an MXML application file appears in the ASDoc output as a subclass of the Application class.

Documenting MXML elements

Use the following syntax to specify an ASDoc comment in an MXML file for an element defined in MXML:

```
<!--- asdoc comment -->
```

The comment must contain three dashes following the opening `<!` characters, and end with two dashes before the closing `>` character, as the following example shows:

```
<?xml version="1.0"?>
<!-- asdoc\MyVBox.mxml -->
<!---
    The class level comment for the component.
    This tag supports all ASDoc tags,
    and does not require a CDATA block.
-->
<mx:VBox xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <!---
        Comment for button
     -->
    <s:Button id="myButton" label="This button has a comment"/>
</mx:VBox>
```

In this example, the first comment is a standard XML comment ignored by ASDoc. The second comment precedes the root tag of the component and uses the three dashes to identify it as an ASDoc comment. An ASDoc comment on the root tag is equivalent to the ASDoc comment before an ActionScript class definition. Therefore, the comment appears at the top of the output ASDoc HTML file.

A leading dash at the beginning of each comment line, and any whitespace characters before the dash, are ignored, as the following example shows:

```
<!---
    - Comment for my class
    - which is implemented as mxml
-->
```

If you copy a comment from an ActionScript file that uses the /**, *, and **/ characters, those characters are also ignored, as the following example shows:

```
<!---
    /**
     * Comment for my class
     * which is implemented as mxml
     */
-->
<!---
    * Comment for my class
    * which is implemented as mxml
-->
```

All MXML elements in the file correspond to public properties of the component. The comment before the Button control defines the ASDoc comment for the public property named myButton of type mx.controls.Button.

You can use any ASDoc tags in these comments, including the `@see`, `@copy`, `@param`, `@return`, and other ASDoc comments.

The ASDoc command-line tool only processes elements of an MXML file that contain an `id` attribute. If the MXML element has an `id` attribute but no comment, the element appears in the ASDoc output with a blank comment. An MXML element with no `id` attribute is ignored, even if it is preceded by an ASDoc comment, as the following example shows:

```
<?xml version="1.0"?>
<!-- asdoc\MyVBoxID.mxml -->
<!---
    The class level comment for the component.
    This tag supports all ASDoc tags,
    and does not require a CDATA block.
    @see mx.container.VBox
-->
<mx:VBox xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <!---
        Comment for first button appears in the output.
     -->
    <s:Button id="myButton" label="This button has a comment"/>
    <s:Button id="myButton2"
        label="Has id but no comment so appears in output"/>
    <!---
        Comment for button with no id is ignored by ASDoc.
     -->
    <s:Button label="This button has no id"/>
</mx:VBox>
```

Comments before Definition, Library, and Private tags are ignored. Also comments inside a private block are ignored.

Documenting ActionScript in <fx:Script> blocks

Insert ASDoc comments for ActionScript code in the `<fx:Script>` block by using the same syntax as you use in an ActionScript file. The only requirement is that the ASDoc comments must be within a `CDATA` block, as the following example shows:

```
<?xml version="1.0"?>
<!-- asdoc\MyVBoxComplex.mxml -->
<!---
    The class level comment for the component.
    This tag supports all ASDoc tags,
    and does not require a CDATA block.
-->
<mx:VBox xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <!---
        Comment for language element - this comment will be ignored.
    -->
    <fx:Script>
        <![CDATA[
            import flash.events.MouseEvent;
            /**
             * For a method in an &lt;Script&gt; block,
             * same rules as in an AS file.
             *
             * @param eventObj The event object.
             */
            public function handleClickEvent(eventObj:MouseEvent):void {
                dispatchEvent(eventObj);
            }
            /**
             * For a property in an &lt;Script&gt; block,
             * same rules as in an AS file.
             */
            public var myString:String = new String();

        ]]>
    </fx:Script>
    <!---
        Comment for first button appears in the output.
     -->
    <s:Button id="myButton" label="This button has a comment"
        click="handleClickEvent(event);"/>
    <s:Button id="myButton2"
        label="Has id but no comment so appears in output"/>
    <!---
        Comment for button with no id is ignored by ASDoc.
     -->
    <s:Button label="This button has no id"/>
</mx:VBox>
```

Documenting MXML declarations

You can add ASDoc comments to `<fx:Declaration>` blocks in MXML, as the following example shows:

```
<fx:Declarations>
    <!---
        Specifies the skin for the first button on the ButtonBar.
        @default spark.skins.default.ButtonBarFirstButtonSkin
    -->
    <fx:Component id="firstButton">
        <s:ButtonBarButton skinClass="spark.skins.default.ButtonBarFirstButtonSkin"       />
    </fx:Component>
</fx:Declarations>
```

Documenting metadata tags

You can insert ASDoc comments for metadata tags in `<fx:Metadata>` blocks in an MXML file. For metadata tags, the ASDoc comments use the same syntax as you us in an ActionScript file. The only requirement is that the ASDoc comments must be within a `CDATA` block, as the following example shows:

```
<?xml version="1.0"?>
<!-- asdoc\MyVBoxMetaData.mxml -->
<!---
    The class level comment for the component.
    This tag supports all ASDoc tags,
    and does not require a CDATA block.
-->
<mx:VBox xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <!---
        Comment for language element - this comment will be ignored.
    -->
    <fx:Script>
        <![CDATA[
            import flash.events.MouseEvent;
            /**
             * For a method in an &lt;Script&gt; block,
             * same rules as in an AS file.
             *
             * @param eventObj The event object.
             */
            public function handleClickEvent(eventObj:MouseEvent):void {
                dispatchEvent(eventObj);
            }

            /**
             * For a property in an &lt;Script&gt; block,
             * same rules as in an AS file.
             */
            public var myString:String = new String();

        ]]>
    </fx:Script>

    <fx:Metadata>
         <![CDATA[
        /**
         * Defines the default style of selected text.
         */
        [Style(name="textSelectedColor",type="Number",format="Color",inherit="yes")]

        /**
```

```
         * The component dispatches the darken event
         * when the darken property changes.
         *
         *  @eventType flash.events.Event
         */
        [Event(name="darken", type="flash.events.Event")]

        /**
         * Played when the component darkens.
         */
        [Effect(name="darkenEffect", event="darken")]
         ]]>

    <!---
        Comment for first button appears in the output.
     -->
    <s:Button id="myButton" label="This button has a comment"
        click="handleClickEvent(event);"/>
</mx:VBox>
```

ASDoc tags

The following table lists the ASDoc tags:

ASDoc tag	Description	Example
@copy reference	Copies an ASDoc comment from the referenced location. The main description, @param, and @return content is copied; other tags are not copied. You typically use the @copy tag to copy information from a source class or interface not in the inheritance list of the destination class. If the source class or interface is in the inheritance list, use the @inheritDoc tag instead. You can add content to the ASDoc comment before the @copy tag. Specify the location by using the same syntax as you do for the @see tag. For more information, see "Using the @see tag" on page 2259.	@copy #stop @copy flash.display.MovieClip#stop()
@default *value*	Specifies the default value for a property, style, or effect. The ASDoc tool automatically creates a sentence in the following form when it encounters an @default tag: The default value is *value*.	@default 0xCCCCCC
@eventType *package.class.CONSTANT*@eventType *String*	Use the first form in a comment for an [Event] metadata tag. It specifies the constant that defines the value of the Event.type property of the event object associated with the event. The ASDoc tool copies the description of the event constant to the referencing class. Use the second form in the comment for the constant definition. It specifies the name of the event associated with the constant. If the tag is omitted, ASDoc cannot copy the constant's comment to a referencing class.	See "Documenting effects, events, and styles" on page 2250

@example *exampleText*	Defines a code example in an ASDoc comment. By preceding the code example with this tag, ASDoc applies style properties, generates a heading, and puts the code example in the correct location.
	Enclose the code in <listing version="3.0"></listing> tags.
	Whitespace formatting is preserved and the code is displayed in a gray, horizontally scrolling box.
	If the code inside the <listing> tags uses literal "<", ">", or"&" characters, convert them to the HTML character-code equivalent.
		@example The following code sets the volume level for your sound:
		<listing version="3.0">
		var mySound:Sound = new Sound();
		mySound.setVolume(VOL_HIGH);
		</listing>

@exampleText *string*	Use this tag in an ASDoc comment in an external example file that is referenced by the @includeExample tag. The ASDoc comment must precede the first line of the example, or follow the last line of the example. External example files support one comment before and one comment after example code.	/** * This text does not appear * in the output. * @exampleText But this does. */

ASDoc tag	**Description**	**Example**
`@includeExample` ***`textFile`***	Imports an example text file into the ASDoc output. ASDoc searches for the example file based on the package name of the class and the directory specified by the `-examples-path` option to the ASDoc tool. For example, you use the `examples-path` option to set the directory to c:\examples. To add an example for the mx.controls.Button class, place it in the mx\controls\directory under c:\examples, meaning the c:\examples\mx\controls directory. You can further qualify the location of the file by specifying a path to the `@includeExample` tag. For example, you specify the `@includeExample` as shown below: `@includeExample buttonExample/ButtonExample.mxml` ASDoc looks for an example in the directory c:\examples\mx\controls\buttonExample. If you insert this tag in the comment for a class, the example appears at the end of the output HTML file. If you insert it in the ASDoc comment for a class element, the example appears in the detailed description of the element.	`@includeExample ButtonExample.mxml`
`@inheritDoc`	Copies the comment from the superclass into the subclass, or from an interface implemented by the subclass. Use this tag in the comment of an overridden method or property. You cannot use this tag with comments on metadata tags. The main ASDoc comment, `@param`, and `@return` content are copied; other tags are not. You can add content to the comment before the `@inheritDoc` tag. When you include this tag, ASDoc uses the following search order: 1. Interfaces implemented by the current class, in alphabetical order of the package and class name, and all their base-interfaces. 2. Immediate superclass of current class. 3. Interfaces of immediate superclass and all their base-interfaces. 4. Repeat steps 2 and 3 until the Object class is reached. You can also use the `@copy` tag, but the `@copy` tag is for copying information from a source class or interface that is not in the inheritance chain of the subclass.	`@inheritDoc`
`@internal` *`text`*	Hides the text attached to the tag in the generated output. The hidden text can be used for internal comments.	`@internal Please do not publicize the undocumented use of the third parameter in this method.`

ASDoc tag	Description	Example
`@param` *`paramNamedescription`*	Adds a descriptive comment to a method parameter. The ***`paramName`*** argument must match a parameter definition in the method signature.	`@param fileName The name of the file to load.`
`@private`	Exclude the element from the generated output. To omit an entire class, put the `@private` tag in the ASDoc comment for the class; to omit a single class element, put the `@private` tag in the ASDoc comment for the element.	`@private`
`@return` *`description`*	Adds a Returns section to a method description with the specified text. ASDoc automatically determines the data type of the return value.	`@return The translated message.`
`@see` *`reference[displayText]`*	Adds a See Also heading with a link to a class element. For more information, see "Using the @see tag" on page 2259. Do not include HTML formatting characters in the arguments to the `@see` tag.	`@see flash.display.MovieClip`
`@since` ***`text`***	Adds a Since section to a class or element.	`@since January 12, 2009`
`@throws` *`package.class.className description`*	Documents an error that a method can throw.	`@throws SecurityError Local untrusted SWFs may not communicate with the Internet.`

Using the @see tag

The `@see` tag lets you create cross-references to elements within a class; to elements in other classes in the same package; and to other packages. You can also cross-reference URLs outside ASDoc. The `@see` tag has the following syntax:

```
@see reference [displayText]
```

where *reference* specifies the destination of the link, and *displayText* optionally specifies the link text. The location of the destination of the `@see` tag is determined by the prefix to the *reference* attribute:

- `#` ASDoc looks in the same class for the link destination.
- *ClassName* ASDoc looks in a class in the same package for the link destination.
- *PackageName* ASDoc looks in a different package for the link destination.
- `effect` ASDoc looks for an effect property for the link destination.
- `event` ASDoc looks for an event property for the link destination.
- `style` ASDoc looks for a style property for the link destination.

***Note:** You cannot insert HTML tags in reference. However, you can add an HTML link without using the `@see` tag by inserting the HTML code in the ASDoc comment.*

The following table shows several examples of the `@see` tag:

Example	Result
@see "Just a label"	Text string
@see http://www.cnn.com	External web site
@see package-detail.html	Local HTML file
@see AccessibilityProperties	Class in same package
@see flash.display.TextField	Class in different package
@see flash.ui.ContextMenu#customItems	Property in class in different package
@see mx.containers.DividedBox#style:dividerAffordance	Style property in class in different package
@see #updateProperties()	Method in same class as @see tag
@see flash.ui.ContextMenu#clone()	Method in class in different package
@see flash.util.#clearInterval()	Package method in flash.util
@see mx.controls.Buttont#style:horizontalGap	Style property in Button class.
@see mx.containers.Accordion#event:change	Event in Accordion class.
@see mx.core.UIComponent#effect:creationCompleteEffect	Effect property in UIComponent class.

Summary of commonly used HTML elements

Write the text of an ASDoc comment in XHTML-compliant HTML. That means your HTML syntax has to conform to XML syntax rules. For example, close all HTML tags, such as `<p>` and `<code>` tags, by inserting the closing `</p>` or `</code>` tag.

The following table lists commonly used HTML tags and character codes within ASDoc comments:

Tag or Code	Description

`<p>`	Starts a new paragraph. You must close `<p>` tags.
	Do not use `<p>` for the first paragraph of a doc comment (the paragraph after the opening `/**`) or the first paragraph associated with a tag. Use the `<p>` tag for subsequent; for example:
	`/**`
	`* The first sentence of a main description.`
	`*`
	`* <p>This line starts a new paragraph.</p>`
	`*`
	`* <p>This line starts a third paragraph.</p>`
	`*/`
	ASDoc ignores white space in comments. To add white space for readability in the AS file, do not use the `<p>` tag but add blank lines.

`class="hide"`	Hides text. Use this tag if you want to add documentation to the source file but do not want it to appear in the output.
`<listing>`	Indicates a program listing (sample code). Use this tag to enclose code snippets that you format as separate paragraphs, in monospace font, and in a gray background to distinguish the code from surrounding text. Close all `<listing>` tags.

Tag or Code	Description
<pre>	Formats text in monospace font, such as a description of an algorithm or a formula. Do not use <br/> tags at end of line. Use <listing> tag for code snippets.
<br/>	Adds a line break. You must close this tag. Comments for most tags are automatically formatted; you do not generally have to add line breaks. To create additional white space, add a new paragraph instead. This tag might not be supported in the future, so use it only if necessary.
<ul>, <li>	Creates a list. You must close these tags.
<table><th><tr><td>	Creates a table. For basic tables that conform to ASDoc style, set the class attribute to `innertable`. Avoid setting any special attributes. Avoid nesting structural items, such as lists, within tables. ASDoc uses a standard CSS stylesheet that has definitions for the <table>, <th>, <tr> and <td> tags. You must close these tags. Use <th> for header cells instead of <td>, so the headers get formatted correctly.
<img>	Inserts an image. To create the correct amount of space around an image, enclose the image reference in <p></p> tags. Captions are optional; if you use a caption, make it boldface. You must close the <img> tag by ending it with />, as the following example shows: `<img src = "../../images/matrix.jpg" />`
<code>	Applies monospace formatting. You must close this tag.
<strong>	Applies bold text formatting. You must close this tag.
<em>	Applies italic formatting. You must close this tag.
&lt;	Less-than operator (<) . Ensure that you include the final semicolon (;).
&gt;	Greater-than operator (>). Ensure that you include the final semicolon (;).
&#38;	Ampersand (&). Do not use &amp;. Ensure that you include the final semicolon (;).
&#42;	Do not use a literal "*" character in the body of a comment; instead, insert the HTML character code &#42;.
&#x2014;	Em dash. Ensure that you include the final semicolon (;).
&#x99;	Trademark symbol (™) that is not registered. This character is superscript by default, so do not enclose it in <sup> tags. Ensure that you include the final semicolon (;).
&#xA0;	Nonbreaking space. Ensure that you include the final semicolon (;).
&#xAE;	Registered trademark symbol (®). Enclose this character in <sup> tags to make it superscript. Ensure that you include the final semicolon (;).
&#xB0;	Degree symbol. Ensure that you include the final semicolon (;).
&#64;	Do not use an @ sign in an ASDoc comment; instead, insert the HTML character code: &#64;.

Using the ASDoc tool

The ASDoc tool, `asdoc`, is in the flex\bin directory of a Flex installation. To run the ASDoc tool, make sure that you either first change to the bin directory, or you add the bin directory to your system path.

To see a list of the command-line options available to the ASDoc tool, use the `-help list` option, as the following example shows:

```
asdoc -help list
```

By default, the ASDoc tool compiles its input files against the library SWC files in the flex\frameworks\libs directory in your Flex installation. If you must add additional SWC files to compile your code, you can add them by using the `library-path` option to specify the directory containing the SWC files:

```
asdoc ... -library-path+=C:\myLibs
```

You can also use a Flex Ant task to run the ASDoc tool. For more information, see "Using the asdoc task" on page 2353.

Defining the input files to the ASDoc tool

Use the following options to specify the list of classes processed by the `asdoc` command: `doc-sources`, `doc-classes`, and `doc-namespaces`. The `doc-classes` and `doc-namespaces` options require you to specify the `source-path` option to specify the root directory of your files.

Note: *The examples below assume that you installed Flex in the c:\flex directory on your machine. All the Flex source code is then available in the C:\flex\frameworks\projects directory.*

The most basic example is to specify the path to a single class by using the `doc-sources` option, as the following example shows:

```
asdoc -doc-sources C:\flex\frameworks\projects\framework\src\mx\controls\Button.as
    -output framework-asdoc
```

This example generates ASDoc content for the Flex Button control shipped with Flex, and writes the output to the flex\bin\framework-asdoc directory.

You can specify multiple input class files, separated by spaces, as the following example shows:

```
asdoc -doc-sources C:\flex\frameworks\projects\framework\src\mx\controls\Button.as
    C:\flex\frameworks\projects\framework\src\mx\controls\ButtonBar.as
    -output framework-asdoc
```

The two previous examples use the `output` option to the directory that contains the ASDoc output. You can specify an absolute or relative path. In the previous example, the output directory is named framework-output relative to the current working directory. To view the output of your ASDoc build, open the index.html file in the output directory.

The `doc-sources` option takes a directory as an argument, as well as a file list. If you specify a directory, the ASDoc tool generates output for all files in the specified directory and any subdirectories. Use this option to build ASDoc output for all the files in the C:\flex\frameworks\projects\framework\src\mx\controls directory, as the following example shows:

```
asdoc -doc-sources C:\flex\frameworks\projects\framework\src\mx\controls
    -output framework-asdoc
```

You can specify multiple directories, separated by spaces.

Use the `doc-classes` option to specify the package and class name of a file to process. Use the `doc-classes` option with the `source-path` option, as the following example shows:

```
asdoc -source-path C:\flex\frameworks\projects\framework\src
    -doc-classes mx.controls.Button mx.controls.ButtonBar
    -output framework-asdoc
```

The `source-path` option adds directories to the source path. The ASDoc tool searches directories in the source path for the files to process. The value to the `doc-classes` option is a space delimited list of input files that use dot notation to specify the package name of each class.

You can combine the `doc-sources` and `doc-classes` options to specify the input to the ASDoc tool, as the following example shows:

```
asdoc -source-path C:\flex\frameworks\projects\framework\src
    -doc-classes mx.controls.Button mx.controls.ButtonBar
    -doc-sources C:\flex\frameworks\projects\framework\src\mx\validators
    -output framework-asdoc
```

In this example, you compile all the validator classes as well as the Button and ButtonBar components.

Compiling dependent files

When performing a build, the ASDoc tool compiles the input files and also attempts to compile any dependent files referenced by the input files. For example, you specify class A as an input by using the `doc-classes` option. If class A imports class B, both class A and class B are compiled and included in the ASDoc output.

The following example specifies only the mx.controls.Button class as input:

```
asdoc -source-path C:\flex\frameworks\projects\framework\src
    -doc-classes mx.controls.Button
    -output framework-asdoc
```

The output of the build includes the mx.controls.Button class, plus any class referenced by the Button class, and any classes referenced by classes referenced by Button. The compiler uses the `source-path` option to locate these dependent classes.

If you set the `exclude-dependencies` option to `true`, dependent classes found when compiling the input classes are not documented. The default value is `false`, which means any classes that would normally be compiled along with the specified classes are documented.

The following example generates ASDoc content only for the Button class:

```
asdoc
    -source-path C:\flex\frameworks\projects\framework\src
    -doc-classes mx.controls.Button
    -output framework-asdoc
    -exclude-dependencies=true
```

Setting the `exclude-dependencies` option to `true` improves the performance of the ASDoc tool because you do not have to build output for all dependent classes.

***Note:** You cannot use `exclude-dependencies` with input class specified by the `doc-sources` option.*

Adding package descriptions

To add package descriptions to the output, you can use the `package` or `package-description-file` options of ASDoc.

The `package` option lets you specify the descriptions on the ASDoc command line. You can specify more than one `package` option. The following example adds two package descriptions to the output:

```
asdoc -doc-sources my_dir -output myDoc
    -package com.my.business "Contains business classes and interfaces"
    -package com.my.commands "Contains command base classes and interfaces"
```

If you have many packages, you can use the `package-description-file` option to specify an XML file that contains the descriptions, as the following example shows:

```
asdoc -source-path C:\\flex\sdk\frameworks\projects\framework\src
    -doc-classes mx.controls.Button mx.controls.ButtonBar
    -package-description-file myPackages.xml -output myDoc
```

In this example, the package descriptions are located in the myPackages.xml file. The file specified by the `package-description-file` option has the following format:

```
<overviews>
    <packages>
        <package name="package.name1">
            <shortDescription>
                <![CDATA[
                    Short description appears on the All Packages page.
                ]]>
            </shortDescription>
            <description>
                <![CDATA[
                    Long description appears on the package page.
                ]]>
            </description>
        </package>
    </packages>
</overviews>
```

For example:

```
<overviews>
    <packages>
        <package name="mx.core">
            <shortDescription>
                <![CDATA[
                    The &lt;b&gt;mx.core package&lt;/b&gt; contains the
                    base classes and interfaces.
                ]]>
            </shortDescription>
            <description>
                <![CDATA[
                    The mx.core package contains the
                    base classes and interfaces,
                    such as UIComponent, used by Flex.
                ]]>
            </description>
        </package>
        <package name="mx.controls">
            <shortDescription>
                <![CDATA[
                    The mx.controls package contains
                    the Flex user-interface controls.
                ]]>
            </shortDescription>
            <description>
                <![CDATA[
                    The mx.controls package contains
                    the Flex user-interface controls.
                ]]>
            </description>
        </package>
    </packages>
</overviews>
```

Notice that the HTML tag for bold text is entered by using the HTML character code for the “<“ and “>” characters.

Using a manifest file as input

If your source code is packaged for distribution as a SWC file, you can use a manifest file to define the content of the SWC file. You can use a manifest file as input to the ASDoc tool to specify the input file list as the following example shows:

```
asdoc
    -source-path C:\a\flex\flex\sdk\frameworks\projects\framework\src
    -doc-classes FrameworkClasses
    -namespace http://www.adobe.com/2006/mxml
C:\flex\sdk\frameworks\projects\framework\manifest.xml
    -doc-namespaces http://www.adobe.com/2006/mxml
    -output framework-asdoc
```

The preceding command line generates ASDoc content for all classes in the Flex framework.swc file. Notice that your specify the FrameworkClasses class file as input using the `doc-classes` option, and the manifest file by using the `doc-namespace` option. Most Flex SWC files are represented by a class file and a manifest file. Therefore, to build ASDoc for the SWC file, you specify both as input.

For more information on manifest files, see "About manifest files" on page 2206.

Excluding classes

All the classes specified by the `doc-classes`, `doc-sources`, and `doc-namespaces` options are documented, with the following exceptions:

- If you specified the class by using the `exclude-classes` option, the class is not documented. You must specify the package name of the files to omit, such as mx.controls.Button, separated by spaces.
- If the ASDoc comment for the class contains the `@private` tag, the class is not documented.
- If the class is found in a SWC, the class is not documented.

In the following example, you generate output for all classes in the current directory and its subdirectories, except for the two classes comps\PageWidget and comps\ScreenWidget.as:

```
asdoc -source-path . -doc-sources . -exclude-classes comps.PageWidget comps.ScreenWidget
```

The excluded classes are still compiled along with all the other input classes; only their content in the output is suppressed.

Use the `exclude-sources` option to exclude a file from being input to the compilation. This option is different from the `exclude-classes` option which you use to exclude a class from the output. However, the `exclude-classes` option still compiles the specified class. When you specify a class by using the `exclude-sources` option, the class is not even compiled.

***Note:** You can only exclude classes added by the `doc-sources` option, not classes added by the `doc-namespaces` or `doc-classes` options.*

For example, the Flex mx/core package contains several include files that are not stand-alone classes, but files included by other classes. If you specify `doc-sources` for mx/core, you get compiler errors because the compiler tries to process all the files in the directory. Instead, you can use the `exclude-source` option to specify the full path to the files to ignore from the compilation, as the following example shows. Specify multiple paths separated by spaces, as the following example shows:

```
asdoc
    -doc-sources C:\a\flex\flex\sdk\frameworks\projects\framework\src\mx\core
    -exclude-sources C:\a\flex\flex\sdk\frameworks\projects\framework\src\mx\core\Version.as
```

Excluding a namespace

To exclude an entire namespace from ASDoc, edit the ASDoc_Config_Base.xml file in the asdoc\templates directory of your Flex installation.

***Note:** Do not edit any other settings in the ASDoc_Config_Base.xml file. Set all other options from the asdoc command line.*

For each namespace that you want to exclude, add a new `<namespace>` tag to the `<namespaces>` tag in the ASDoc_Config_Base.xml file, as the following example shows:

```
<namespaces hideAll="false">
...
    <namespace hide="true">my_custom_namespace</namespace>
</namepaces>
```

Adding ASDoc XML files to a SWC files

Flex SWC files include a docs folder that contains the intermediate XML files created by the ASDoc tool. These files are used by Adobe® Flash® Builder™ to show code hints and documentation.

You can add these XML files to your own SWC files. Normally, these intermediate XML files are deleted when the ASDoc tool completes. If you run the ASDoc tool with the `keep-xml` and `skip-xsl` options set to `true`, the XML files are retained.

By default, the ASDoc tool writes these XML files to the tempdita directory in the output directory of your build. You have to manually package them in your SWC file.

Handling ASDoc errors

The ASDoc tool compiles all the input source files to generate its output. Therefore, your source code must be valid to generate ASDoc output. The ASDoc tool writes any compilation, such as syntax errors, errors to the console window.

Errors in ASDoc comments are not compilation errors but they do cancel the ASDoc build. For example, you can cause an error in an ASDoc comment by omitting a closing `</code>` or `</p>` tag. The source code still compiles, but ASDoc fails because it cannot generate the output.

The following example shows the error message for an ASDoc comment that omits a closing `</code>` tag:

```
[Fatal Error] :10:5: The element type "code" must be terminated by the matching end-tag
"</code>".
Encountered not well-formed text. Please see C:\flex\bin\framework-asdoc\validation_errors.log
for details.
```

The error message describes the condition that caused the error, and specifies to view the validation_errors.log file for more information. The validation_errors.log file contains additional information that describes the error and the location of the error in the input file.

Use the `lenient` option to configure the ASDoc tool to generate output even when it encounters an error in an ASDoc comment. When specified, the `lenient` option causes the tool to omit the incorrect ASDoc comment from the output, but to complete the build. The following example uses the `lenient` option:

```
asdoc -doc-sources C:\flex\frameworks\projects\framework\src\mx\controls\Button.as
    -lenient
    -output framework-asdoc
```

With the `lenient` option, you see the same error message, and the ASDoc tool writes the same information to the validation_errors.log file. But, the tool generates the output, as the following message shows:

```
[Fatal Error] :10:5: The element type "code" must be terminated by the matching end-tag
"</code>".
Encountered not well-formed text. Please see C:\flex\bin\framework-asdoc\validation_errors.log
for details.
Documentation was created in C:\flex\bin\framework-asdoc\
```

Using a configuration file with the ASDoc tool

Depending on the number of input files, the input specification to the ASDoc tool can get complex. To simplify it, you can use a configuration file with the ASDoc tool. The configuration file is an XML file that lets you specify the command-line arguments to the tool in a file. YOu then run the tool as show below:

```
asdoc -load-config+=configFileName.xml -output framework-asdoc
```

By default, the ASDoc tool uses the flex\frameworks\flex-config.xml configuration file. This configuration file contains many settings, including the location of the Flex SWC files required to compile the input files. You can want to look at this file for an example of the types of information that you can write to a configuration file.

The previous example uses the `load-config` option to specify the name of the configuration file. Notice that this option uses the += syntax to add configFileName.xml to the list of configuration files so that the tool still includes the flex\frameworks\flex-config.xml configuration file. If you use the = syntax to specify the name of the configuration file, you must also define much of the information in the flex\frameworks\flex-config.xml configuration file.

The following configuration file creates the same output as the example in the section "Using a manifest file as input" on page 2265 to generates ASDoc content for all classes in the Flex framework.swc file:

```
<?xml version="1.0"?>
<flex-config xmlns="http://www.adobe.com/2006/flex-config">
    <compiler>
        <source-path>
            <path-element>C:\flex\frameworks\projects\framework\src</path-element>
        </source-path>
        <namespaces>
            <namespace>
                <uri>http://www.adobe.com/2006/mxml</uri>
                <manifest>C:\flex\frameworks\projects\framework\manifest.xml</manifest>
            </namespace>
        </namespaces>
    </compiler>
    <doc-classes>
        <class>FrameworkClasses</class>
    </doc-classes>

    <doc-namespaces>
        <uri>http://www.adobe.com/2006/mxml</uri>
    </doc-namespaces>
</flex-config>
```

For more information on configuration files, see "About configuration files" on page 2171.

Options to the asdoc tool

The `asdoc` tool works the same way as the mxmlc compiler and takes all the same command-line options. For more information on mxmlc, see "Flex compilers" on page 2164.

The following table lists the command-line options specific to the `asdoc` tool:

Option	Description
`-doc-classes` *`path-element [...]`*	A list of classes to document. These classes must be in the source path. This is the default option. This option works the same way as does the -include-classes option for the `compc` component compiler. For more information, see "Using compc, the component compiler" on page 2194.
`-doc-namespaces` *`uri manifest`*	A list of URIs to document. The classes must be in the source path. You must include a URI and the location of the manifest file that defines the contents of this namespace. This option works the same way as does the -include-namespaces option for the `compc` component compiler. For more information, see "Using compc, the component compiler" on page 2194.
`-doc-sources` *`path-element [...]`*	A list of files to document. If a directory name is in the list, it is recursively searched. This option works the same way as does the -include-sources option for the `compc` component compiler. For more information, see "Using compc, the component compiler" on page 2194.
`-examples-path` ***`path-element`***	Specifies the location of the include examples used by the `@includeExample` tag. This option specifies the root directory. The examples must be located under this directory in subdirectories that correspond to the package name of the class. For example, you specify the `examples-path` as c:\myExamples. For a class in the package myComp.myClass, the example must be in the directory c:\myExamples\myComp.myClass.
`-exclude-classes` *`string`*	A list of classes not documented. You must specify individual class names. Alternatively, if the ASDoc comment for the class contains the `@private` tag, is not documented.
`-exclude-dependencies true|false`	Whether all dependencies found by the compiler are documented. If `true`, the dependencies of the input classes are not documented. The default value is `false`.
`-exclude-sources` ***`path-element [...]`***	Exclude a file from compilation. This option is different from the `-exclude-classes` option which you use to exclude a class from the output. However, the `-exclude-classes` option still compiles the specified class. You can only exclude classes added by the `doc-sources` option, not classes added by the `doc-namespaces` or `doc-classes` options.
`-footer` *`string`*	The text that appears at the bottom of the HTML pages in the output documentation.
`-keep-xml=false|true`	When `true`, retain the intermediate XML files created by the ASDoc tool. The default value is `false`.
`-left-frameset-width` *`int`*	An integer that changes the width of the left frameset of the documentation. You can change this size to accommodate the length of your package names. The default value is 210 pixels.
`-lenient`	Ignore XHTML errors (such as a missing </p> tag) and produce the ASDoc output. All errors are written to the validation_errors.log file.
`-main-title` *`"string"`*	The text that appears at the top of the HTML pages in the output documentation. The default value is "`API Documentation`".
`-output` *`string`*	The output directory for the generated documentation. The default value is "`asdoc-output`".

Option	**Description**
`-package` *`name"description"`*	The descriptions to use when describing a package in the documentation. You can specify more than one `package` option. The following example adds two package descriptions to the output: `asdoc -doc-sources my_dir -output myDoc -package com.my.business "Contains business classes and interfaces" -package com.my.commands "Contains command base classes and interfaces"`
`-package-description-file`*fileName*	Specifies an XML file containing the package descriptions.
`-skip-xsl=false|true`	When `true`, configures the ASDoc tool to generate the intermediate XML files only, and not perform the final conversion to HTML. The default value is `false`.
`-strict=false|true`	Disable strict compilation mode. By default, classes that do not define constructors, or contain methods that do not define return values cause compiler failures. If necessary, set `strict` to `false` to override this default and continue compilation.
`-templates-path` *`string`*	The path to the ASDoc template directory. The default is the asdoc/templates directory in the ASDoc installation directory. This directory contains all the HTML, CSS, XSL, and image files used for generating the output.
`-window-title` *`"string"`*	The text that appears in the browser window in the output documentation. The default value is "`API Documentation`".

The `asdoc` command also recognizes the following options from the compc component compiler:

- `-source-path`
- `-library-path`
- `-namespace`
- `-load-config`
- `-actionscript-file-encoding`
- `-help`
- `-advanced`
- `-benchmark`
- `-strict`
- `-warnings`

  For more information, see “Using mxmlc, the application compiler” on page 2174. All other application compiler options are accepted but ignored so that you can use the same command-lines and configuration files for the ASDoc tool that you can use for mxmlc and compc.

Chapter 9: Testing and automation

Creating applications for testing

You can create applications and components that can be tested with automated testing tools such as HP QuickTest Professional™ (QTP). The information in this topic is intended for Adobe® Flex™ developers who write applications that are tested by Quality Control (QC) professionals who use these testing tools. For information on installing and running the Flex plug-in with QTP, QC professionals should see *Testing Adobe Flex Applications with HP QuickTest Professional*.

Full support for the Flex automation features is included in Adobe® Flash® Builder™ Premium. Adobe Flash Builder Standard allows only limited use of this feature.

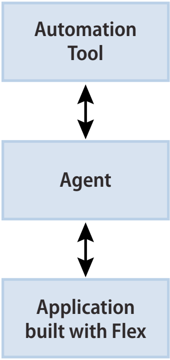
About automating applications with Flex

The automation feature provides developers with the ability to create applications that use the automation APIs. You can use these APIs to create automation agents or to ensure that your applications are ready for testing. In addition, the automation feature includes support for the QTP automation tool.

When working with the automation APIs, you should understand the following terms:

- *automation agent* (or, simply, *agent*) — An agent facilitates communication between an application and an automation tool. The Flex Automation Package includes a plugin that acts as an agent between your applications and the QTP testing tool.
- *automation tool* — Automation tools are applications that use the data that is derived through the agent. These tools include QTP, Omniture, and Segue.
- *delegates* — Flex framework components are instrumented by attaching a delegate class to each component at run time. The *delegate class* defines the methods and properties required to perform instrumentation.

The following illustration shows the relationship between an application, an agent, and an automation tool.



As this illustration shows, the automation tool uses an agent to communicate with the application built with Flex. The agent can be an ActiveX control or other type of utility that fascilitates the interaction between the tool and the application.

The Flex automation feature includes the following:

- Automation libraries — The SWC files in the libs/automation directory are the implementations of the automation API for the Flex framework components. The following table describes these SWC files.

SWC file	Description
automation.swc	Provides the delegates for the core Flex classes. This includes the Halo component set.
automation_agent.swc	Provides the classes for creating a custom agent.
automation_dmv.swc	Provides the delegates for the Flex charting and AdvancedDataGrid classes.
automation_air.swc	Provides the delegates for AIR.
automation_airspark.swc	Provides the delegates for the Spark components that are used in AIR.
automation_spark.swc	Provides the delegates for the Spark component set.
automation_flashflexkit.swc	Provides the delegates for the FlashFlexKit.
qtp.swc	Provides the classes that allow QTP to communicate with an application built with Flex.
qtp_air.swc	Provides the classes that allow QTP to communicate with AIR applications.

- QTP files — The QTP files let QTP and applications built with Flex communicate directly. You can only use these files if you also have QTP. These files include the QTP plug-in, a QTP demonstration video, a QTP-specific environment XML file, and the QTP-specific libraries, qtp.swc and qtp_air.swc. For more information, see *Testing Adobe Flex Applications with HP QuickTest Professional*.

Tasks and techniques for testable applications overview

Flex developers should review the information about tasks and techniques for creating testable applications, and then update their applications accordingly. QC testing professionals who use QTP should use the documentation provided in the separate book, *Testing Adobe Flex Applications with HP QuickTest Professional*. That document is available for download with the Flex plug-in for QTP.

Use the following general steps to create a testable application:

1. Review the guidelines for creating testable applications. For more information, see "Creating test-friendly applications" on page 2274.
2. Prepare the application to load the automation classes at run time or compile time.
   - To create an application that loads the automation classes at run time, you compile it as normal. At run time, you load your application into a wrapper SWF file that has the automation libraries built in. This wrapper SWF file uses the SWFLoader to load your application SWF file that you plan to test only at run time. For more information, see "Using run-time loading" on page 2273.
   - To compile an application that includes the automation classes, you include the needed automation libraries at compile time. Compile the application with the automation SWC files by using the compiler's `include-libraries` option. For information on the compilation process, see "Using compile-time loading" on page 2272.
3. Prepare customized components for testing. If you have custom components that extend UIComponent, make them testable. For more information, see "Instrumenting custom components" on page 2284.
4. Create an HTML wrapper that follows proper application naming practices. For more information, see "Writing the wrapper" on page 2277.

5 Deploy the application's assets to a web server. Assets can include the SWF file; HTML wrapper and related files; external assets such as theme files, graphics, and video files; module SWF files; resource modules; CSS SWF files; and run-time shared libraries (RSLs). For information about what files to deploy with your application, see "Deployment checklist" on page 2548.

Using compile-time loading

When you embed functional testing classes in your application SWF file at compile time, you increase the size of the SWF file. If the size of the application SWF file is not important, you can use the same SWF file for functional testing and deployment. If the size of the SWF file is important, you typically generate two SWF files: one with functional testing classes embedded and one without.

To compile a testable application, you must reference the necessary automation SWC files with the `include-libraries` compiler option. Typically, this includes the automation.swc and automation_spark.swc files. If your application uses charts or the AdvancedDataGrid classes, you must also add the automation_dmv.swc file. You might also be required to add automation tool-specific SWC files; for example, for QTP, you must also add the qtp.swc file to your application's library path. For a complete list of automation SWC files, see "About automating applications with Flex" on page 2270.

By default, Flash Builder includes the automation SWC files in its library path, but you must add these libraries by using the `include-libraries` compiler option.

Including automation SWC files

To include the SWC file in your application, you can add them to the compiler's configuration file or as a command-line option. For the SDK, the configuration file is located at *sdk_install_dir*/frameworks/flex-config.xml. To add the automation.swc and automation_spark.swc libraries, for example, add the following lines to the configuration file:

```
<include-libraries>
    <library>/libs/automation/automation.swc</library>
    <library>/libs/automation/automation_spark.swc</library>
</include-libraries>
```

You must uncomment the `include-libraries` code block. By default it is commented out in the configuration file.

You can also specify the location of the SWC files when you use the command-line compiler with the `include-libraries` compiler option. The following example adds the automation.swc and automation_spark.swc files to the application:

```
mxmlc -include-libraries+=../frameworks/libs/automation/automation.swc;
    ../frameworks/libs/automation/automation_spark.swc MyApp.mxml
```

Explicitly setting the `include-libraries` option on the command line overwrites, rather than appends, any existing libraries that you include in the configuration file. As a result, if you add the automation.swc and automation_spark.swc files by using the `include-libraries` option on the command line, ensure that you use the += operator. This does not overwrite the existing libraries that might be included.

To add automated testing support to a Flash Builder project, you also add the SWC files to the `include-libraries` compiler option.

Add SWC files to Flash Builder projects

1 In Flash Builder, select your Flex project in the Navigator.

2 Select Project > Properties. The Properties dialog box appears.

3 Select Flex Compiler in the tree to the left. The Flex Compiler properties panel appears.

4 In the "Additional compiler arguments" field, enter the following command:

```
-include-
libraries+="sdks\4.6.0\frameworks\libs\automation\automation.swc","sdks\4.6.0\frameworks\l
ibs\automation\automation_spark.swc"
```

In Flash Builder, the entries in the `include-libraries` compiler option are relative to the Flash Builder installation directory; the default location of this directory on Windows is C:\Program Files\Adobe\Flash Builder 4.6.

5 Click OK to save your changes.

Deploying the application

When you create the final release version of your application, you recompile the application without the references to the automation SWC files.

If you do not deploy your application to a server, but instead request it by using the file protocol or run it from within Adobe Flash Builder, you must put the SWF file into the local-trusted sandbox. This requires configuration information that is separate from the SWF file and the wrapper. For more information that is specific to QTP, see *Testing Adobe Flex Applications with HP QuickTest Professional*.

Using run-time loading

You can use the run-time testing files rather than compiling the automation libraries into your applications. This lets you test SWF files that have already been compiled without automated testing support. It also helps keep the SWF file size small. To do this, you use a SWF file that *does* include the automated testing libraries. In that SWF file, the SWFLoader class loads your application's SWF file which does not include the testing libraries. The result is that you can test the target SWF file in a testing tool such as QTP, even though the application SWF file was not compiled with automated testing support.

Flash Builder includes the following files necessary for run-time loading in the *flash_builder_install_dir*/sdks/4.6.0/templates/automation-runtimeloading-files directory:

- RunTimeLoading.html — The HTML wrapper that loads the run-time loader SWF file. This template includes code that converts the `automationswfurl` query string parameter to a `flashVars` variable that it passes to the application. You use this query string parameter to specify the name of the application you want to load and test.
- runtimeloading.mxml — The source code for the runtimeloading.swf file that you compile. The SWF file acts as a wrapper for your application. This SWF file includes the testing libraries so that you do not have to compile them into your application SWF file.

To use run-time loading:

1 Compile the runtimeloading.swf application from the runtimeloading.mxml file. You can use the batch file in the *flash_builder_install_dir*/sdks/4.6.0/templates/automation-runtimeloading-files directory. Execute this batch file from the sdks/4.6.0/frameworks directory. This batch file ensures that your runtimeloading.swf file includes the automation SWC files. You might need to add or remove SWC files to this file, depending on what features your application uses.

2 Deploy the runtimeloading.swf, RunTimeLoading.html, and your application's SWF file to a web server.

3 Request the RunTimeLoading.html file and pass the name of your SWF file as the value to the `automationswfurl` query string parameter. For example:

```
http://localhost/RunTimeLoading.html?automationswfurl=MyApp.swf
```

You can also create a custom HTML wrapper to use with the run-time loading feature, but it must use proper object naming. If you are using Flash Builder, you can generate a wrapper automatically. If you are using the SDK, you can use the wrapper template in the *flex_sdk*/templates/swfobject directory to create a wrapper for your application. When using a wrapper, the value of the `id` attributes can not contain any periods or hyphens.

If you want to recompile the runtimeloading.swf file without the batch file, be sure to include automated testing support by adding the appropriate automation SWC files with the `include-libraries` compiler option.

The batch file for compiling the runtimeloading.swf file is Windows only. To compile the SWF file on Mac OS or Linux, you can use the command line compiler or write your own batch file.

Creating test-friendly applications

As a Flex developer, there are some techniques that you can employ to make applications as “test friendly” as possible. One of the most important tasks that you can perform is to make sure that objects are identifiable in the testing tool’s scripts. This means that you should explicitly set the value of the `id` property or whatever property the testing tool uses to identify the object. Also be sure to use a meaningful string for that property so that the testing scripts are more readable. Finally, use unique IDs for each control so that the tool does not encounter ambiguous references.

Providing meaningful identification of objects

When working with testing tools such as QTP, a QC professional only sees the visual representation of objects in your application. A QC professional generally does not have access to the underlying code. When a QC professional records a script, it’s very helpful to see IDs that help the tester identify the object clearly. You should take some time to understand how testing tools interpret applications and determine what names to use for the test objects in the test scripts.

In most cases, testing tools use a visual cue, such as the label of a Button control, to identify the control in the script. Sometimes, however, testing tools use the Flex `id` property of an MXML tag to identify an object in the test script; if there is no value for the `id` property, testing tools use other properties, such as the `childIndex` property. In addition, the automation APIs provide an `automationName` property that you can use to explicitly set the ID of an object as it appears in the tool’s scripts.

You should give all testable MXML components an ID to ensure that the test script has a unique identifier to use when referring to that Flex control. You should also try to make these identifiers as human-readable as possible to make it easier for a QC professional to identify that object in the testing script. For example, set the `id` property of a Panel container inside a TabNavigator to *submit_panel* rather than *myPanel* or *p1*.

In some cases, agents do not use the `id` property, but it is a good practice to include it to avoid naming collisions or confusion. For more information about how QTP identifies Flex objects, see *Testing Adobe Flex Applications with HP QuickTest Professional*.

You should also set the value of the `automationName` property for all objects that are part of the application’s test. The value of this property appears in the testing scripts. Providing a meaningful name makes it easier for QC professionals to identify that object. For more information about using the `automationName` property, see “Setting the automationName property” on page 2289.

Avoiding renaming objects

Automation agents rely on the fact that some object’s properties should not be changed during run time. If you change the application property that is used by the agent as the object name at run time, unexpected results can occur.

For example, if you create a Button control without an `automationName` property, and you do not set the value of its `label` property during initialization, and then later set the value of the `label` property, the agent might get confused. This is because agents often use the value of the `label` property of a Button control to identify it in its object repository if the `automationName` property is not set. If you later set the value of the `label` property, or change the value of an existing `label` while the QC professional is recording a test, an automation tool such as QTP will create a new object in its repository instead of using the exising reference.

As a result, you should try to understand what properties are used to identify objects in the agent, and try to avoid changing those properties at run time. You should set unique, human-readable `id` or `automationName` properties for all objects that are included in the recorded script.

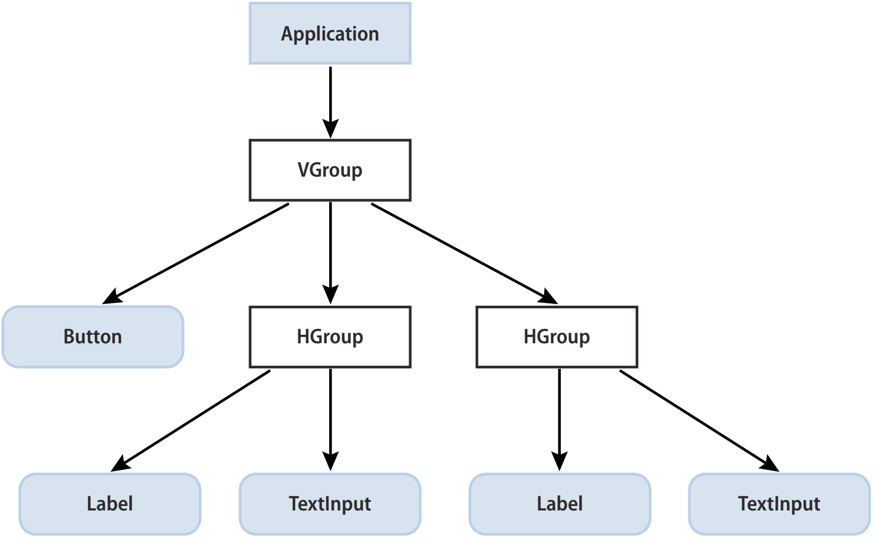
Coding containers

Containers are different from other kinds of controls because they are used both to record user interactions (such as when a user moves to the next pane in an Accordion container) and to provide layout logic.

Adding and removing containers from the automation hierarchy

In general, the automated testing tools reduce the amount of detail about nested containers in their scripts. They remove containers that have no impact on the results of the test or on the identification of the controls from the script. This applies to containers that are used exclusively for layout, such as the HGroup, VGroup and Canvas containers.

The following image shows the layout for a simple form-based application. The components with gray backgrounds appear in the automation tool's scripts because they can be interacted with by the user. Components with white backgrounds do not appear in the tool's scripts because they only provide layout logic.



Automation flowchart

In some cases, containers that are being used in multiple-view navigator containers, such as the ViewStack, TabNavigator or Accordion containers, do appear in the automation hierarchy. In these cases, they are added to the automation hierarchy to provide navigation.

Many composite components use containers, such as VGroup or HGroup, to organize their children. These containers do not have any visible impact on the application. So, these containers are usually excluded from the test scripts because there is no user interaction and no visual need for their operations to be recordable. By excluding a container from being tested, the test scripts are shorter and more readable.

To exclude a container from being recorded (but not exclude its children), set the container's `showInAutomationHierarchy` property to `false`. This property is defined by the UIComponent class, so all containers that subclass UIComponent have this property. Children of containers that are not visible in the hierarchy appear as children of the next highest visible parent. You can also use this property to exclude controls that you want to omit from testing, such as a Help button or decorative object.

The default value of the `showInAutomationHierarchy` property depends on the type of container. For containers that have visual elements or support user interaction, such as lists, Panel, Accordion, Application, DividedBox, and Form, the default value is `true`. For containers used exclusively for layout, such as Group, Canvas, Box, and FormItem, the default value is `false`.

The following example forces the VGroup containers to be included in the test script's hierarchy:

```
<?xml version="1.0"?>
<!-- agent/NestedButton.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:Panel title="ComboBox Control Example">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <s:HGroup id="hg">
            <s:VGroup id="vg1" showInAutomationHierarchy="true">
                <mx:Canvas id="c1">
                    <s:Button id="b1"
                        automationName="Nested Button 1"
                        label="Click Me"/>
                </mx:Canvas>
            </s:VGroup>
            <s:VGroup id="vg2" showInAutomationHierarchy="true">
                <mx:Canvas id="c2">
                    <s:Button id="b2"
                        automationName="Nested Button 2"
                        label="Click Me 2"/>
                </mx:Canvas>
            </s:VGroup>
        </s:HGroup>
    </s:Panel>
</s:Application>
```

For additional information, see More about showInAutomationHierarchy.

Working with multiview containers

You should avoid using the same label on multiple tabs in multiview containers, such as TabNavigator and Accordion containers. Although the compiler allows you to use the same labels for each view, this is generally not an acceptable UI design practice and can cause problems with control identification in your testing environment. QTP, for example, uses the `label` properties of multiview containers to identify those views to testers. When two labels are the same, QTP uses different strategies to uniquely identify the tabs, which can result in a confusing name list.

Also, dynamically adding children to multiview containers can cause delays that might confuse the testing tool. You should try to avoid this.

Testing sub-applications

When testing applications that load sub-applications, you should be aware of the different types of applications that a main application can load. These include applications that:

- Were compiled with the same version of the compiler as the main application (single-versioned applications).
- Were compiled with different versions of the compiler in different application domains (multi-versioned applications).
- Are loaded into different security domains (sandboxed applications). These applications can be multi-versioned.

When testing applications that load other applications, there is a single point of communication between the automation tool and the applications built with Flex. This point is the main application. It acts as a gateway between the sub-applications and the automation tool. All events dispatched by the sub-applications are routed through the main application to the tool. And conversely, all calls from the tool are sent to the main application. The main application is responsible for routing those messages to the sub-applications.

When creating applications that will be tested, compile each sub-application and the main application with its own tool library, automation manager, and delegates. In other words, compile the application against the automation libraries.

When recording an application that loads sub-applications, the tool typically uses the IAutomationManager2's `getUniqueApplicationId()` method. This method returns a unique ID for each application. The resulting scripts contain longer strings to identify objects, but you can see the heirarchy of the applications in them. For example, a Spark Button control in a sub-application might be referenced as follows:

```
FlexApplication("loader1").FlexApplication("local2.swf").SparkButton("Submit Form");
```

A script that was written for the main application can be reused within a multi-application environment. You might be required to provide the application ID to the operations so that the target application can be uniquely identified.

Support for sub-application testing is built into your applications by default. As a developer, you do not need to add custom code to ensure that multi-application tests work. However, if you write a custom agent for a multi-application environment, keep the following in mind:

- Multi-versioned applications should use the sandbox root application to dispatch events. This is required for events that are communicated across application boundaries. You can use the following code to get a reference to the sandbox root:

  ```
  private  var sandboxRoot:IEventDispatcher;
  var sm:ISystemManager = Application.application.systemManager;
  sandboxRoot = sm.getSandboxRoot();
  ```

- Untrusted (or sandboxed) applications use the SWFBridge to communicate across security domain boundaries. Each application has a SWFBridge. The SWFBridge has a child that corresponds to the sub-application that was loaded with a SWFLoader in that application.

Writing the wrapper

In most cases, the testing tool requests a file from a web server that embeds the application. This file, known as the *wrapper*, is often written in HTML, but can also be a JSP, ASP, or other file that browsers interpret. You can request the SWF file directly in the testing tool by using the file protocol, but then you must ensure that the SWF file is trusted.

If you are using Adobe LiveCycle Data Services ES or Flash Builder, you can generate a wrapper automatically. If you are using the Flex SDK, you can use the *flex_sdk*/templates/swfobject/index.template.html file as a basis to create a wrapper for your application.

When you careate a custom wrapper, your wrapper's `<object>` tag must have an `id` attribute, and the value of the `id` attribute can not contain any periods or hyphens. The convention is to set the `id` to match the name of the root MXML file in the application.

When you use the SWFObject 2 wrapper as a template, you must set the id of the application on the `attributes.id` property.

When you use Flash Builder to generate a wrapper, the value of the `id` attribute is the name of the root application file. You do not have to make any changes to this attribute.

When you generate a wrapper with the LiveCycle Data Services ES server, the object tag's `id` attribute is valid. The following example shows the default object tag for a file named MainApp.swf:

```
<object id='MainApp' classid='clsid:D27CDB6E-AE6D-11cf-96B8-444553540000'
codebase='http://fpdownload.macromedia.com/get/flashplayer/current/swflash.cab' height='600'
width='600'>
```

You are not required to change the value of the name in the `<embed>` tag because `<embed>` is used by Netscape-based browsers that do not support the testing feature. The `<object>` tag is used by Microsoft Internet Explorer.

Ensure that the object tag's `id` attribute is the same in the `<script>` and the `<noscript>` blocks of the wrapper.

Understanding the automation framework

The automation interfaces and the flow of the automation framework change as you initialize, record, and play back an automatable event.

About the automation interfaces

The Flex class hierarchy includes the following interfaces in the mx.automation.* package that enable automation:

Interface	Description
IAutomationClass and IAutomationClass2	Defines the interface for a component class descriptor.
IAutomationEnvironment	Provides information about the objects and properties of automatable components needed for communicating with agents.
IAutomationEventDescriptor	Defines the interface for an event descriptor.
IAutomationManager and IAutomationManager2	Defines the interface expected from an AutomationManager by the automation module.
IAutomationMethodDescriptor	Defines the interface for a method descriptor.
IAutomationMouseSimulator	Describes an object that simulates mouse movement so that components capturing the mouse use the simulated versions of the mouse cursor instead of the live Flash Player version.
IAutomationObject	Defines the interface for a delegate object implementing automation for a component.
IAutomationObjectHelper	Provides helper methods for the IAutomationObject interface.
IAutomationPropertyDescriptor	Describes a property of a test object as well as properties of an event object.
IAutomationTabularData	Defines the interface for components that provide their content information in a tabular form.

For more information about each of these interfaces, see the class's description in the ActionScript 3.0 Reference for the Adobe Flash Platform.

About the IAutomationObjectHelper interface

The IAutomationObjectHelper interface helps the components accomplish the following tasks:

- Replay mouse and keyboard events; the helper generates proper sequence of player level mouse and key events.
- Generate AutomationIDPart for a child: AutomationIDPart would be requested by the Automation for representing a component instance to agents.
- Find a child matching a AutomationIDPart: Automation would request the component to locate a child matching the AutomationIDPart supplied by an agent to it.
- Avoid synchronization issues: Agents invoke methods on Automation requesting operations on components in a sequence. Components may not be ready all the time to perform operations.

For example, an agent can invoke `comboBox.Open`, `comboBox.select "Item1"` operations in a sequence. Because it takes time for the drop-down list to open and initialize, it is not possible to run the select operation immediately. You can place a wait request during the open operation execution. The wait request should provide a function for automation, which can be invoked to check the ComboBox control's readiness before invoking the next operation.

Automated testing workflow with the QTP automation tool

Before you automate custom components, you might find it helpful to see the order of events during which Flex's automation framework initializes, records, and plays back events with a tool such as QTP. You should keep in mind that the QTP adapter class' implementation is only one way to use the automation API for automated testing.

Automated testing initialization

1. The user launches the application. Automation initialization code associates component delegate classes with component classes. Component delegate classes implement the IAutomationObject interface.
2. AutomationManager is a mixin. Its instance is created in the mixin `init()` method.
3. The SystemManager initializes the application. Component instances and their corresponding delegate instances are created. Delegate instances add event listeners for events of interest.
4. QTPAgent class is a mixin. In its `init()` method, it registers itself for the `FlexEvent.APPLICATION_COMPLETE` event which is dispatched from the SystemManager. On receiving the event, it creates a QTPAdapter object.
5. QTPAdapter sets up the ExternalInterface function map. QTPAdapter loads the QTP Plugin DLLs by creating the ActiveX object to communicate with QTP.
6. The QTPAdapter requests the XML environment information from the plugin and passes it to the AutomationManager.
7. The XML information is stored in a chain of AutomationClass, AutomationMethodDescriptor, and AutomationPropertyDescriptor objects.

Automated testing recording

1. The user clicks the Record button in QTP.
2. QTP calls the `QTPAdapter.beginRecording()` method. QTPAdapter adds a listener for `AutomationRecordEvent.RECORD` from the AutomationManager.
3. The QTPAdapter notifies AutomationManager about this by calling the `beginRecording()` method. The AutomationManager adds a listener for the `AutomationRecordEvent.RECORD` event from the SystemManager.
4. The user interacts with the application. In this example, suppose the user clicks a Button control.
5. The `ButtonDelegate.clickEventHandler()` method dispatches an AutomationRecordEvent event with the `click` event and Button instance as properties.

6 The AutomationManager `record` event handler determines which properties of the `click` event to store, based on the XML environment information. It converts the values into proper type or format. It dispatches the `record` event.

7 The QTPAdapter event handler receives the event. It calls the `AutomationManager.createID()` method to create the AutomationID object of the button. This object provides a structure for object identification.

The AutomationID structure is an array of AutomationIDParts. An AutomationIDPart is created by using IAutomationObject. (The `UIComponent.id`, `automationName`, `automationValue`, `childIndex`, and `label` properties of the Button control are read and stored in the object. The `label` property is used because the XML information specifies that this property can be used for identification for the Button.)

8 The QTPAdapter uses the `AutomationManager.getParent()` method to get the logical parent of the Button control. The AutomationIDPart objects of parent controls are collected at each level up to the application level.

9 All these AutomationIDParts are made part of an AutomationID object.

10 The QTPAdapter sends the information in a call to QTP.

11 At this point, QTP might call the `AutomationManager.getProperties()` method to get the property values of the Button control. The property type information and codec that should be used to modify the value format are gotten from the AutomationPropertyDescriptor.

12 User stops recording. This is propagated by a call to the `QTPAdapter.endRecording()` method.

Automated testing playback

1 The user clicks the Playback button in QTP.

2 The `QTPAdapter.findObject()` method is called to determine whether the object on which the event has to be played back can be found. The AutomationID object is built from the XML data received. The `AutomationManager.resolveIDToSingleObject()` method is invoked to see if QTP can find one unique object matching the AutomationID. The `AutomationManager.getChildren()` method is invoked from application level to find the child object. The `IAutomationObject.numAutomationChildren` property and the `IAutomationObject.getAutomationChildAt()` method are used to navigate the application.

3 The `AutomationManager.isSynchronized()` and `AutomationManager.isVisible()` methods ensure that the object is fully initialized and is visible so that it can receive the event.

4 QTP invokes the `QTPAdpater.run()` method to play back the event. The `AutomationManager.replayAutomatableEvent()` method is called to replay the event.

5 The AutomationMethodDescriptor for the `click` event on the Button is used to copy the property values (if any).

6 The `AutomationManager.replayAutomatableEvent()` method invokes the `IAutomationObject.replayAutomatableEvent()` method on the delegate class. The delegate uses the `IAutomationObjectHelper.replayMouseEvent()` method (or one of the other replay methods, such as `replayKeyboardEvent()`) to play back the event.

7 If there are check points recorded in QTP, the `AutomationManager.getProperties()` method is invoked to verify the values.

Instrumenting events

When you extend components that are already instrumented, you do not have to change anything to ensure that those components' events can be recorded by a testing tool. For example, if you extend a Button class, the class still dispatches the automation events when the Button is clicked, unless you override the Button control's default event dispatching behavior.

Automation events (sometimes known in automation tools such as QTP as *operations*) are not the same as Flex events. Flex must dispatch an automation event as a separate action. Flex dispatches them at the same time as Flex events, and uses the same event classes, but you must decide whether to make a Flex event visible to the automation tool.

Not all events on a control are instrumented. You can instrument additional events by using the instructions in "Instrumenting existing events" on page 2281.

If you change the instrumentation of a component, you might also be required to edit that component's entry in the class definitions file. This is described in "Using the class definitions file" on page 2286.

Instrumenting existing events

Events have different levels of relevance for the QC professional. For example, a QC professional is generally interested in recording and playing back a `click` event on a Button control. The QC professional is not generally interested in recording all the events that occur when a user clicks the Button, such as the `mouseOver`, `mouseDown`, `mouseUp`, and `mouseOut` events. For this reason, when a tester clicks on a Button control with the mouse, testing tools only record and play back the `click` event for the Button control and not the other, lower-level events.

There are some circumstances where you would want to record events that are normally ignored by the testing tool. But the testing tool's object model only records events that represent the end-user's gesture (such as a click or a drag and drop). This makes a script more readable and it also makes the script robust enough so that it does not fail if you change the application slightly. So, you should carefully consider whether to add a new event to be tested or rely on events in the existing object model.

You can see a list of events that the QTP automation tool can record for each component in the *QTP Object Type Information* (or *class definition*) documents. The MX Button control, for example, supports the following operations, based on its entry in the TEAFlex.xml file:

- `ChangeFocus`
- `Click`
- `MouseMove`
- `SetFocus`
- `Type`

All of these operations except for `MouseMove` are automatically recorded by QTP by default. The QC professional must explicitly add the `MouseMove` operation to their QTP script for QTP to record play back the related event.

However, you can alter the behavior of your application so that this event is recorded by the testing tool. To add a new event to be tested, you override the `replayAutomatableEvent()` method of the IAutomationObject interface. Because the UIComponent class implements this interface, all subclasses of UIComponent (which include all visible Flex controls) can override this method. To override the `replayAutomatableEvent()` method, you create a custom class, and override the method in that class.

The `replayAutomatableEvent()` method has the following signature:

```
public function replayAutomatableEvent(event:Event):Boolean
```

The *event* argument is the Event object that is being dispatched. In general, you pass the Event object that triggered the event. Where possible, you pass the specific event, such as a MouseEvent, rather than the generic Event object.

The following example shows a custom Spark Button control that overrides the `replayAutomatableEvent()` method. This method checks for the `mouseMove` event and calls the `replayMouseEvent()` method if it finds that event. Otherwise, it calls its superclass' `replayAutomatableEvent()` method.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- agent/CustomButton.mxml -->
<s:Button xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
        <fx:Script>
        <![CDATA[
            import flash.events.Event;
            import flash.events.MouseEvent;
            import mx.automation.Automation;
            import mx.automation.IAutomationObjectHelper;
            override public function
                replayAutomatableEvent(event:Event):Boolean {
                trace('in replayAutomatableEvent()');
                var help:IAutomationObjectHelper = Automation.automationObjectHelper;

                if (event is MouseEvent && event.type == MouseEvent.MOUSE_MOVE) {
                    return help.replayMouseEvent(this, MouseEvent(event));
                } else {
                    return super.replayAutomatableEvent(event);
                }
            }
        ]]>
    </fx:Script>
</s:Button>
```

In the application, you call the AutomationManager's `recordAutomatableEvent()` method when the user moves the mouse over the button. The following application uses this custom class:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- agent/CustomButtonApp.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:ns1="*" initialize="doInit()">
    <fx:Script>
        <![CDATA[
            import mx.automation.*;
            public function doInit():void {
                b1.addEventListener(MouseEvent.MOUSE_MOVE, dispatchLowLevelEvent);
            }
            public function dispatchLowLevelEvent(e:MouseEvent):void {
                var help:IAutomationManager = Automation.automationManager;
                help.recordAutomatableEvent(b1,e,false);
            }
        ]]>
    </fx:Script>
    <ns1:CustomButton id="b1"
        toolTip="Mouse moved over"
        label="CustomButton"/>

</s:Application>
```

If the event is not one that is currently recordable, you also must define the new event for the agent. Typically, you do this by adding a new entry to a class definitions file. For a tool such as QTP, the class definitions are in the TEAFlex.xml file. Automation tools can use files like this to define the events, properties, and arguments for each class of test object. For more information, see “Instrumenting events” on page 2280. If you wanted to add support for the mouseOver event in QTP, for example, you add the following to the SparkButton object’s entry in the TEAFlex.xml file:

```
<Operation Name="MouseOver" PropertyType="Method" ExposureLevel="CommonUsed">
    <Implementation Class="flash.events::MouseEvent" Type="mouseOver"/>
        <Argument Name="keyModifier" IsMandatory="false" DefaultValue="0">
            <Type VariantType="Enumeration"
                ListOfValuesName="FlexKeyModifierValues" Codec="keyModifier"/>
            <Description>Occurs when the user moves mouse over the component</Description>
        </Argument>
</Operation>
```

In the preceding example, however, the mouseMove event is already in the SparkButton object’s entry in that file, so no editing is necessary. The difference now is that the QC professional does not have to explicitly add the event to their script. After you compile this application and deploy the new TEAFlex.xml file to the QTP testing environment, QTP records the mouseMove event for all of the CustomButton objects.

For more information about the class definitions file, see “Using the class definitions file” on page 2286.

Instrumenting custom events

When you extend components, you often add events that are triggered by new functionality of that component. You can instrument custom events by adding a call to the Automation.automationManager2 class’s recordCustomAutomationEvent() method. You usually do this in the same place that you call the dispatchEvent() method. You do not replace the call to the dispatchEvent() method.

The following example from a custom event class builds a new AutomationRecordEvent and calls the recordCustomAutomationEvent() method to ensure that it is recorded:

```
this.addEventListener(MyComponentEvent.myEvent, myHandler);
private function myHandler(event:MyComponentEvent) {
    var eventToRecord:AutomationRecordEvent =
        new AutomationRecordEvent(AutomationRecordEvent.CUSTOM_RECORD);
    eventToRecord.automationObject = this;
     // Provide the name of the event:
    eventToRecord.name = "MyCustomEventName";
    // Provide the details to be recorded. This should be of basic data types.
    eventToRecord.args = [MySelectionDetails];
    Automation.automationManager2.recordCustomAutomationEvent(eventToRecord);
}
```

For a tool such as QTP to recognize the event as a recordable operation, you must also add the event to the control’s entry in the class definitions file (TEAFlex.xml).

To replay the custom event, you listen for the AutomationCustomReplayEvent, get the details about it, and replay the event, as the following example shows:

```
Automation.automationManager2.addEventListener(AutomationCustomReplayEvent.Replay,
    handleReplay,false, EventPriority.DEFAULT+1);
private function handleReplay(event:AutomationCustomReplayEvent):void {
    if (event.automationObject  == this) {
        // take the name and args:
        var name:String = event.name;
        var args:Array = event.args;
        // Use the above do the required replay:
        event.preventDefault(); // prevent the default replay
    }
}
```

Blocking and overriding events

In some cases, you might want to block or override the default events that are recorded for a component. You might even want to replace them with a different event. This is often the case with events dispatched from custom components.

For example, suppose you have an application that uses a custom component that consists of a List and a Button control. When the user selects an item from the list, the application records a `change` event. However, if you change the List control to a RadioButtonGroup in your custom component, you no longer want to record the `change` event, but rather, you want to record the `itemClick` event.

The result is that automation scripts can break due to changes in the custom component. To get around this, you can block the events and dispatch a higher-level event that corresponds to the user's gesture rather than the specific event.

To block the recording of the default events, create an event listener that listens for all `AutomationRecordEvent.RECORD` events. Set its priority to be higher than other listeners. In the handler, call the event's `preventDefault()` method, as the following example shows:

```
Automation.automationManager2.addEventListener(AutomationRecordEvent.RECORD,
    blockEvents,false, EventPriority.DEFAULT+1);
private function blockEvent(event:AutomationRecordEvent):void {
    // Block all events on list1 and button1:
    if ((event.automationObject == list1) || (if (event.automationObject == button1)) {
        event.preventDefault();
    }
}
```

You can then dispatch the more generic event that resembles the user's gesture as shown in "Instrumenting custom events" on page 2283.

Instrumenting custom components

The process of creating a custom component that supports automated testing is called instrumentation. Flex framework components are instrumented by attaching a delegate class to each component at run time. The *delegate class* defines the methods and properties required to perform instrumentation.

If you extend an existing component that is instrumented, such as a Button control, you inherit its parent's instrumentation, and are not required to do anything else to make that component testable. If you create a component that inherits from UIComponent, you must instrument that class in one of the following ways:

- Create a delegate class that implements the required interfaces.
- Add testing-related code to the component.

You usually instrument components by creating delegate classes. You can also instrument components by adding automation code inside the components, but this is not a recommended practice. It creates tighter coupling between automated testing code and component code, and it forces the automated testing code to be included in a production SWF file.

In both methods of instrumenting a component, you must specify any new events to the agent. With QTP, for example, you must add your new component's information to the class definitions file so that QTP recognizes that component. For more information about this file, see "Using the class definitions file" on page 2286.

Consider the following additional factors when you instrument custom components:

- Composition. When instrumenting components, you must consider whether the component is a simple component or a composite component. Composite components are components made up of several other components. For example, a TitleWindow that contains form elements is a composite component.
- Container hierarchy. You should understand how containers are viewed in the automation hierarchy so that the QC professional can easily test the components. Also, you should be aware that you can manipulate the hierarchy to better suit your application by setting some automation-related properties.
- Automation names. Custom components sometimes have ambiguous or unclear default automation names. The ambiguous names make it more difficult in automation tools to determine what component a script is referring to. Component authors can manually set the value of the `automationName` property for all components except item renderers. For item renderers, use the `automationValue`.

Creating a delegate class

To instrument custom components with a delegate, you must do the following:

- Create a delegate class that implements the required interfaces. In most cases, you extend the UIComponentAutomationImpl class. You can instrument any component that implements IUIComponent.
- Register the delegate class with the AutomationManager.
- Define the component in a class definitions XML file.

The delegate class is a separate class that is not embedded in the component code. This helps to reduce the component class size and also keeps automated testing code out of the final production SWF file.

All visual Flex controls have their own delegate classes. These classes are in the spark.automation.delegates.components.* package for Spark controls, and the mx.automation.delegates.* package for MX components. The class names follow a pattern of *Class_name*AutomationImpl. For example, the delegate class for the Spark Button control is spark.automation.delegates.components.SparkButtonAutomationImpl. The delegate class for the MX Button control is mx.automation.delegates.controls.ButtonAutomationImpl.

The delegate class defines the following:

- The `enableAutomation()` method
- `The replayAutomatableEvent()` method
- Event listeners

All subclasses of UIComponent store a reference to their delegate in the `automationDelegate` property. This behavior is defined in the UIComponent initializer, which calls the delegate's `enableAutomation()` method. If you create a custom component that does not subclass UIComponent, then you must manually call the delegate's `enableAutomation()` method in your custom component's initilization code.

You map the delegate's unique name and value properties to the `automationName` and `automationValue` properties.

Instrument with a delegate class

1. Create a delegate class.
2. Mark the delegate class as a mixin by using the `[Mixin]` metadata keyword.
3. Register the delegate with the AutomationManager by calling the `Automation.registerDelegateClass()` method in the `init()` method. The following code is a simple example:

```
[Mixin]
public class MyCompDelegate {
    public static init(root:DisplayObject):void {
        // Pass the component and delegate class information.
        Automation.registerDelegateClass(MyComp, MyCompDelegate);
    }
}
```

   You pass the custom class and the delegate class to the `registerDelegateClass()` method.

4. Add the following code to your delegate class:
   a. Override the getter for the `automationName` property and define its value. This is the name of the object as it usually appears in automation tools such as QTP. If you are defining an item renderer, use the `automationValue` property instead.
   b. In the constructor, add event listeners for events that the automation tool records.
   c. Override the `replayAutomatableEvent()` method. The AutomationManager calls this method for replaying events. In this method, return whether the replay was successful. You can use methods of the helper classes to replay common events.

      For examples of delegates, see the source code for the Flex controls in the spark.automation.delegates.components.* package.

5. Link the delegate class with the application SWF file in one of these ways:
   - Add the following `includes` compiler option to link in the delegate class:

     ```
     mxmlc -includes MyCompDelegate -- FlexApp.mxml
     ```

   - Build a SWC file for the delegate class by using the compc component compiler:

     ```
     compc -source-path+=. -include-classes MyCompDelegate -output MyComp.swc
     ```

     Then include this SWC file with your application by using the following `include-libraries` compiler option:

     ```
     mxmlc -include-libraries MyComp.SWC -- FlexApp.mxml
     ```

     This approach is useful if you have many components and delegate classes and want to include them as a single library so that you can share them with other developers.

6. After you compile your application with the new delegate class, you must define the new interaction for the agent and the automation tool. For QTP, you must add the new component to QTP's custom class definition XML file. For more information, see "Using the class definitions file" on page 2286.

Using the class definitions file

The class definitions file contains information about all instrumented components. This file provides information about the components to the automation agent, including what events can be recorded and played back, the name of the component, and the properties that can be tested.

An example of a class definitions file is the TEAFlex.xml file, which is specific to the QTP automation tool. This file is included in the Flex Automation Package.

The TEAFlex.xml file is located in the "*QTP_plugin_install*/Adobe Flex 4 Plug-in for HP QuickTest Pro" directory. QTP recognizes any file in that directory that matches the pattern TEAFlex*.xml, where * can be any string. This directory also contains a TEAFlexCustom.xml file that you can use as a starting point for adding custom component definitions.

The TEAFlex.xml and FlexEnv.xml class definitions files describe instrumented components with the following basic structure:

```
<TypeInformation>
    <ClassInfo>
        <Description/>
        <Implementation/>
        <TypeInfo>
            <Operation/>
            ...
        </TypeInfo>
        <Properties>
            <Property/>
            ...
        </Properties>
    </ClassInfo>
</TypeInformation>
```

The top level tag is `<TypeInformation>`. You define a new class that uses the `<ClassInfo>` tag, which is a child tag of the `<TypeInformation>` tag. The `<ClassInfo>` tag has child tags that further define the instrumented classes. The following table describes these tags:

Tag	Description
ClassInfo	Defines the class that is instrumented, for example, SparkButton. This is the name that the automation tools use for the Spark Button control. (For the MX Button control, the name is FlexButton.) Attributes of this tag include `Name`, `GenericTypeID`, `Extends`, and `SupportsTabularData`.
Description	Defines the text that appears in the automation tool to define the component. This is not implemented in the AutoQuick example, but is implemented for QTP.
Implementation	Defines the class name, as it is known by the Flex compiler, for example, Button or MyComponent. There is an optional property of the `<Implementation>` element, `version`. You use the `version` property to differentiate controls that are in same package and have the same name, but have differences in their API across the versions. For example: `<Implementation Class="my.custom.controls::BigButton" version="1.5"/>`
TypeInfo	Defines events for this class. Each event is defined in an `<Operation>` child tag, which has two child tags: • The `<Implementation>` child tag associates the operation with the actual event. • Each operation can also define properties of the event object by using an `<Argument>` child tag.
Properties	Defines properties of the class. Each property is defined in a `<Property>` child tag. Inside this tag, you define the property's type, name, and description. For each `Property`, if the `ForDescription` attribute is `true`, the property is used to uniquely identify a component instance in the automation tool; for example, the `label` property of a Button control. QTP lists this property as part of the object in QTP object repository. If the `ForVerfication` attribute is `true`, the property is visible in the properties dialog box in QTP. If the `ForDefaultVerification` tag is `true`, the property appears selected by default in the dialog box in QTP. This results in verification of the property value in the checkpoint.

The following example adds a new component, MyComponent, to the class definition file. This component has one instrumented event, `click`:

```
<TypeInformation xsi:noNamespaceSchemaLocation="ClassesDefintions.xsd" Priority="0"
PackageName="TEA" Load="true" id="Flex" xmlns:xsi="http://www.w3.org/2001/XMLSchema-
instance">
    <ClassInfo Name="MyComponent" GenericTypeID="mycomponent"
        Extends="FlexObject" SupportsTabularData="false">
        <Description>FlexMyComponent</Description>
        <Implementation Class="MyComponent"/>
        <TypeInfo>
            <Operation Name="Select" PropertyType="Method"
                ExposureLevel="CommonUsed">
                <Implementation Class="myComponentClasses::MyComponentEvent" Type="click"/>
            </Operation>
        </TypeInfo>
        <Properties>
            <Property Name="automationClassName" ForDescription="true">
                <Type VariantType="String"/>
                <Description>This is MyComponent.</Description>
            </Property>
            <Property Name="automationName" ForDescription="true">
                <Type VariantType="String"/>
                <Description>The name used by tools to id an object.</Description>
            </Property>
            <Property Name="className" ForDescription="true">
                <Type VariantType="String"/>
                <Description>To be written.</Description>
            </Property>
            <Property Name="id" ForDescription="true" ForVerification="true">
                <Type VariantType="String"/>
                <Description>Developer-assigned ID.</Description>
            </Property>
            <Property Name="index" ForDescription="true">
                <Type VariantType="String"/>
                <Description>The index relative to its parent.</Description>
            </Property>
        </Properties>
    </ClassInfo>
    ...
</TypeInformation>
```

You can edit the class definitions file to add a new recordable event to an existing component. To do this, you insert a new `<Operation>` in the control’s `<TypeInfo>` block. This includes the implementation class of the event, and any arguments that the event might take.

The following example adds a new event, `MouseOver`, with several arguments to the Button control:

```
<TypeInfo>
    <Operation ExposureLevel="CommonUsed" Name="MouseOver" PropertyType="Method">
        <Implementation Class="flash.events::MouseEvent" Type="mouseOver"/>
        <Argument Name="inputType" IsMandatory="false"
            DefaultValue="mouse">
            <Type VariantType="String"/>
        </Argument>
        <Argument Name="shiftKey" IsMandatory="false" DefaultValue="false">
            <Type VariantType="Boolean"/>
        </Argument>
        <Argument Name="ctrlKey" IsMandatory="false" DefaultValue="false">
            <Type VariantType="Boolean"/>
        </Argument>
        <Argument Name="altKey" IsMandatory="false" DefaultValue="false">
            <Type VariantType="Boolean"/>
        </Argument>
    </Operation>
</TypeInfo>
```

When you finish editing the class definitions file, you must distribute the new file to the automation tool users. For QTP, users must copy this file manually to the "*QTP_plugin_install*\Adobe Flex 4 Plug-in for HP QuickTest Pro" directory. When you replace the class definitions file in the QTP environment, you must restart QTP.

Setting the automationName property

The `automationName` property defines the name of a component as it appears in testing scripts. The default value of this property varies depending on the type of component. For example, a Button control's `automationName` is the label of the Button control. Sometimes, the `automationName` is the same as the control's `id` property, but this is not always the case.

For some components, Flex sets the value of the `automationName` property to a recognizable attribute of that component. This helps QC professionals recognize that component in their scripts. For example, a Spark Button labeled "Process Form Now" appears in the testing scripts as `SparkButton("Process Form Now")`.

If you implement a new component, or subclass an existing component, you might want to override the default value of the `automationName` property. For example, UIComponent sets the value of the `automationName` to the component's `id` property by default, but some components use their own methods of setting its value.

The following example sets the `automationName` property of the ComboBox control to "Credit Card List"; rather than using the `id` property, the testing tool typically uses "Credit Card List" to identify the ComboBox in its scripts:

```
<?xml version="1.0"?>
<!-- agent/SimpleComboBox.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
            [Bindable]
            public var cards: Array = [
                {label:"Visa", data:1},
                {label:"MasterCard", data:2},
                {label:"American Express", data:3}
            ];

            [Bindable]
            public var selectedItem:Object;
        ]]>
    </fx:Script>
    <s:Panel title="ComboBox Control Example">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>

        <mx:ComboBox id="cb1" dataProvider="{cards}" width="150"
            close="selectedItem=ComboBox(event.target).selectedItem"
            automationName="Credit Card List"/>
        <s:VGroup width="250">
            <s:Label width="200" color="blue"
                text="Select a type of credit card."/>
            <s:Label text="You selected: {selectedItem.label}"/>
            <s:Label text="Data: {selectedItem.data}"/>
        </s:VGroup>
    </s:Panel>
</s:Application>
```

If you do not set the value of the `automationName` property, the name of an object that appears in a testing tool is sometimes a property that can change while the application runs. If you set the value of the `automationName` property, testing scripts use that value rather than the default value. For example, by default, QTP uses a Button control's `label` property as the name of the Button in the script. If the label changes, the script can break. You can prevent this from happening by explicitly setting the value of the `automationName` property.

Buttons that have no label, but have an icon, are recorded by their index number. In this case, you should ensure that you set the `automationName` property to something meaningful so that the QC professional can recognize the Button in the script. This might not be necessary if you set the `toolTip` property of the Button because some tools such as QTP use that value if there is no label.

After the value of the `automationName` property is set, you should not change the value during the component's life cycle.

For item renderers, use the `automationValue` property rather than the `automationName` property. You do this by overriding the `createAutomationIDPart()` method and returning a new value that you assign to the `automationName` property, as the following example shows:

```
<mx:List xmlns:mx="http://www.adobe.com/2006/mxml">
    <fx:Script>
        <![CDATA[
            import mx.automation.IAutomationObject;
            override public function
                createAutomationIDPart(item:IAutomationObject):Object {
                    var id:Object = super.createAutomationIDPart(item);
                    id["automationName"] = id["automationIndex"];
                    return id;
            }
        ]]>
    </fx:Script>
</mx:List>
```

This technique works for any container or list-like control to add index values to their children. There is no method for a child to specify an index for itself.

Instrumenting composite components

Composite components are custom components made up of two or more components. A common composite component is a form that contains several text fields, labels, and buttons. Composite components can be MXML files or ActionScript classes.

By default, you can record operations on all instrumented child controls of a container. If you have a Button control inside a custom TitleWindow container, the QA professional can record actions on that Button control just like on any Button control. You can, however, create a composite component in which some of the child controls are instrumented and some are not. To prevent the operations of a child component from being recorded, you override the following methods:

- `numAutomationChildren` getter
- `getAutomationChildAt()`

The `numAutomationChildren` property is a read-only property that stores the number of automatable children that a container has. This property is available on all containers that have delegate implementation classes. To exclude some children from being automated, you return a number that is less than the total number of children.

The `getAutomatedChildAt()` method returns the child at the specified index. When you override this method, you return null for the unwanted child at the specified index, but return the other children as you normally would.

The following custom composite component is written in ActionScript. It consists of a VGroup container with three buttons (OK, Cancel, and Help). You cannot record the operations of the Help button. You can record the operations of the other Button controls, OK and Cancel. The following example sets the values of the OK and Cancel buttons' `automationName` properties. This makes those button controls easier to recognize in the automated testing tool's scripts.

```
// agent/MyVGroup.as
package { // Empty package
    import mx.core.UIComponent;
    import spark.components.VGroup;
    import spark.components.Button;
    import mx.automation.IAutomationObject;
    import spark.automation.delegates.components.SparkGroupAutomationImpl;
    public class MyVGroup extends VGroup {
        public var btnOk : Button;
        public var btnHelp : Button;
        public var btnCancel : Button;
        public function MyVGroup():void { // Constructor
        }

        override protected function createChildren():void {
            super.createChildren();

            btnOk = new Button();
            btnOk.label = "OK";
            btnOk.automationName = "OK_custom_form";
            addElement(btnOk);

            btnCancel = new Button();
            btnCancel.label = "Cancel";
            btnCancel.automationName = "Cancel_custom_form";
            addElement(btnCancel);

            btnHelp = new Button();
            btnHelp.label = "Help";
            btnHelp.showInAutomationHierarchy = false;
            addElement(btnHelp);
        }

        override public function get numAutomationChildren():int {
            return 2; //instead of 3
        }
        override public function
            getAutomationChildAt(index:int):IAutomationObject {
            switch(index) {
                case 0:
                    return btnOk;
                case 1:
                    return btnCancel;
            }
            return null;
        }
    } // Class
} // Package
```

The following application uses the MyVGroup custom component:

```
<?xml version="1.0"?>
<!-- agent/NestedButton.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:comps="*">
    <s:Panel title="Composite VGroup with Custom Automation Settings">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <comps:MyVGroup/>
    </s:Panel>
</s:Application>
```

To make this solution more portable, you could create a custom Button control and add a property that determines whether a Button should be testable. You could then set the value of this property based on the Button instance (for example, `btnHelp.useInAutomation = false`), and check against it in the overridden `getAutomationChildAt()` method, before returning null or the button instance.

For better performance, you can use the `getAutomationChildren()` method rather than the `getAutomationChildAt()` method; for example:

```
var childList:Array = getAutomationChildren();
var n:int = childList ? childList.length : 0;
for (var i:int = 0; i < n; i++) {
    var child:IAutomationObject = childList[i];
    ...
}
```

Custom agents

The Automation Framework defines a single API that has two parts:

- Component API — Components must implement this API to support automation features. Developers can choose to put the code either in the main component itself or in a mixin class. Mixin classes implement this API for Flex components.
- Agent API — Agents use this API to communicate with the component API.

Component developers implement the component API for their component once and then the component is ready to converse with any agent. Agent developers implement the agent API for their specific feature or tool and it is able to work with any application built with Flex. For more information, see “About the automation APIs” on page 2294.

Uses for agents

You can use agents to gather metrics information, to use automated testing, and to run applications at different locations at the same time.

Metrics

You might want to analyze how your online applications are being used. By gathering metrics information, you can answer the following questions:

- What product views are most popular?
- When do users abandon the checkout process?
- What is a typical path through my application?

- How many product views does a user look at during a session?

Automated testing

Maintaining the quality of a large software application is difficult. Verifying lots of functionality in any individual build can take a QA engineer many hours or even days, and much of the work between builds is repetitive. To alleviate this difficulty, automated testing tools have been created that can use applications and verify behavior without human intervention. Major application environments such as Java and .NET have testing tool support from vendors such as QTP and Segue.

By using the Flex automation API, you can:

- Record and replay events in a separate tool
- Manage communication between components and agents

Co-browsing

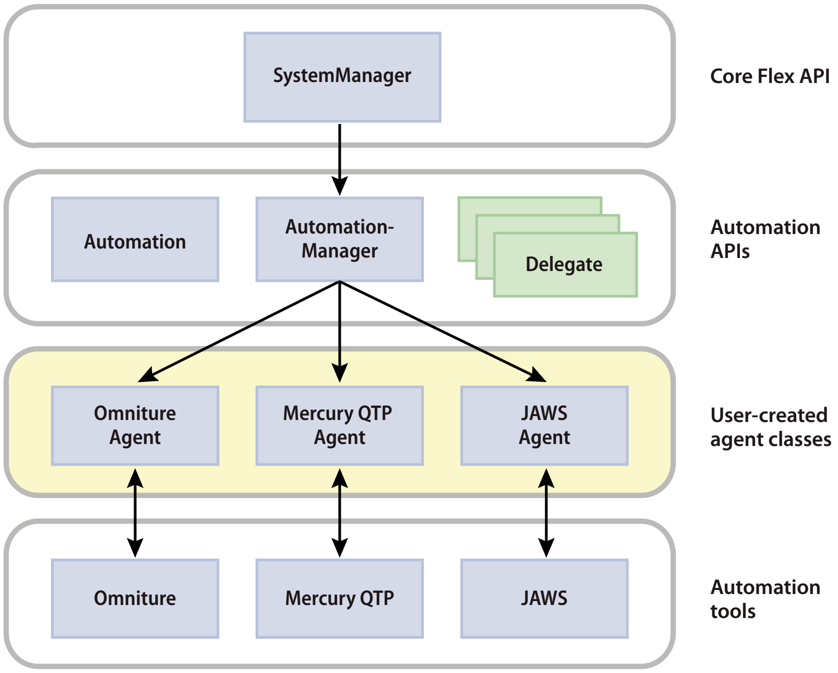
You might want to run the same application at different locations and view the application at the same time. By using the automation API, you can ensure that the applications are synchronized as users navigate through the them. User interaction at any location can be played at other locations and other users can see the action in real time.

About the automation APIs

There are four main parts that enable the automation framework in Flex:

- Core Flex API
- Automation APIs
- Agent class (also known as an adapter)
- Automation tools

The following illustration shows the relationship between these parts:



About the SystemManager class

The SystemManager class is one of the highest level classes in an application built with Flex. Every application built with Flex has a SystemManager class. It is the parent of all displayable objects in the application, such as the main spark.components.Application instance and all pop-up windows, ToolTip instances, cursors, and so on.

SystemManager calls the `init()` method on all mixins. The SystemManager class is responsible for creating the AutomationManager class as well as the Agent and the delegate classes. The SystemManager class is also responsible for adding the Application object to Adobe® Flash® Player or Adobe® AIR™ stage (root).

About the AutomationManager class

The AutomationManager class is a Singleton that extends the EventDispatcher class. It implements the IAutomationManager, IAutomationObjectHelper, and IAutomationMouseSimulator interfaces.

AutomationManager is a mixin, so its `init()` method is called by the SystemManager class when the application is initialized. In the `init()` method, the AutomationManager class adds an event listener for the `Event.ADDED` event. This event is dispatched by Flash Player or AIR whenever a display object is added to the display list. When that happens, Flash Player or AIR calls the `childAddedHandler()` method:

```
root.addEventListener(Event.ADDED, childAddedHandler, false, 0, true);
```

In the `childAddedHandler()` method, the AutomationManager class:

- Creates a new instance of a delegate for each display object.
- Adds the display object to a delegate class map. This maps the display object to a delegate instance; for example:

  ```
  Automation.delegateDictionary[componentClass] = Automation.delegateDictionary[className];
  ```

  The delegate class map is a property of the Automation class.
- Ensures that all children of the new display object are added to the class map as well.

In the `recordAutomatableEvent()` method, the AutomationManager:

- Creates an `AutomationRecordEvent.RECORD` event.
- Dispatches the `RECORD` events. The agent listens for these events.

The `recordAutomatableEvent()` method is called by the delegates.

About the Automation class

During application initialization, an instance of the Automation class is created. This is a static class that maintains a map of its delegate class to its component class.

This object does the following for recording events:

- Provides access to the AutomationManager class
- Creates a `delegateDictionary` as a static property

For example, there is a MyButton class that extends the Button class, but it does not have its own delegate class (MyButton might not add any new functionality to be recorded or played back). When the AutomationManager encounters an instance of the MyButton class, it checks with the Automation class for a corresponding delegate class. When it fails to find one, it uses the `getSuperClassName()` method to get the super class of the MyButton class, which is the Button class.

The AutomationManager then tries to find the delegate for this Button class. At that point, the AutomationManager adds a new entry into the delegate-component class for the MyButton class, associating it with the ButtonDelegateAutomationImpl class, so that next time the AutomationManager can find this mapping without searching the inheritance hierarchy.

About the delegate classes

The delegate classes provide automation hooks to the Flex components. The delegate classes are in the spark.automation.delegates.* and mx.automation.delegates.* packages. They extend the UIComponentAutomationImpl class. The delegates for the Spark components are named Spark*ControlName*AutomationImpl. The delegates for the MX components are named *ControlName*AutomationImpl. For example, the Spark Button control's delegate class is SparkButtonAutomationImpl.

The delegate classes register themselves with their associated Automation class by providing the component class and their own class as input. The AutomationManager class uses the Automation class-to-delegate class map to create a delegate instance that corresponds to a component instance in the `childAddedHandler()` method.

The delegate classes are mixins, so their `init()` method is called by the SystemManager class. The `init()` method of the delegate classes:

1 Calls the `registerDelegateClass()` method of the Automation class. This method maps the class to an automation component class; for example:

```
var className:String = getQualifiedClassName(compClass);
delegateDictionary[className] = delegateClass;
```

2 Adds event listeners for the mouse and keyboard events; for example:

```
obj.addEventListener(KeyboardEvent.KEY_UP, btnKeyUpHandler, false,
EventPriority.DEFAULT+1, true);
obj.addEventListener(MouseEvent.CLICK, clickHandler, false, EventPriority.DEFAULT+1,
true);
```

These event handlers call the AutomationManager class's `recordAutomatableEvent()` method, which in turn dispatches the `AutomationRecordEvent.RECORD` events that the automation agent listens for.

All core framework and charting classes have delegate classes already created. You are not required to create any delegate classes unless you have custom components that dispatch events that you want to automate. In this case, you must create a custom delegate class for inclusion in your application.

About the agent

The agent facilitates communication between the application built with Flex and automation tools such as QTP and Segue.

When recording, the agent class is typically responsible for implementing a persistence mechanism in the automation process. It gets information about events, user sessions, and application properties and typically writes them out to a database, log file, LocalConnection, or some other persistent storage method.

When you create an agent, you compile it and its supporting classes into a SWC file. You then add that SWC file to your application by using the `include-libraries` command-line compiler option. This compiles the agent into the application, regardless of whether you instantiate that agent in the application at compile time.

A custom agent class must be a mixin, which means that its `init()` method is called by the SystemManager class. The `init()` method of the agent:

- Defines a handler for the `RECORD` events.
- Defines the environment. The environment indicates what components and their methods, properties, and events can be recorded with the automation API.

A typical custom agent class uses an XML file that contains Flex component API information. The agent typically loads this information with a call to the `URLRequest()` constructor, as the following example shows:

```
var myXMLURL:URLRequest = new URLRequest("AutomationGenericEnv.xml");
myLoader = new URLLoader(myXMLURL);
automationManager.automationEnvironment = new CustomEnvironment(new XML(source));
```

In this example, the source is an XML file that defines the Flex metadata (or environment information). This metadata includes the events and properties of the Flex components.

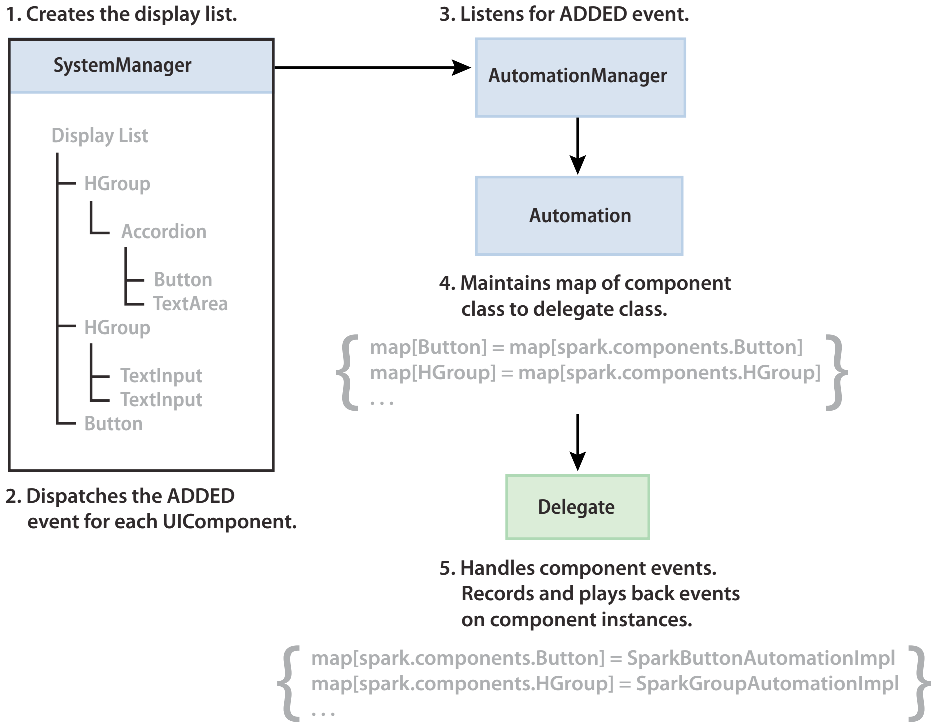
Note that representing events as XML is agent specific. The general-purpose automation API does not require it, but the XML file makes it easy to adjust the granularity of the events that are recorded.

You are not required to create an instance of your adapter in the `init()` method. You can also create this instance in the `APPLICATION_COMPLETE` event handler if your agent requires that the application must be initialized before it is instantiated.

Understanding the automation flow

When the application is initialized, the AutomationManager object is created. In its `init()` method, it adds a listener for `Event.ADDED` events.

The following image shows the order of events when the application is initialized and the AutomationManager class constructs the delegate map.



1. Creates the display list.
SystemManager
Display List
HGroup
Accordion
Button
TextArea
HGroup
TextInput
TextInput
Button
2. Dispatches the ADDED event for each UIComponent.
3. Listens for ADDED event.
AutomationManager
Automation
4. Maintains map of component class to delegate class.
map[Button] = map[spark.components.Button]
map[HGroup] = map[spark.components.HGroup]
. . .
Delegate
5. Handles component events. Records and plays back events on component instances.
map[spark.components.Button] = SparkButtonAutomationImpl
map[spark.components.HGroup] = SparkGroupAutomationImpl
. . .

1 The SystemManager class creates the display list, a tree of visible objects that make up your application.

2 Each time a new component is added, either at the root of the display list or as a child of another member of the display list, SystemManager dispatches an `Event.ADDED` event.

3 The AutomationManager listens for the `ADDED` event. In its `ADDED` event handler, it calls methods on the Automation class. It then instantiates the delegate for that class.

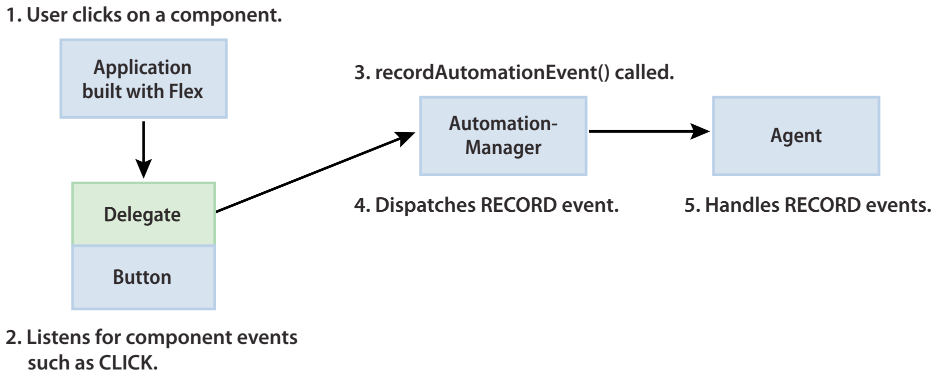
4 The Automation class maps each component in the display list to its full class name.

5 When it is created, the delegate class adds a reference to its instance in the delegate class map. The delegate class then handles events during record and play-back sequences.

The delegate is now considered *registered* with the component. It adds event listeners for the component's events and calls the AutomationManager when the component triggers those events.

After the components in the display list are instantiated and mapped to instances of their delegate classes, the AutomationManager is ready to listen for events and forward them to the agent for processing.

The following image shows the flow of operation when a user performs an action that is a recordable event. In this case, the user clicks a Button control in the application.



1. User clicks on a component.
Application built with Flex
3. recordAutomationEvent() called.
Automation-Manager
Agent
Delegate
Button
4. Dispatches RECORD event.
5. Handles RECORD events.
2. Listens for component events such as CLICK.

1 The user clicks the Button control in the application. The SystemManager dispatches a `MouseEvent.CLICK` event.

2 The SparkButtonAutomationImpl class, the Button control's automation delegate, listens for `click` events. In the delegate's `click` event handler, the delegate calls the AutomationManager `recordAutomationEvent()` method. (It is likely that the button also defines a `click` event handler to respond to the user action, but that is not shown.)

3 The AutomationManager's `recordAutomationEvent()` method dispatches an `AutomationRecordEvent.RECORD` event. In that event, the `replayableEvent` property points to the original `click` event.

4 The custom agent class listens for `RECORD` events. When it receives the `RECORD` event, it uses the `replayableEvent` property to access the properties of the original event.

5 The agent records the event properties in a database, logs the event properties, or gets information about the user before recording them.

Creating agents

You create an agent as a SWC file and link it into the application by using the `include-libraries` compiler option. You can link multiple agents in any number of SWC files to the same application. However, to use multiple agents at the same time, you must use the same environment configuration files for all agents.

The general process for creating a custom agent is:

- Mark the agent class as a mixin; this triggers a call to a static `init()` method from the SystemManager class on application start up.
- Get a reference to the AutomationManager class.
- Add event listeners for the `APPLICATION_COMPLETE` and `RECORD` events.
- Load the environment information (Flex metadata that describes the objects and operations of the application). Environment information can be an XML file or it can be in some other data format.

- Define a static `init()` method that creates an instance of the agent.
- Define a method that handles `RECORD` events. In that method, you can access:
  - Automation details such as the automation name
  - User information such as the FlexSession object (through a RemoteObject)
  - The event that triggered the `RECORD` event and its target

The `RECORD` event handler in the agent gets an `AutomationRecordEvent` whose target is the object on which recording happened. The `automationManager.createID()` method converts the object to a string that can be recorded on the screen. Some tools may require the entire automation hierarchy that needs to be generated in this method.

You also use the custom agent class to enable and disable recording of automation events.

Optimizing applications

Improving client-side performance

Tuning software to achieve maximum performance is not an easy task. You must commit to producing efficient implementations and monitor software performance continuously during the software development process.

Employ the following general guidelines when you test applications for performance, such as using the getTimer() method and checking initialization time.

Before you begin actual testing, you should understand some of the influences that client settings can have on performance testing. For more information, see “Configuring the client environment” on page 2303.

In addition to these techniques, you should also consider using the Adobe® Flex® profiler in Adobe® Flash® Builder™. For more information, see Profiling Tools in Flash Builder.

General guidelines

You can use the following general guidelines when you improve your application and the environment in which it runs:

- Set performance targets early in the software design stage. If possible, try to estimate an acceptable performance target early in the application development cycle. Certain usage scenarios dictate the performance requirements. It would be disappointing to fully implement a product feature and then find out that it is too slow to be useful.
- Understand performance characteristics of the application framework, and employ the strategies that maximize the efficiency of components and operations.
- Understand performance characteristics of the application code. In medium-sized or large-sized projects, it is common for a product feature to use codes or components written by other developers or by third-party vendors. Knowing what is slow and what is fast in dependent components and code is essential in getting the design right.
- Do not attempt to test a large application’s performance all at once. Rather, test small pieces of the application so that you can focus on the relevant results instead of being overwhelmed by data.
- Test the performance of your application early and often. It is always best to identify problem areas early and resolve them in an iterative manner, rather then trying to shove performance enhancements into existing, poorly performing code at the end of your application development cycle.

- Avoid optimizing code too early. Even though early testing can highlight performance hot spots, refrain from fixing them while you are still developing those areas of the application; doing so might unexpectedly delay the implementation schedule. Instead, document the issues and prioritize all the performance issues as soon as your team finishes the feature implementation.

Testing applications for performance

You can use various techniques to test start-up and run-time performance of your applications, such as monitoring memory consumption, timing application initialization, and timing events. The Flex profiler provides this type of information without requiring you to write any additional code. If you are using Flash Builder, you should use the profiler for testing your application's performance. For more information, see Profiling Tools in Flash Builder.

Calculating application initialization time

One approach to performance profiling is to use code to gauge the start-up time of your application. This can help identify bottlenecks in the initialization process, and reveal deficiencies in your application design, such as too many components or too much reliance on nested containers.

The getTimer() method in flash.utils returns the number of milliseconds that have elapsed since Adobe® Flash® Player or Adobe AIR™ was initialized. This indicates the amount of time since the application began playing. The Timer class provides a set of methods and properties that you can use to determine how long it takes to execute an operation.

Before each update of the screen, Flash Player calls the set of functions that are scheduled for the update. Sometimes, a function should be called in the next update to allow the rest of the code scheduled for the current update to execute. You can instruct Flash Player or AIR to call a function in the next update by using the callLater() method. This method accepts a function pointer as an argument. The method then puts the function pointer on a queue, so that the function is called the next time the player dispatches either a `render` event or an `enterFrame` event.

The following example records the time it takes the Application object to create, measure, lay out, and draw all of its children. This example does not include the time to download the SWF file to the client, or to perform any of the server-side processing, such as checking the Flash Player version, checking the SWF file cache, and so on.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- optimize/ShowInitializationTime.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="callLater(showInitTime)">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script><![CDATA[
        import flash.utils.Timer;
        [Bindable]
        public var t:String;
        private function showInitTime():void {
            // Record the number of ms since the player was initialized.
            t = "App startup: " + getTimer() + " ms";
        }
    ]]></fx:Script>
    <s:Label id="tb1" text="{t}"/>
</s:Application>
```

This example uses the `callLater()` method to delay the recording of the startup time until after the application finishes and the first screen updates. The reason that the `showInitTime` function pointer is passed to the `callLater()` method is to make sure that the application finishes initializing itself before calling the `getTimer()` method.

For more information on using the `callLater()` method, see "Using the callLater() method" on page 2340.

Calculating elapsed time

Some operations take longer than others. Whether these operations are related to data loading, instantiation, effects, or some other factor, it's important for you to know how long each aspect of your application takes.

You can calculate elapsed time from application startup by using the getTimer() method. The following example calculates the elapsed times for the `preinitialize` and `creationComplete` events for all the form elements. You can modify this example to show individual times for the initialization and creation of each form element.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- optimize/ShowElapsedTime.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    initialize="init()"
    height="750">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script><![CDATA[

    </s:Form>
</s:Application>
```

Calculating memory usage

You use the `totalMemory` property in the System class to find out how much memory has been allocated to Flash Player or AIR on the client. The `totalMemory` property represents all the memory allocated to Flash Player or AIR, not necessarily the memory being used by objects. Depending on the operating system, Flash Player or AIR will be allocated more or less resources and will allocate memory with what is provided.

You can record the value of `totalMemory` over time by using a Timer class to set up a recurring interval for the timer event, and then listening for that event.

The following example displays the total amount of memory allocated (totmem) to Flash Player at 1-second intervals. This value will increase and decrease. In addition, this example shows the maximum amount of memory that had been allocated (maxmem) since the application started. This value will only increase.

```
<?xml version="1.0"?>
<!-- optimize/ShowTotalMemory.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    initialize="initTimer()">
    <fx:Script><![CDATA[
        import flash.utils.Timer;
        import flash.events.TimerEvent;
        [Bindable]
        public var time:Number = 0;
        [Bindable]
        public var totmem:Number = 0;
        [Bindable]
        public var maxmem:Number = 0;
        public function initTimer():void {
            // The first parameter is the interval (in milliseconds). The
            // second parameter is number of times to run (0 means infinity).
            var myTimer:Timer = new Timer(1000, 0);
            myTimer.addEventListener("timer", timerHandler);
            myTimer.start();
        }

        public function timerHandler(event:TimerEvent):void {
            time = getTimer()
            totmem = flash.system.System.totalMemory;
            maxmem = Math.max(maxmem, totmem);
        }
    ]]></fx:Script>

    <s:Form>
        <s:FormItem label="Time:">
            <s:Label text="{time} ms"/>
        </s:FormItem>
        <s:FormItem label="totalMemory:">
            <s:Label text="{totmem} bytes"/>
        </s:FormItem>
        <s:FormItem label="Max. Memory:">
            <s:Label text="{maxmem} bytes"/>
        </s:FormItem>
    </s:Form>
</s:Application>
```

Configuring the client environment

When testing applications for performance, it is important to configure the client properly.

Choosing the version of Flash Player

When you test your applications for performance, use the standard version of Adobe® Flash® Player or AIR rather than the debugger version of Flash Player or ADL, if possible. The debugger version of Flash Player provides support for the trace() method and the Logging API. Using logging or the `trace()` method can significantly slow player performance, because the player must write log entries to disk while running the application.

If you do use the debugger version of Flash Player, you can disable logging and the `trace()` method by setting the `TraceOutputFileEnable` property to 0 in your mm.cfg file. You can also set the `omit-trace-statements` compiler option to `false`.

You can keep `trace()` logging working, but disable the Logging API that you might be using in your application, by setting the logging level of the TraceTarget logging target to `NONE`, as the following example shows:

```
myLogger.log(LogEventLevel.NONE, s);
```

For performance testing, consider writing run-time test results to text components in the application rather than calling the `trace()` method so that you can use the standard version of Flash Player and not the debugger version of Flash Player.

For more information about configuring `trace()` method output and logging, see “Logging” on page 2222.

Disabling SpeedStep

If you are running performance tests on a Windows laptop computer, disable Intel SpeedStep functionality. SpeedStep toggles the speed of the CPU to maximize battery life. SpeedStep can toggle the CPU at unpredictable times, which makes the results of a performance test less accurate than they would otherwise be.

1 Select Start > Settings > Control Panel.

2 Double-click the Power Settings icon. The Power Options Properties dialog box displays.

3 Select the Power Schemes tab.

4 Select High System Performance from the Power Schemes drop-down box.

5 Click OK.

Changing timeout length

When you test your application, be aware of the `scriptTimeLimit` property. If an application takes too long to initialize, Flash Player warns users that a script is causing Flash Player to run slowly and prompts the user to abort the application. If this is the situation, you can set the `scriptTimeLimit` property of the `<s:Application>` tag to a longer time so that the application has enough time to initialize.

However, the default value of the `scriptTimeLimit` property is 60 seconds, which is also the maximum, so you can only increase the value if you have previously set it to a lower value. You rarely need to change this value.

The following example sets the `scriptTimeLimit` property to 30:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- optimize/ChangeScriptTimeLimit.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    scriptTimeLimit="30">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
</s:Application>
```

Preventing client-side caching

When you test performance, ensure that you are not serving files from the local cache to Flash Player. Otherwise, this can give false results about download times. Also, during development and testing, you might want to change aspects of the application such as embedded images, but the browser continues to use the old images from your cache.

If the date and time in the If-Modified-Since request header matches the date and time in the Last-Modified response header, the browser loads the SWF file from its cache. Then the server returns the “304 Not Modified” message. If the Last-Modified header is more recent, the server returns the SWF file.

You can use the following techniques to disable client-side caching:

- Delete the Flex files from the browser’s cache after each interaction with your application. Browsers typically store the SWF file and other remote assets in their cache. On Microsoft Internet Explorer in Windows XP, for example, you can delete all the files in c:\Documents and Settings\username\Local Settings\Temporary Internet Files to force a refresh of the files on the next request. For more information, see “Caching” on page 122.
- Set the HTTP headers for the SWF file request in the HTML wrapper to prevent caching of the SWF file on the client. The following example shows how to set headers that prevent caching in JSP:

  ```
  // Set Cache-Control to no-cache.
  response.setHeader("Cache-Control", "no-cache");
  // Prevent proxy caching.
  response.setHeader("Pragma", "no-cache");
  // Set expiration date to a date in the past.
  response.setDateHeader("Expires", 946080000000L); //Approx Jan 1, 2000
  // Force always modified.
  response.header("Last-Modified", new Date());
  ```

  Note that in some cases, setting the `Pragma` header to `"no-cache"` can cause a runtime error with GET requests over SSL with the HTTPService class. In this case, setting just the `Cache-control` header should work.

Marc Speck has a blog entry that describes the issue and presents several solutions.

Reducing SWF file sizes

You can improve initial user experience by reducing the time it takes to start an application. Part of this time is determined by the download process, where the SWF file is returned from the server to the client. The smaller the SWF file, the shorter the download wait. In addition, reducing the size of the SWF file also results in a shorter application initialization time. Larger SWF files take longer to unpack in Flash Player.

The mxmlc compiler includes several options that can help reduce SWF file size.

Using the bytecode optimizer

The bytecode optimizer can reduce the size of the application's SWF file by using bytecode merging and peephole optimization. Peephole optimization removes redundant instructions from the bytecode.

If you are using Flash Builder or the mxmlc command-line compiler, you can set the `optimize` compiler option to `true`, as the following example shows:

```
mxmlc -optimize=true MyApp.mxml
```

The default value of the `optimize` option is `true`.

Disabling debugging

Disabling debugging can make your SWF files smaller. When debugging is enabled, the Flex compilers include line numbers and other navigational information in the SWF file that are only used in a debugging environment. Disabling debugging reduces functionality of the fdb command-line debugger and the debugger built into Flash Builder.

To disable debugging in Flash Builder, select Project > Export Release Build when you build your application.

To disable debugging when using the command-line compiler, set the `debug` compiler option to `false`. The default value for the mxmlc compiler is `false`. The default value for the compc compiler is `true`. Setting this to `false` reduces the size of hte SWF file inside the SWC file.

For more information about debugging, see "Command-line debugger" on page 2209.

Using the size report

The `size-report` compiler option outputs a high-level summary of the size of each type of data within your application's SWF file. You can use this information to identify problem areas in an application. For example, if you embed multiple fonts, you can compare the size that each embedded font takes up. If one font is considerably larger than the others, you could reduce the number of symbols embedded by that font.

The following example creates a size report called mysizereport.xml for the MainApp application:

```
mxmlc -size-report=mysizereport.xml MainApp.mxml
```

To use this option in Flash Builder, you must add it to the Additional Compiler Arguments field.

The following table describes the areas of the report:

Report tag	**Description**
`<swf>`	The compressed and uncompressed SWF file size, in bytes.
`<headerData>`	The size of the actual SWF file format header, product info, and other marker data.
`<actionScript>`	The ActionScript data associated with this SWF file. For non-debug SWFs, ActionScript bytecode (abc) and constant pool data is consolidated into a single block within the frame that it is associated with. For debug SWF or SWC files, the ActionScript bytecode blocks are generally broken down by symbol. All entries are sorted largest to smallest.
`<frames>`	A frame by frame summary of all script and tag data for each frame. Applications usually consist of two or more frames, with the first frame containing all preloader logic as well as the top level SystemManager definition.
`<frameData>`	Additional SWF tags that are related to frame definitions. For example, frame labels, symbol definitions, export definitions, and showFrame tags.
`<bitmaps>`	The embedded bitmap data. All entries are sorted largest to smallest. If appropriate, the symbol name of each bitmap is provided. The original file name of the embedded asset is not provided.
`<fonts>`	The embedded font data. All entries are sorted largest to smallest. If appropriate, the symbol name of each font is provided. The original font face name or path is not provided, nor any enumeration of the embedded glyphs.
`<sprites>`	The sprite data. All entries are sorted largest to smallest. If appropriate, the symbol name of each sprite definition is provided.
`<shapes>`	The shape data. All entries are sorted largest to smallest. If appropriate, the symbol name of each shape definition is provided.
`<bindaryData>`	The generic binary data. This includes embedded SWF files, PixelBender shaders, or any other miscellaneous embed data. All entries are sorted largest to smallest. If appropriate, the symbol name of each data definition is provided.The original file name for each asset is not provided.
`<sounds>`	The embedded sound data. All entries are sorted largest to smallest. If appropriate, the symbol name of each sound is provided.The original file name for each asset is not provided.
`<videos>`	The embedded video data. All entries are sorted largest to smallest. If appropriate, the symbol name of each video asset is provided.The original file name for each asset is not provided.

The following is a sample size report:

```
<?xml version="1.0" encoding="UTF-8"?>
<report>
  <swf size="614011" compressedSize="318895">
    <!-- Header data (SWF attributes, product info, markers, etc.) -->
    <headerData totalSize="533">
      <data type="metaData" size="465"/>
      <data type="productInfo" size="28"/>
      <data type="swfHeader" size="21"/>
      <data type="fileAttributes" size="6"/>
      <data type="scriptLimits" size="6"/>
      <data type="backgroundColor" size="5"/>
      <data type="endMarker" size="2"/>
    </headerData>
    <!-- Cumulative frame size summary. -->
    <frames totalSize="613478">
      <frame name="_MultipleFaces_mx_managers_SystemManager" size="76648" frame="1"/>

frame="2"/>
      <data name="mx.graphics.shaderClasses.HueShader_ShaderClass" size="2268" frame="2"/>
      <data name="mx.graphics.shaderClasses.SoftLightShader_ShaderClass" size="1920" 
frame="2"/>
      <data name="mx.graphics.shaderClasses.LuminosityShader_ShaderClass" size="1282" 
frame="2"/>
      <data name="mx.graphics.shaderClasses.ColorShader_ShaderClass" size="1272" frame="2"/>
      <data name="mx.graphics.shaderClasses.ColorBurnShader_ShaderClass" size="1144" 
```

```
frame="2"/>
      <data name="mx.graphics.shaderClasses.ColorDodgeShader_ShaderClass" size="1074"
frame="2"/>
      <data name="mx.graphics.shaderClasses.ExclusionShader_ShaderClass" size="624"
frame="2"/>
      <data name="mx.graphics.shaderClasses.LuminosityMaskShader_ShaderClass" size="624"
frame="2"/>
    </binaryData>
    <!-- Additional frame tags (symbolClass, exportAssets, showFrame, etc). -->
    <frameData totalSize="1423">
      <tag type="symbolClass" size="774" frame="2"/>
      <tag type="exportAssets" size="539" frame="2"/>
      <tag type="symbolClass" size="47" frame="1"/>
      <tag type="frameLabel" size="43" frame="1"/>
      <tag type="frameLabel" size="16" frame="2"/>
      <tag type="showFrame" size="2" frame="1"/>
      <tag type="showFrame" size="2" frame="2"/>
    </frameData>
  </swf>
</report>
```

Using strict mode

When you set the `strict` compiler option to `true`, the compiler verifies that definitions and package names in `import` statements are used in the application. If the imported classes are not used, the compiler reports an error.

The following example shows some examples of when strict mode throws a compiler error:

```
package {
    import flash.utils.Timer; // Error. This class is not used.
    import flash.printing.* // Error. This class is not used.
    import mx.controls.Button; // Error. This class is not used.
    import mx.core.Application; // No error. This class is used.

    public class Foo extends Application {
    }
}
```

The `strict` option also performs compile-time type checking, which provides a small optimization increase in the application at run time.

The default value of the `strict` compiler option is `true`.

Examining linker dependencies

To find ways to reduce SWF file sizes, you can look at the list of ActionScript classes that are linked into your SWF file.

You can generate a report of linker dependencies by using the `link-report` compiler option. This option takes a single file name. The compiler generates a report, and writes it to the specified file, that shows an application’s linker dependencies in an XML format.

The following example shows the dependencies for the ProgrammaticSkin script as it appears in the linker report:

```
<script name="C:\flex3sdk\frameworks\libs\framework.swc(mx/skins/ProgrammaticSkin)"
mod="1141055632000" size="5807">
    <def id="mx.skins:ProgrammaticSkin"/>
    <pre id="mx.core:IFlexDisplayObject"/>
    <pre id="mx.styles:IStyleable"/>
    <pre id="mx.managers:ILayoutClient"/>
    <pre id="flash.display:Shape"/>
    <dep id="String"/>
    <dep id="flash.geom:Matrix"/>
    <dep id="mx.core:mx_internal"/>
    <dep id="uint"/>
    <dep id="mx.core:UIComponent"/>
    <dep id="int"/>
    <dep id="Math"/>
    <dep id="Object"/>
    <dep id="Array"/>
    <dep id="mx.core:IStyleClient"/>
    <dep id="Boolean"/>
    <dep id="Number"/>
    <dep id="flash.display:Graphics"/>
</script>
```

The following table describes the tags used in this file:

Tag	Description
`<script>`	Indicates the name of a compilation unit used in the creation of the application SWF file. Compilation units must contain at least one public definition, such as a class, function, or namespace. The `name` attribute shows the origin of the script, either from a source file or from a SWC file (for example, frameworks.swc). If you set the value of the `keep-generated-actionscript` compiler argument to `true`, all classes in the generated folder are listed as scripts in this file. The `size` attribute shows the class' uncompressed size, in bytes. The `mod` attribute shows the time stamp when the script was created.
`<def>`	Indicates the name of a definition. A definition, like a script, can be a class, function, or namespace.
`<pre>`	Indicates a definition that must be linked in to the SWF file before the current definition is linked in. This tag means prerequisite. For class definitions, this tag shows the direct parent class (for example, flash.events:Event), plus all implemented interfaces (for example, mx.core:IFlexDisplayObject and mx.managers:ILayoutClient) of the class.
`<dep>`	Indicates other definitions that this definition depends on (for example, String, _ScrollBarStyle, and mx.core:IChildList). This is a reference to a definition that the current script requires. Some script definitions have no dependencies, so the `<script>` tag might have no `<dep>` child tags.
`<ext>`	Indicates a dependency to an asset that was not linked in. These dependencies show up in the linker report when you use the `external-library-path`, `externs`, or `load-externs` compiler options to add assets to the SWF file.

You can examine the list of prerequisites and dependencies for your application definition. You do this by searching for your application's root MXML file by its name; for example, MyApp.mxml. You might discover that you are linking in some classes inadvertently. When writing code, it is common to make a reference to a class but not actually require that class in your application. That reference causes the referenced class to be linked in, and it also links in all the classes on which the referenced class depends.

If you look through the linker report, you might find that you are linking in a class that is not needed. If you do find an unneeded class, try to identify the linker dependency that is causing the class to be linked in, and try to find a way to rewrite the code to eliminate that dependency.

Viewing SWC file dependencies

The swcdepends command line tool has a small set of options that lets you view dependencies on SWC files in your application. This tool is located in the sdk/bin directory. By default, the tool outputs a list of SWC files ordered by dependencies. For each SWC file in the list, the tool shows a sub-list of SWC files that the SWC file is dependent on.

The output is sorted by the number of dependencies. SWC files with the fewest dependencies are listed first, followed by those with the most dependencies. For each SWC file in the list, SWC files that are dependent on it are listed below it and indented in the output.

The swcdepends tool supports all the options of the mxmlc command line compiler. In addition, it has several options that let you customize the output. The following table describes these options:

Option	Description
`dependency.minimize-dependency-set=true|false`	Determines whether all SWC files are included for depencies, or just the first one. For example, some classes are defined in more than one SWC file. When this option is `true`, only the first SWC file in which the class is defined is added as a dependency. When this option is `false`, all SWC files that define a class appear as dependencies.
`dependency.show-external-classes=false|true`	Shows classes that cause a dependency from one SWC to another. The default value is `false`.
`dependency.show-swcsswc_filename`	Limits the output to show just the given SWC files. Does not change the set of SWC files used to determine dependencies.
`dependency.show-types`	Shows the dependency type(s) of a class.
`dependency.typestype`	Limits the dependency checking to only the specified types. By default all the dependency types are specified. This option is useful when you want to see what RSLs are needed by the RSL from a given SWC file. The set of types is as follows: • e - expression • i - inheritance • n - namespace • s - signature You can specify "i" to see all the SWC files that have an inheritance dependency on a SWC file. Some or all of the dependent SWC files must be RSLs; as a result, be sure that the required classes are loaded before the RSL for the SWC file is loaded. You can specify multiple dependency types by using a comma-separated list, as the following example shows: `-dependency.types=i,e` This example limits the dependency list to external classes with either inheritance or expression dependency types.

Avoiding initializing unused classes

Some common ways to avoid unnecessary references include avoiding initializing classes that you do not use and performing type-checking with the `getQualifiedClassName()` method.

The following example checks if the class is a Button control. This example forces the compiler to include a Button in the SWF file, even if the child is not a Button control and the entire application has no Button controls.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- optimize/UnusedClasses.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="checkChildType()">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script><![CDATA[
        import spark.components.Button;
        [Bindable]
        private var s:String;
        public function checkChildType():void {
            var child:DisplayObject = getChildAt(0);
            var childIsButton:Boolean = child is spark.components.Button;
            s = "child is spark.components.Button: " + childIsButton.toString(); // False.
        }
    ]]></fx:Script>
    <!-- This control is here so that the getChildAt() method succeeds. -->
    <s:DataGrid/>
    <s:Group>
        <s:Label text="{s}"/>
    </s:Group>
</s:Application>
```

You can use the `getQualifiedClassName()` method to accomplish the same task as the previous example. This method returns a String that you can compare to the name of a class without causing that class to be linked into the SWF.

The following example does not create a linker dependency on the Button control:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- optimize/GetQualifiedClassNameExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="checkChildType()">
    <s:layout>
         <s:VerticalLayout/>
    </s:layout>
    <fx:Script><![CDATA[
    [Bindable]
    private var s:String;
    [Bindable]
    private var t:String;
    public function checkChildType():void {
        var child:DisplayObject = vg1.getChildAt(0);
        var childClassName:String = getQualifiedClassName(child);
        var childIsButton:Boolean = childClassName == "spark.components::Button"
        s = "child class name = Button (" + childIsButton + ")";
        t = "child is " + childClassName;
    }
    ]]></fx:Script>
    <s:VGroup id="vg1">
        <s:DataGrid/>
        <s:Label text="{s}"/>
        <s:Label text="{t}"/>
    </s:VGroup>
</s:Application>
```

Externalizing assets

There are various methods of externalizing assets used by your applications; these include:

- Using modules
- Using run-time stylesheets
- Using Runtime Shared Libraries (RSLs)
- Loading assets at run time rather than embedding them

This section describes loading assets at run time. For information about modules and run-time stylesheets, see "Modular applications" on page 138 and "Loading style sheets at run time" on page 1547. For information about RSLs, see "Using RSLs to reduce SWF file size" on page 2315.

One method of reducing the SWF file size is to externalize assets; that is, to load the assets at run time rather than embed them at compile time. You can do this with assets such as images, SWF files, and sound files.

Embedded assets load immediately, because they are already part of the Flex SWF file. However, they add to the size of your application and slow down the application initialization process. Embedded assets also require you to recompile your applications whenever your asset changes.

The following example embeds the butterfly.gif file into the application at compile time:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- optimize/EmbedAtCompileTime.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
         <s:VerticalLayout/>
    </s:layout>
    <s:Image source="@Embed(source='../assets/butterfly.gif')"/>
</s:Application>
```

The following example loads the butterfly.gif file into the application at run time:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- optimize/EmbedAtRunTime.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
         <s:VerticalLayout/>
    </s:layout>
    <s:Image source="assets/butterfly.gif"/>
</s:Application>
```

The only supported image type that you cannot load at run time is SVG. Flash Player and AIR require that the compiler transcodes that file type at compile time. The Player and AIR runtime cannot transcode that file type at run time.

When you load SWF files from domains that are not the same as the loading SWF file, you must use a crossdomain.xml file or other mechanism to enable the proper permissions. For more information on using the crossdomain.xml file, see “Using cross-domain policy files” on page 125.

Using character ranges for embedded fonts

By specifying a range of symbols that compose the face of an embedded font, you reduce the size of an embedded font. Each character in a font must be described; if you remove some of these characters, it reduces the overall size of the description information that Flex must include for each embedded font.

You can set the range of glyphs in the flex-config.xml file or in the `@font-face` declaration in each MXML file. You specify individual characters or ranges of characters using the Unicode values for the characters, and you can set multiple ranges for each font declaration.

In CSS, you can set the Unicode range with the `unicodeRange` property, as the following example shows:

```
@font-face {
    src:url("../assets/MyriadWebPro.ttf");
    fontFamily: myFontFamily;
    unicodeRange:
        U+0041-005A, /* Upper-Case [A..Z] */
        U+0061-007A, /* Lower-Case a-z */
        U+0030-0039, /* Numbers [0..9] */
        U+002E-002E; /* Period [.] */
    embedAsCFF:true;
}
```

In the flex-config.xml file, you can set the Unicode range with the `<language-range>` block, as the following example shows:

```
<language-range>
    <lang>Latin I</lang>
    <range>U+0020,U+00A1-00FF,U+2000-206F,U+20A0-20CF,U+2100-2183</range>
</language-range>
```

For more information, see “Fonts” on page 1568.

Using multiple SWF files

One way to reduce the size of an application’s file is to break the application up into logical parts that can be sent to the client and loaded over a series of requests rather than all at once. By breaking a monolithic application into smaller applications, users can interact with your application more quickly, but possibly experience some delays while the application is running.

One approach is to use the SWFLoader control to load sub-applications. This technique can work with SWF files that add graphics or animations to an application, or SWF files that act as stand-alone applications inside the main application. It also provides some level of interoperability between the main application and loaded sub-applications. If you load SWF files that require a large amount of user interaction, however, consider building them as custom components.

When loading sub-applications into a main application, you should be aware of the following factors:

Versioning SWF files produced with earlier versions of Flex or ActionScript may not work properly when loaded with the SWFLoader control. You can use the `loadForCompatibility` property of the SWFLoader control to ensure that sub-applications loaded into a main application will work, even if the applications were compiled with a different version of the compiler.

Security When loading sub-applications, especially ones that were created by a third-party, you should consider loading them into their own SecurityDomain. While this places additional limitations on the level of interoperability between the main application and the sub-application, it ensures that the content is safe from attack.

For more information about creating and loading sub-applications, see “Developing and loading sub-applications” on page 176.

Rather than loading SWF files into the main application with the SWFLoader control, consider having the SWF files communicate with each other as separate applications. You can do this with local SharedObjects, LocalConnection objects, or with the ExternalInterface API.

You can also use modules to externalize sections of your application into dynamically loaded SWFs. While modules do not work as standalone applications, they can be loaded and unloaded in your main application. For more information, see “Modular applications” on page 138.

Comparing dynamic and static linking

Most large applications use libraries of ActionScript classes and components. You must decide whether to use static or dynamic linking when using these libraries in your applications.

When you use *static linking*, the compiler includes all components, classes, and their dependencies in the application SWF file when you compile the application. The result is a larger SWF file that takes longer to download but loads and runs quickly because all the code is in the SWF file. To compile your application that uses libraries and to statically link those definitions into your application, you use the `library-path` and `include-libraries` options to specify the locations of SWC files.

Dynamic linking is when some classes used by an application are left in an external file that is loaded at run time. The result is a smaller SWF file size for the main application, but the application relies on external files that are loaded during run time.

To dynamically link classes and components, you compile a library. You then instruct the compiler to exclude that library's contents from the application SWF file. You must still provide link-checking at compile time even though the classes are not going to be included in the final SWF file.

You use dynamic linking by creating component libraries and compiling them with your application by using the `external-library-path`, `externs`, or `load-externs` compiler options. These options instruct the compiler to exclude resources defined by their arguments from inclusion in the application, but to check links against them and prepare to load them at run time. The `external-library-path` option specifies SWC files or directories for dynamic linking. The `externs` option specifies individual classes or symbols for dynamic linking. The `load-externs` option specifies an XML file that describes which classes to use for dynamic linking. This XML file has the same syntax as the file produced by the `link-report` compiler option.

For more information about linking, see "About linking" on page 254. For more information about compiler options, see "Flex compilers" on page 2164.

Using RSLs to reduce SWF file size

One way to reduce the size of your application's SWF file is by externalizing shared assets into stand-alone files that can be separately downloaded and cached on the client. These shared assets are loaded by any number of applications at run time, but must be transferred only once to the client. These shared files are known as *Runtime Shared Libraries* (RSLs).

If you have multiple applications but those applications share a core set of custom components or classes, your users will be required to download those assets only once as an RSL. The applications that share the assets in the RSL use the same cached RSL as the source for the libraries as long as they are in the same domain. The resulting file size for your applications can be reduced. The benefits increase as the number of applications that use the RSL increases.

When you create an RSL, be sure to optimize it prior to deployment. This removes debugging information as well as unnecessary metadata from the RSL, which can dramatically reduce its size.

By default, Flex compiles your applications against the framework RSLs.

For more information, see "Runtime Shared Libraries" on page 253.

Application coding

The MXML language provides a rich set of controls and classes that you can use to create interactive applications. This richness sometimes can reduce performance. However, there are some techniques that a Flex developer can use to improve the run-time performance of the application.

To measure the effects of the following techniques, you should use the Flex profiler. For more information, see Profiling Tools in Flash Builder.

Object creation and destruction

Object creation is the task of instantiating all the objects in your application. These objects include controls, components, and objects that contain data and other dynamic information. Optimizing the process of object creation and destruction can result in significant performance gains. *Object destruction* is the act of reallocating memory for objects after all references to those objects have been removed. This task is carried out by the garbage collector at regular intervals. You can improve the frequency that Flash Player and AIR destroy objects by removing references to objects.

No single task during application initialization takes up the most time. The best way to improve performance is to create fewer objects. You can do this by deferring the instantiation of objects, or changing the order in which they are created to improve perceived performance.

Using deferred creation

To improve the start-up time of your application, you can minimize the number of objects that are created when the application is first loaded. If a user-interface component is not initially visible at start up, create that component only when you need it. This is called deferred creation. Containers that have multiple views, such as an Accordion, provide built-in support for this behavior. You can use ActionScript to customize the creation order of multiple-view containers or defer the creation of other containers and controls.

To use deferred creation, you set the value of a component's creationPolicy property to `all`, `auto`, or `none`. If you set it to `none`, Flex does not instantiate a control's children immediately, but waits until you instruct Flex to do so. If you set the `creationPolicy` property on a container, then the children of that container are affected by its setting. So, for example, if you set the `creationPolicy` property to none on a Panel container, then all children of the Panel are not created when the application starts up. The children are only created when you manually instantiate them.

For Spark containers that extend SkinnableContainer, you call the `createDeferredContent()` method to create deferred components. Only SkinnableContainer and containers that extend it support deferred instantiation; Groups do not. When a Group is created, its children are always created.

In the following example with a Spark container, the children of the Panel container are not instantiated when the application is first loaded, but only after the user clicks the button:

```
<?xml version="1.0"?>
<!-- optimize/CreationPolicyNoneSpark.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script><![CDATA[
        private function createButtons(e:Event):void {
            myPanel.createDeferredContent();
        }
    ]]></fx:Script>
    <s:Panel id="myPanel" title="Panel with Deferred Content" creationPolicy="none">
        <s:VGroup>
            <s:Button id="b1" label="Hurley"/>
            <s:Button id="b2" label="Jack"/>
            <s:Button id="b3" label="Sawyer"/>
        </s:VGroup>
    </s:Panel>

    <s:Button id="myButton" click="createButtons(event)" label="Create Buttons"/>
</s:Application>
```

For MX containers, call methods such as createComponentFromDescriptor() and createComponentsFromDescriptor() on the container to instantiate its children at run time.

In the following example with an MX container, the children of the VBox container are not be instantiated when the application is first loaded, but only after the user clicks the button:

```
<?xml version="1.0"?>
<!-- optimize/CreationPolicyNone.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script><![CDATA[
        private function createButtons(e:Event):void {
            myVBox.createComponentsFromDescriptors();
        }
    ]]></fx:Script>
    <s:Panel title="VBox with Deferred Content">
        <mx:VBox id="myVBox" height="100" width="125" creationPolicy="none">
            <s:Button id="b1" label="Hurley"/>
            <s:Button id="b2" label="Jack"/>
            <s:Button id="b3" label="Sawyer"/>
        </mx:VBox>
    </s:Panel>
    <s:Button id="myButton" click="createButtons(event)" label="Create Buttons"/>

</s:Application>
```

For more information on using deferred instantiation, see “Using deferred creation” on page 2335.

Destroying unused objects

Flash Player provides built-in garbage collection that frees up memory by destroying objects that are no longer used. To ensure that the garbage collector destroys your unused objects, remove all references to that object, including the parent’s reference to the child.

For more information about garbage collection, see Profiling Tools in Flash Builder.

For Spark containers, you can call the `removeElement()`, `removeAllElements()`, or `removeElementAt()` methods to remove references to child controls. For MX containers, you can call the removeChild() or removeChildAt() method to remove references to child controls that are no longer needed.

The following example removes references to button instances from the MX myVBox and Spark myGroup containers:

```
<?xml version="1.0"?>
<!-- optimize/DestroyObjects.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script><![CDATA[
        private function destroyButtons(e:Event):void {
            myVBox.removeChild(b1);
            myVBox.removeChild(b2);
            myVBox.removeChild(b3);

            myGroup.removeElement(b4);
        }
    ]]></fx:Script>
    <s:Panel title="VBox and Group">
        <s:VGroup>
            <mx:VBox id="myVBox" height="100" width="125">
                <s:Button id="b1" label="Hurley"/>
                <s:Button id="b2" label="Jack"/>
                <s:Button id="b3" label="Sawyer"/>
            </mx:VBox>
            <s:Group id="myGroup">
                <s:Button id="b4" label="Other"/>
            </s:Group>
        </s:VGroup>
    </s:Panel>

    <s:Button id="myButton2" click="destroyButtons(event)" label="Destroy Buttons"/>
</s:Application>
```

You can clear references to unused variables by setting them to `null` in your ActionScript; for example:

```
myDataProvider = null
```

To ensure that destroyed objects are garbage collected, you must also remove event listeners on them by using the removeEventListener() method, as the following example shows:

```
<?xml version="1.0"?>
<!-- optimize/RemoveListeners.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp(event)">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script><![CDATA[
        private function initApp(e:Event):void {
            b1.addEventListener("click",myClickHandler);
            b2.addEventListener("click",myClickHandler);
            b3.addEventListener("click",myClickHandler);
        }
        private function destroyButtons(e:Event):void {
            b1.removeEventListener("click",myClickHandler);
            b2.removeEventListener("click",myClickHandler);
            b3.removeEventListener("click",myClickHandler);
            myVGroup.removeAllElements();
        }

        private function myClickHandler(e:Event):void {
            // Do something here.
        }
    ]]></fx:Script>
    <s:Panel title="VGroup with child controls">
        <s:VGroup id="myVGroup" height="100" width="125">
            <s:Button id="b1" label="Hurley"/>
            <s:Button id="b2" label="Jack"/>
            <s:Button id="b3" label="Sawyer"/>
        </s:VGroup>
    </s:Panel>

    <s:Button id="myButton" click="destroyButtons(event)" label="Destroy Buttons"/>
</s:Application>
```

You cannot call the `removeEventListener()` method on an event handler that you added inline. In the following example, you cannot call `removeEventListener()` on b1's `click` event handler, but you can call it on b2's and b3's event handlers:

```
<?xml version="1.0"?>
<!-- optimize/RemoveSomeListeners.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp(event)">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script><![CDATA[
        private function initApp(e:Event):void {
            b2.addEventListener("click",myClickHandler);
            b3.addEventListener("click",myClickHandler);
        }
        private function destroyButtons(e:Event):void {
            b2.removeEventListener("click",myClickHandler);
            b3.removeEventListener("click",myClickHandler);
            myVGroup.removeAllElements();
        }

        private function myClickHandler(e:Event):void {
            // Do something here.
        }
    ]]></fx:Script>
    <s:Panel title="VGroup with child controls">
        <s:VGroup id="myVGroup" height="100" width="125">
            <s:Button id="b1" label="Hurley" click="myClickHandler(event)"/>
            <s:Button id="b2" label="Jack"/>
            <s:Button id="b3" label="Sawyer"/>
        </s:VGroup>
    </s:Panel>

    <s:Button id="myButton" click="destroyButtons(event)" label="Destroy Buttons"/>
</s:Application>
```

The *weakRef* parameter to the `addEventListener()` method provides you with some control over memory resources for listeners. A strong reference (when `weakRef` is `false`) prevents the listener from being garbage collected. A weak reference (when `weakRef` is `true`) does not. The default value of the *weakRef* parameter is `false`.

For more information about the `removeEventListener()` method, see “Events” on page 54.

Using styles

You use styles to define the look and feel of your applications. You can use them to change the appearance of a single component, or apply them globally. Be aware that some methods of applying styles are more computationally expensive than others. You can increase your application’s performance by changing the way you apply styles.

For more information about using styles, see “Styles and themes” on page 1492.

Loading stylesheets at run time

You can load stylesheets at run time by using the StyleManager. These style sheets take the form of SWF files that are dynamically loaded while your application runs.

By loading style sheets at run time, you can load images (for graphical skins), fonts, type and class selectors, and programmatic skins into your application without embedding them at compile time. This lets skins and fonts be partitioned into separate SWF files, away from the main application. As a result, the application's SWF file size is smaller, which reduces the initial download time. However, the first time a run-time style sheet is used, it takes longer for the styles and skins to be applied because Flex must download the necessary CSS-based SWF file.

Reducing calls to the setStyle() method

Run-time cascading styles are very powerful, but use them sparingly and in the correct context. Calling the setStyle() method can be an expensive operation because the call requires notifying all the children of the newly-styled object. The resulting tree of children that must be notified can be quite large.

A common mistake that impacts performance is overusing or unnecessarily using the `setStyle()` method. In general, you only use the `setStyle()` method when you change styles on existing objects. Do not use it when you set up styles for an object for the first time. Instead, set styles in an `<fx:Style>` block, as style properties on the MXML tag, through an external CSS style sheet, or as global styles.

Some applications must call the `setStyle()` method during the application or object instantiation. If this is the case, call the `setStyle()` method early in the instantiation phase. Early in the instantiation phase means setting styles from the component or application's `preinitialize` event, instead of the `initialize` or `creationComplete` event. By setting the styles as early as possible during initialization, you avoid unnecessary style notification and lookup.

If you programmatically create a component and want to set styles on that component, call the `setStyle()` method before you attach it to the display list with a call to the `addElement()` method, as the following example shows:

```
<?xml version="1.0"?>
<!-- optimize/CreateStyledButton.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp(event)">
    <fx:Script><![CDATA[
        import spark.components.Button;

        public function initApp(e:Event):void {
            var b:Button = new Button();
            b.label="Click Me";
            b.setStyle("color", 0x00CCFF);
            panel1.addElement(b);
        }
    ]]></fx:Script>

    <s:Panel id="panel1"/>

</s:Application>
```

Setting global styles

Changing global styles (changing a CSS ruleset that is associated with a class or type selector) at run time is an expensive operation. Any time you change a global style, Flash Player must perform the following actions:

- Traverse the entire application looking for instances of that control.
- Check all the control's children if the style is inheriting.

- Redraw that control.

The following example globally changes the Button control’s color style property:

```
<?xml version="1.0"?>
<!-- optimize/ApplyGlobalStyles.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp(event)">
    <fx:Script><![CDATA[
        public function initApp(e:Event):void {
            styleManager.getStyleDeclaration("spark.components.Button").setStyle("color", 
0x00CCFF);
        }
    ]]></fx:Script>

    <s:Panel id="panel1">
        <s:Button id="b1" label="Click Me"/>
        <s:Button id="b2" label="Click Me"/>
        <s:Button id="b3" label="Click Me"/>
    </s:Panel>

</s:Application>
```

If possible, set global styles at authoring time by using CSS. If you must set them at run time, try to set styles by using the techniques described in “Reducing calls to the setStyle() method” on page 2321.

Calling the setStyleDeclaration() and loadStyleDeclarations() methods

The setStyleDeclaration() method is computationally expensive. You can prevent Flash Player from applying or clearing the new styles immediately by setting the `update` parameter to `false`.

The following example sets new class selectors on different targets, but does not trigger the update until the last style declaration is applied:

```
<?xml version="1.0"?>
<!-- optimize/SetStyleDeclarationExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp()">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
        private var myButtonStyle:CSSStyleDeclaration =
            new CSSStyleDeclaration('myButtonStyle');
        private var myLabelStyle:CSSStyleDeclaration =
            new CSSStyleDeclaration('myLabelStyle');
        private var myTextAreaStyle:CSSStyleDeclaration =
            new CSSStyleDeclaration('myTextAreaStyle');
        private function initApp():void {
            myButtonStyle.setStyle('color', 'blue');
            myLabelStyle.setStyle('color', 'blue');
            myTextAreaStyle.setStyle('color', 'blue');
        }
        private function applyStyles():void {
           styleManager.setStyleDeclaration("spark.components.Button", myButtonStyle, false);
            styleManager.setStyleDeclaration("spark.components.Label", myLabelStyle, false);
            styleManager.setStyleDeclaration("spark.components.TextArea", myTextAreaStyle,
true);
        }
        ]]>
    </fx:Script>
    <s:Button id="myButton" label="Click Me" click="applyStyles()"/>
    <s:Label id="myLabel" text="This is a label"/>
    <s:TextArea id="myTextArea" text="This is a TextArea"/>
</s:Application>
```

When you pass `false` for the `update` parameter, Flash Player stores the selector but does not apply the style. When you pass `true` for the `update` parameter, Flash Player recomputes the styles for every visual component in the application.

The `loadStyleDeclarations()` method is similarly computationally expensive. When you load a new style sheet, this method triggers an update to the display list by default. You can prevent Flash Player from applying or clearing the new style sheets immediately by setting the `update` parameter to `false`. When you chain calls to `loadStyleDeclarations()` methods, set the update parameter to `false` for all calls except the last one.

Working with containers

Containers provide a hierarchical structure that lets you control the layout characteristics of container children. You can use containers to control child sizing and positioning, or to control navigation among multiple child containers.

When you develop your application, try to minimize the number of containers that you use. This is because most containers provide relative sizing and positioning, which can be resource-intensive operations, especially when an application first starts.

Minimizing container nesting

One common mistake is to create a container that contains a single child. Sometimes having a single child in a container is necessary, such as when you use the container's padding to position the child. But try to identify and remove containers such as these that provide no real functionality. Also keep in mind that the root of an MXML component does not need to be a container.

Another sign of possibly too many containers is when you have a container nested inside another container, where both the parent and child containers have the same type (for example, the HBox or HGroup containers).

It is good practice to avoid deeply nested layouts when possible. For simple applications, if you have nested containers more than three levels deep, you can probably produce the same layout with fewer levels of containers. Deep nesting can lead to performance problems. For larger applications, deeper nesting might be unavoidable.

When you nest containers, each container instance runs measuring and sizing algorithms on its children (some of which are containers themselves, so this measuring procedure can be recursive). When the layout algorithms have processed, and the relative layout values have been calculated, Flash Player draws the complex collection of objects comprising the view. By eliminating unnecessary work at object creation time, you can improve the performance of your application.

Using Grid containers

A Grid container is useful for aligning multiple objects. When you use Grid containers, however, you introduce additional levels of containers with the GridItem and GridRow controls. In many cases, you can achieve the same results by using the HGroup and VGroup containers, and these containers use fewer levels of nesting.

Using absolute layout for containers

You can sometimes improve application start-up time by using containers that support absolute positioning of their children, instead of relative layout containers. Containers that support absolute layout include all Spark containers, plus the MX containers Canvas, Application, and Panel. Containers that only use relative layout include MX containers like Form, HBox, VBox, Grid, and Tile.

All Spark containers support both absolute and relative layout.

Containers that use absolute positioning eliminate the layout logic that relative layout containers use to perform automatic positioning of their children at startup, and replace it with explicit pixel-based positioning. When you use absolute positioning, you must remember to set the *x* and *y* positions of all of the container's children. If you do not set the *x* and *y* positions, the container's children lay out on top of each other at the default *x*, *y* coordinates (0,0).

Container that use absolute positioning are not always more efficient than relative layout containers, however, because they must measure themselves to make sure that they are large enough to contain their children.

Applications that use absolute positioning typically contain a much flatter containment hierarchy. As a result, using these containers can lead to less nesting and fewer overall containers, which improves performance.

Containers that use absolute positioning support constraints, which means that if the container changes size, the children inside the container move with it.

Using absolute sizing

Writing object widths and heights into the code can save time because the Flex layout containers do not have to calculate the size of the object at run time. By specifying container or control widths or heights, you lighten the relative layout container's processing load and subsequently decrease the creation time for the container or control. This technique works with any container or control.

Improving effect performance

Effects let you add animation and motion to your application in response to user or programmatic action. For example, you can use effects to cause a dialog box to bounce slightly when it receives focus, or to slowly fade in when it becomes visible.

Effects can be one of the most processor-intensive tasks performed by an application. Use the techniques described in this section to improve the performance of effects. For more information, see "Introduction to effects" on page 1784.

Increasing effect duration

Increase the duration of your effect with the `duration` property. Doing this spreads the distinct, choppy stages over a longer period of time, which lets the human eye fill in the difference for a smoother effect.

Hiding parts of the target view

Make parts of the target view invisible when the effect starts, play the effect, and then make those parts visible when the effect has completed. To do this, you add logic in the `effectStart` and `effectEnd` event handlers that controls what is visible before and after the effect.

When you apply a Resize effect to a Panel container, for example, the measurement and layout algorithm for the effect executes repeatedly over the duration of the effect. When a Panel container has many children, the animation can be jerky because Flex cannot update the screen quickly enough. Also, resizing one Panel container often causes other Panel containers in the same view to resize.

To solve this problem, you can use the Resize effect's `hideChildrenTargets` property to hide the children of Panel containers while the Resize effect is playing. The value of the `hideChildrenTargets` property is an Array of Panel containers that should include the Panel containers that resize during the animation. When the `hideChildrenTargets` property is `true`, and before the Resize effect plays, Flex iterates through the Array and hides the children of each of the specified Panel containers.

Avoiding bitmap-based backgrounds

Designers often give their views background images that are solid colors with gradients, slight patterns, and so forth. To ease what Flash Player redraws during an effect, try using a solid background color for your background image. Or, if you want a slight gradient instead of a solid color, use a background image that is a SWF or FXG file. These are easier for Flash Player to redraw than standard JPG or PNG files.

Suspending background processing

To improve the performance of effects, you can disable background processing in your application for the duration of the effect by setting the `suspendBackgroundProcessing` property of the Effect to `true`. The background processing that is blocked includes component measurement and layout, and responses to data services for the duration of the effect.

Using the cachePolicy property

An effect can use bitmap caching in Flash Player to speed up animations. An effect typically uses bitmap caching when the target component's drawing does not change while the effect is playing.

The cachePolicy property of UIComponents controls the caching operation of a component during an effect. The `cachePolicy` property can have the following values:

CachePolicy.ON Specifies that the effect target is always cached.

CachePolicy.OFF Specifies that the effect target is never cached.

CachePolicy.AUTO Specifies that Flex determines whether the effect target should be cached. This is the default value.

The cachePolicy property is useful when an object is included in a redraw region but the object does not change. The cachePolicy property provides a wrapper for the cacheAsBitmap property.

Improving rendering speed

The actual rendering of objects on the screen can take a significant amount of time. Improving the rendering times can dramatically improve your application's performance. Use the techniques in this section to help improve rendering speed. In addition, use the techniques described in the previous section, "Improving effect performance" on page 2325, to improve effect rendering speed.

Setting movie quality

You can use the quality property of the wrapper's <object> and <embed> tags to change the rendering of your application in Flash Player. Valid values for the quality property are low, medium, high, autolow, autohigh, and best. The default value is best.

The low setting favors playback speed over appearance and never uses anti-aliasing. The autolow setting emphasizes speed at first but improves appearance whenever possible. The autohigh setting emphasizes playback speed and appearance equally at first, but sacrifices appearance for playback speed if necessary. The medium setting applies some anti-aliasing and does not smooth bitmaps. The high setting favors appearance over playback speed and always applies anti-aliasing. The best setting provides the best display quality and does not consider playback speed. All output is anti-aliased and all bitmaps are smoothed.

For information on these settings, see "About the object and embed tags" on page 2564.

Understanding redraw regions

A *redraw region* is the region around an object that must be redrawn when that object changes. Everything in a redraw region is redrawn during the next rendering phase after an object changes. The area that Flash Player redraws includes the object, and any objects that overlap with the redraw region, such as the background or the object's container.

You can see redraw regions at run time in the debugger version of Flash Player by selecting View > Show Redraw Regions in the player's menu. When you select this option, the debugger version of Flash Player draws red rectangles around each redraw region while the application runs.

By looking at the redraw regions, you can get a sense of what is changing and how much rendering is occurring while your application runs. Flash Player sometimes combines the redraw regions of several objects into a single region that it redraws. As a result, if your objects are spaced close enough together, they might be redrawn as part of one region, which is better than if they are redrawn separately. If the number of regions is too large, Flash Player might redraw the entire screen.

Using the cacheAsBitmap property

To improve rendering speeds, make careful use of the cacheAsBitmap property. You can set this property on any UIComponent.

When you set the cacheAsBitmap property to true, Flash Player stores a copy of the initial bitmap image of an object in memory. If you later need that object, and the object's properties have not changed, Flash Player uses the cached version to redraw the object. This can be faster than using the vectors that make up the object.

Setting the cacheAsBitmap property to true can be especially useful if you use animations or other effects that move objects on the screen. Instead of redrawing the object in each frame during the animation, Flash Player can use the cached bitmap.

The downside is that changing the properties of objects that are cached as bitmaps is more computationally expensive. Each time you change a property that affects the cached object's appearance, Flash Player must remove the old bitmap and store a new bitmap in the cache. As a result, only set the `cacheAsBitmap` property to `true` for objects that do not change much.

Enable bitmap caching only when you need it, such as during the duration of an animation, and only on a few objects at a time because it can be a memory-intensive operation. The best approach might be to change this property at various times during the object's life cycle, rather than setting it once.

Using filters

To improve rendering speeds, do not overuse filters such as DropShadowFilter. The expense of the filter is proportional to the number of pixels in the object that you are applying the filter to. As a result, it is best to use filters on smaller objects. An alternative to the DropShadowFilter is to use the `dropShadowEnabled` property. For more information, see "Using the dropShadowEnabled property" on page 1558.

Using device text

Mixing device text and vector graphics can slow rendering speeds. For example, a DataGrid control that contains both text and graphics inside a cell will be much slower to redraw than a DataGrid that contains just text.

Using clip masks

Using the `scrollRect` and `mask` properties of an object are expensive operations. Try to minimize the number of times you use these properties.

Virtualizing lists and containers

When you use item renderers or list-based controls where not every child is visible on the screen, you should use virtualization to reduce memory usage.

Ideally, you want a parent control to reuse children as the children scroll off the screen, instead of creating a new child for each newly-visible list item. This is the process of virtualization. For example, suppose there is a list of 10 items, but only 5 are visible on the screen at one time. When the user scrolls down to view the sixth item, you want item 1 to be reassigned to item 2, item 2 to be reassigned to item 1, and so on. The result is that only 5 items are in memory at any given time, rather than all 10.

To enable virtualization, use the `useVirtualLayout` property. The default value of this property for list-based controls such as ButtonBar, TabBar, DropDownList, and ComboBox is `true`.

For containers, which wrap item renderers, you can set the virtualization on the layout. The default value of `useVirtualLayout` on layouts such as BasicLayout, VerticalLayout, TileLayout, and HorizontalLayout is `false`. Set this property to `true` to enable virtualization for the containers.

Using large data sets

You can minimize overhead when working with large data sets.

Paging

When you use a DataService class to get your remote data, you might have a collection that does not initially load all of its data on the client. You can prevent large amounts of data from traveling over the network and slowing down your application while that data is processed using paging. The data that you get incrementally is referred to as *paged* data, and the data that has not yet been received is *pending* data.

Paging data using the DataService class provides the following benefits:

- Maximum message size on the destination can be configured.

- If size exceeds the maximum value, multiple message batches are used.
- Client reassembles separate messages.
- Asynchronous data paging across the network.
- User interface elements can display portions of the collection without waiting for the entire collection to load.

For more information, see “Data providers and collections” on page 898.

Disabling live scrolling

Using a DataGrid control with large data sets might make it slow to scroll when using the scrollbar. When the DataGrid displays newly visible data, it calls the `getItemAt()` method on the data provider.

The default behavior of a DataGrid is to continuously update data when the user is scrolling through it. As a result, performance can degrade if you just simply scroll through the data on a DataGrid because the DataGrid is continuously calling the `getItemAt()` method. This can be a computationally expensive method to call.

You can disable this *live scrolling* so that the view is only updated when the scrolling stops by setting the `liveScrolling` property to false.

The default value of the `liveScrolling` property is true. All subclasses of ScrollControlBase, including the MX TextArea, HorizontalList, TileList, and DataGrid classes, have this property.

Dynamically repeating components

There are relative benefits of using List-based controls (rather than the Repeater control) to dynamically repeat components. If you must use the Repeater, however, there are techniques for improving the performance of that control.

Comparing MX List-based controls to the Repeater control

To dynamically repeat components, you can choose between the Repeater or List-based controls, such as HorizontalList, TileList, or List. To achieve better performance, you can often replace layouts you created with a Repeater with the combination of a HorizontalList or TileList and an item renderer.

The Repeater object is useful for repeating a small set of simple user interface components, such as RadioButton controls and other controls typically used in Form containers. You can use the HorizontalList, TileList, or List control when you display more than a few repeated objects.

The HorizontalList control displays data horizontally, similar to the HBox container. The HorizontalList control always displays items from left to right. The TileList control displays data in a tile layout, similar to the Tile container. The TileList control provides a direction property that determines if the next item is down or to the right. The List control displays data in a single vertical column.

Unlike the Repeater object, which instantiates all objects that are repeated, the HorizontalList, TileList, and List controls only instantiate what is visible in the list. The Repeater control takes a data provider (typically an Array) that creates a new copy of its children for each entry in the Array. If you put the Repeater control’s children inside a container that does not use deferred instantiation, your Repeater control might create many objects that are not initially visible.

For example, a VBox container creates all objects within itself when it is first created. In the following example, the Repeater control creates all the objects whether or not they are initially visible:

```
<?xml version="1.0"?>
<!-- optimize/VBoxRepeater.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script><![CDATA[
        import mx.collections.ArrayCollection;

        [Bindable]
        public var imgList:ArrayCollection = new ArrayCollection([
            {img:"butterfly.gif"},
            {img:"butterfly-gray.gif"},
            {img:"butterfly-silly.gif"}
        ]);
    ]]></fx:Script>
    <mx:Panel title="VBox with Repeater">
        <mx:VBox height="150" width="250">
            <mx:Repeater id="r" dataProvider="{imgList}">
                <mx:Image source="../assets/{r.currentItem.img}"/>
            </mx:Repeater>
        </mx:VBox>
    </mx:Panel>
</s:Application>
```

If you use a List-based control, however, Flex only creates those controls in the list that are initially visible. The following example uses the List control to create only the image needed for rendering:

```
<?xml version="1.0"?>
<!-- optimize/ListItems.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
   <fx:Script><![CDATA[
        import mx.collections.ArrayCollection;

        private static var birdList:Array = ["../assets/butterfly.gif","../assets/butterfly-
gray.gif","../assets/butterfly-silly.gif"];
        [Bindable]
        private var birdListAC:ArrayCollection = new ArrayCollection(birdList);
        private function initCatalog():void {
            birdlist.dataProvider = birdListAC;
        }
    ]]></fx:Script>
    <s:Panel title="List">
        <mx:List id="birdlist"
            rowHeight="150"
            width="250"
            rowCount="1"
            itemRenderer="mx.controls.Image"
            creationComplete="initCatalog()">
        </mx:List>
    </s:Panel>
</s:Application>
```

Using the Repeater control

When using a Repeater control, keep the following techniques in mind:

- Avoid repeating objects that have clip masks because using clip masks is a resource- intensive process.
- Ensure that the containers used as the children of the Repeater control do not have unnecessary container nesting and are as small as possible. If a single instance of the repeated view takes a noticeable amount of time to instantiate, repeating makes it worse. For example, multiple Grid containers in a Repeater object do not perform well because Grid containers themselves are resource-intensive containers to instantiate.
- Set the `recycleChildren` property to `true`. The `recycleChildren` property is a Boolean value that, when set to `true`, binds new data items into existing Repeater children, incrementally creates children if there are more data items, and destroys extra children that are no longer required.

The default value of the `recycleChildren` property is `false` to ensure that you do not leave stale state information in a repeated instance. For example, suppose you use a Repeater object to display photo images and each Image control has an associated NumericStepper control for how many prints you want to order.

Some of the state information, such as the image, comes from the `dataProvider` property. Other state information, such as the print count, is set by user interaction. If you set the `recycleChildren` property to `true` and page through the photos by incrementing the Repeater object's `startingIndex` value, the Image controls bind to the new images, but the NumericStepper control maintains the old information. Use `recycleChildren="false"` only if it is too cumbersome to reset the state information manually, or if you are confident that modifying your `dataProvider` property should not trigger a recreation of the Repeater object's children.

Keep in mind that the `recycleChildren` property has no effect on a Repeater object's speed when the Repeater object loads the first time. The `recycleChildren` property improves performance only for subsequent changes to the Repeater control's data provider. If you know that your Repeater object creates children only once, you do not have to use the `recycleChildren` property or worry about the stale state situation.

Using FXG

If you use FXG to draw graphic elements in your application, or to draw skin parts, you should consider some of the performance issues around how you use it.

When using FXG, do not convert it to MXML graphics and mix the tags inline with your application or other components. Instead, store the FXG file as a separate document. This causes the mxmlc compiler to convert the FXG to Flash primitives rather than map the FXG elements to Flex tags. Flash primitives are much more optimized.

For more information, see "Using FXG in applications built with Flex" on page 1722.

Comparing ArrayLists and ArrayCollections

The ArrayList and ArrayCollection classes store data and provide access to the backing arrays through methods and properties.

The ArrayList class implements the IList interface. The ArrayCollection class implements the IList and ICollectionView interfaces. As a result, the ArrayList class is more lightweight. However, ArrayLists have fewer features than ArrayCollections. ArrayLists do not support:

- Cursors
- Filters
- Sorts

In many cases, you can use an ArrayList instead of an ArrayCollection for data-driven UI components as long as you do not require cursors, filters, and sorts. The following example shows an ArrayList and an ArrayCollection. The control that uses an ArrayList should be faster and use less memory.

```
<?xml version="1.0"?>
<!-- optimize/ArrayListVersusArrayCollection.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <s:Label text="This ComboBox uses an ArrayList as a data provider:"/>
    <!-- Using an ArrayList is more efficient. -->
   <s:ComboBox>
      <s:ArrayList>
         <fx:String>AK</fx:String>
         <fx:String>AL</fx:String>
         <fx:String>AR</fx:String>
      </s:ArrayList>
   </s:ComboBox>

    <s:Label text="This ComboBox uses an ArrayCollection as a data provider:"/>
   <s:ComboBox>
      <s:ArrayCollection>
         <fx:String>AK</fx:String>
         <fx:String>AL</fx:String>
         <fx:String>AR</fx:String>
      </s:ArrayCollection>
   </s:ComboBox>
</s:Application>
```

In most cases, you cannot get an ArrayList from a web service or remote object call. The results should be set as an ArrayCollection.

Improving charting component performance

You can use various techniques to improve the performance of charting controls.

Avoiding filtering series data

When possible, set the `filterData` property to `false`. In the transformation from data to screen coordinates, the various series types filter the incoming data to remove any missing values that are outside the range of the chart; missing values would render incorrectly if drawn to the screen. For example, a chart that represents vacation time for each week in 2003 might not have a value for the July fourth weekend because the company was closed. If you know your data model will not have any missing values at run time, or values that fall outside the chart's data range, you can instruct a series to explicitly skip the filtering step by setting its `filterData` property to `false`.

Coding the LinearAxis object

If possible, do not let a LinearAxis object autocalculate its range. A LinearAxis control calculating its numeric range can be a resource-intensive calculation. If you know reasonable minimum and maximum values for the range of your LinearAxis, specify them to help your charts render more quickly.

In addition to specifying the range for a LinearAxis, specify an interval (the numeric distance between label values along the axis) value. Otherwise, the chart control must calculate this value.

Coding the CategoryAxis object

Modifying a CategoryAxis object's data provider is more resource intensive than modifying a Series object's data provider. If the data bound to your chart is going to change, but the categories in your chart will stay static, have the CategoryAxis' data provider and Series' data provider refer to different objects. This prevents the CategoryAxis from reevaluating its data provider, which is a resource-intensive computation.

Styling AxisRenderer objects

Improve the rendering time of your AxisRenderers objects by setting particular styles. The AxisRenderers perform many calculations to ensure that they render correctly in all situations. The more help you can give them in restricting their options, the faster they render. Setting the `labelRotation` and `canStagger` styles on the AxisRenderer improve performance. You can set these styles within the tag or in CSS.

Specifying gutter styles

Specify gutter styles when possible. The gutter area of a Cartesian chart is the area between the margins and the actual axis lines. With default values, the chart adjusts the gutter values to accommodate axis decorations. Calculating these gutter values can be resource intensive. By explicitly setting the values of the `gutterLeft`, `gutterRight`, `gutterTop`, and `gutterBottom` style properties, your charts draw quicker and more efficiently.

Using drop shadows

To improve performance, do not use drop-shadows on your series items unless they are necessary. You can selectively add shadows to individual chart series by using renderers such as the ShadowBoxItemRenderer and ShadowLineRenderer classes.

Shadows are implemented as filters in charting controls. As a result, you must remove these shadows by setting the chart control's `seriesFilters` property to an empty Array. The following example removes the shadows from all series, but then changes the renderer for the third series to be a shadow renderer:

```
<?xml version="1.0"?>
<!-- optimize/RemoveShadowsColumnChart.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    height="600">
    <fx:Script><![CDATA[
        import mx.collections.ArrayCollection;
        [Bindable]
        public var expenses:ArrayCollection = new ArrayCollection([
            {Month: "Jan", Income: 2000, Expenses: 1500, Profit: 500},
            {Month: "Feb", Income: 1000, Expenses: 200, Profit: 800},
            {Month: "Mar", Income: 1500, Expenses: 500, Profit: 1000}
        ]);
    ]]></fx:Script>

    <s:Panel title="Column Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <mx:ColumnChart id="myChart" dataProvider="{expenses}">
            <mx:seriesFilters>
                <fx:Array/>
            </mx:seriesFilters>
            <mx:horizontalAxis>
                <mx:CategoryAxis dataProvider="{expenses}" categoryField="Month"/>
            </mx:horizontalAxis>
            <mx:series>
                <mx:ColumnSeries xField="Month" yField="Income" displayName="Income"/>
                <mx:ColumnSeries xField="Month" yField="Expenses" displayName="Expenses"/>
                <mx:ColumnSeries xField="Month" yField="Profit" displayName="Profit"
                    itemRenderer="mx.charts.renderers.ShadowBoxItemRenderer"/>
            </mx:series>
        </mx:ColumnChart>
        <mx:Legend dataProvider="{myChart}"/>
    </s:Panel>
</s:Application>
```

Improving startup performance

About startup performance

You could increase the startup time and decrease performance of your applications if you create too many objects or put too many objects into a single view. To improve startup time, minimize the number of objects that are created when the application is first loaded. If a user-interface component is not initially visible at startup, avoid creating that component until you need it. This is called deferred creation. Containers that have multiple views, such as an Accordion container, provide built-in support for this behavior. You can use ActionScript to customize the creation order of multiple-view containers or defer the creation of other containers and controls.

After you improve the *actual* startup time of your application as much as possible, you can improve *perceived* startup time by ordering the creation of containers in the initial view. The default behavior of Flex is to create all containers and their children in the initial view, and then display everything at one time. The user will not be able to interact with the application or see meaningful data until all the containers and their children are created. In some cases, you can improve the user's initial experience by displaying the components in one container before creating the components in the next container. This process is called *ordered creation*.

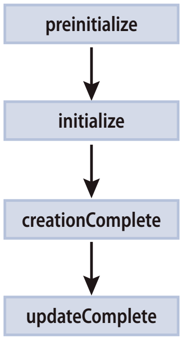
The remaining sections of this topic describe how to use deferred creation to reduce overall application startup time and ordered creation to make the initial startup time appear as short as possible to the user. But before you can fully understand ordered creation and deferred creation, you must also understand the differences between single-view and multiple-view containers, the order of events in a component's startup life cycle, and how to manually instantiate controls from their child descriptors.

About startup order

All Flex components trigger a number of events during their startup procedure. These events indicate when the component is first created, plotted internally, and drawn on the screen. The events also indicate when the component is finished being created and, in the case of containers, when its children are created.

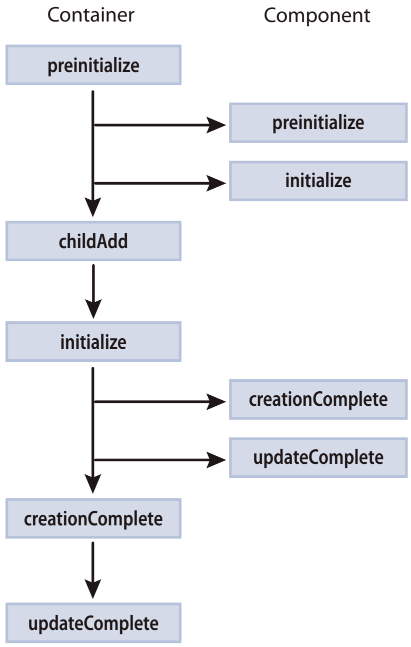
Components are instantiated, added or linked to a parent, and then sized and laid out inside their container. The component creation order is as follows:

The following example shows the major events that are dispatched during a component's creation life cycle:



The creation order is different for containers and components because containers can be the parent of other components or containers. Components within the containers must also go through the creation order. If a container is the parent of another container, the inner container's children must also go through the creation order.

The following example shows the major events that are dispatched during a container's creation life cycle:



After all components are created and drawn, the Application object dispatches an `applicationComplete` event. This is the last event dispatched during an application startup.

The creation order of multiview containers (navigators) is different from standard containers. By default, all top-level views of the navigator are instantiated. However, Flex creates only the children of the initially visible view. When the user navigates to the other views of the navigator, Flex creates those views' children. For more information on the deferred creation of children of multiview containers, see "Using deferred creation" on page 2335.

For a detailed description of the component creation life cycle, see "Using container events" on page 333.

Using deferred creation

By default, containers create only the controls that initially appear to the user. Flex creates the container's other descendants if the user navigates to them. Containers with a single view, such as Group, Box, Form, and Grid containers, create all of their descendants during the container's instantiation because these containers display all of their descendants immediately.

Containers with multiple views, called navigator containers, only create and display the descendants that are visible at any given time. These containers are the MX ViewStack, Accordion, and TabNavigator containers.

When navigator containers are created, they do not immediately create all of their descendants, but only those descendants that are initially visible. Flex defers the creation of descendants that are not initially visible until the user navigates to a view that contains them.

The result of this deferred creation is that an MXML application with navigator containers loads more quickly, but the user experiences brief pauses when he or she moves from one view to another when interacting with the application.

You can instruct each container to create their children or defer the creation of their children at application startup by using the container's `creationPolicy` property. This can improve the user experience after the application loads. For more information, see "About the creationPolicy property" on page 2336.

You can also create individual components whose instantiation is deferred by using the `createDeferredContent()` method (for Spark containers) or the `createComponentsFromDescriptors()` method (for MX containers). For more information, see "Creating deferred components" on page 2339.

About the creationPolicy property

To defer the creation of any component, container, or child of a container, you use the `creationPolicy` property. Every container has a `creationPolicy` property that determines how the container decides whether to create its descendants when the container is created. You can change the policy of a container using MXML or ActionScript.

The valid values for the `creationPolicy` property are `auto`, `all`, and `none`. The meaning of these settings depends on whether the container is a navigator container (multiple-view container) or a single-view container.

The `creationPolicy` property is inheritable when set on the MX Container or Spark SkinnableContainer class. This means that if you set the value of the `creationPolicy` property to `none` on an outer container, all containers within that container inherit that value of the `creationPolicy` property, unless otherwise overridden.

This inheritance does not apply to sibling containers. If you have two containers at the same level (of the same type) and you set the `creationPolicy` of one of them, the other container continues to have the default value of the `creationPolicy` property unless you explicitly set it.

Single-view containers

Single-view containers by default create all their children when the application first starts. You can use the `creationPolicy` property to change this behavior. The following table describes the values of the `creationPolicy` property when you use it with single-view containers:

Value	Description
`all`, `auto`	Creates all controls inside the single-view container. The default value is `auto`, but `all` results in the same behavior.
`none`	Instructs Flex to not instantiate any component within the container until you manually instantiate the controls. When the value of the `creationPolicy` property is `none`, you generally set a width and height for that container explicitly. Normally, Flex scales the container to fit the children that are inside it, but because no children are created, proper scaling is not possible. If you do not explicitly size the container, it grows to accommodate the children when they are created. To manually instantiate controls, you use the `createDeferredContent()` method (for Spark containers) or the `createComponentsFromDescriptors()` method (for MX containers). For more information, see "Creating deferred components" on page 2339.

The following example sets the value of a Spark Panel container's `creationPolicy` property to `auto`, the default value:

```
<?xml version="1.0"?>
<!-- layoutperformance/AutoCreationPolicy.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:Panel id="myPanel" creationPolicy="auto">
        <s:Button id="b1" label="Get Weather"/>
    </s:Panel>
</s:Application>
```

The default behavior of all single-view containers is that they and their children are entirely instantiated when the application starts. If you set the `creationPolicy` property to `none`, however, you can selectively instantiate controls within the containers by using the techniques described in “Creating deferred components” on page 2339.

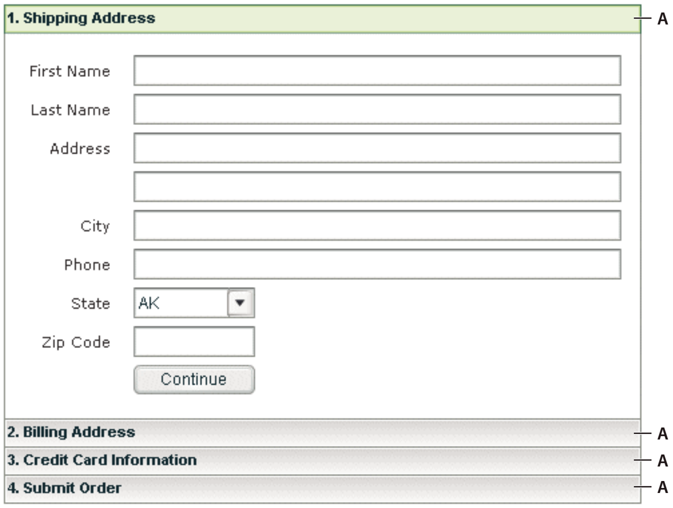
Multiple-view containers

Containers with multiple views, such as the ViewStack and Accordion, do not immediately create all of their descendants, but only those descendants that are visible in the initial view. Flex defers the instantiation of descendants that are not initially visible until the user navigates to a view that contains them. The following containers have multiple views and, so, are defined as navigator containers:

- ViewStack
- TabNavigator
- Accordion

When you instantiate a navigator container, Flex creates all of the top-level children. For example, creating an Accordion container triggers the creation of each of its views, but not the controls within those views. The `creationPolicy` property determines the creation of the child controls inside each view.

When you set the `creationPolicy` property to `auto` (the default value), navigator containers instantiate only the controls and their children that appear in the initial view. The first view of the Accordion container is the initial pane, as the following example shows:



When the user navigates to another panel in the Accordion container, the navigator container creates the next set of controls, and recursively creates the new view’s controls and their descendants. You can use the Accordion container’s `creationPolicy` property to modify this behavior. The following table describes the values of the `creationPolicy` property when you use it with navigator containers:

Value	Description
`all`	Creates all controls in all views of the navigator container. This setting causes a delay in application startup time and an increase in memory usage, but results in quicker response time for user navigation. You should generally not use `all` because of the performance hit that your application will take when it starts up.
`auto`	Creates all controls only in the initial view of the navigator container. This setting causes a faster startup time for the application, but results in slower response time for user navigation. This setting is the default for multiple-view containers.
`none`	Instructs Flex to not instantiate any component within the navigator container or any of the navigator container's panels until you manually instantiate the controls. To manually instantiate controls, you use the `createDeferredContent()` method (for Spark containers) or the `createComponentsFromDescriptors()` method (for MX containers). For more information, see "Creating deferred components" on page 2339.

The following example sets the `creationPolicy` property of an Accordion container to `all`, which instructs the container to instantiate all controls for every panel in the navigator container when the application starts:

```
<?xml version="1.0"?>
<!-- layoutperformance/AllCreationPolicy.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:Panel title="Accordion">
        <mx:Accordion id="myAccordion" creationPolicy="all">
            <mx:VBox label="Accordion Button for Panel 1">
                <mx:Label text="Accordion container panel 1"/>
                <s:Button label="Click Me"/>
            </mx:VBox>
            <mx:VBox label="Accordion Button for Panel 2">
                <mx:Label text="Accordion container panel 2"/>
                <s:Button label="Click Me"/>
            </mx:VBox>
            <mx:VBox label="Accordion Button for Panel 3">
                <mx:Label text="Accordion container panel 3"/>
                <s:Button label="Click Me"/>
            </mx:VBox>
        </mx:Accordion>
    </s:Panel>
</s:Application>
```

Setting a container's `creationPolicy` property does not override the policies of the containers within that container.

In the following example, the button1 control is never created because its immediate parent container specifies a `creationPolicy` of `none`, even though the outer container sets the `creationPolicy` property to `all`:

```
<?xml version="1.0"?>
<!-- layoutperformance/TwoCreationPolicies.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:Panel title="Outer Panel where creationPolicy=all" creationPolicy="all">
        <s:Panel title="Inner Panel where creationPolicy=none" creationPolicy="none">
            <s:Button id="button1" label="Click Me"/>
        </s:Panel>
    </s:Panel>
</s:Application>
```

Creating deferred components

When you set a container's `creationPolicy` property to `none`, components declared as MXML tags inside that container are not created.

For Spark containers, you use the `createDeferredContent()` method to manually instantiate deferred components. This method is defined on the spark.components.SkinnableContainer class.

For MX containers, you use the `createComponentsFromDescriptors()` method to manually instantiate deferred components. This method is defined on the MX Container base class.

Using the createDeferredContent() method

You use the `createDeferredContent()` method to create deferred child components in a Spark container.

In the following example with a Spark container, the children of the Panel container are not instantiated when the application is first loaded, but only after the user clicks the button:

```
<?xml version="1.0"?>
<!-- layoutperformance/CreationPolicyNoneSpark.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script><![CDATA[
        private function createButtons(e:Event):void {
            myPanel.createDeferredContent();
        }
    ]]></fx:Script>
    <s:Panel id="myPanel" title="Panel with Deferred Content" creationPolicy="none">
        <s:VGroup>
            <s:Button id="b1" label="Hurley"/>
            <s:Button id="b2" label="Jack"/>
            <s:Button id="b3" label="Sawyer"/>
        </s:VGroup>
    </s:Panel>

    <s:Button id="myButton" click="createButtons(event)" label="Create Buttons"/>
</s:Application>
```

Only SkinnableContainer and containers that extend the SkinnableContainer class support deferred instantiation; Groups do not. When a Group is created, its children are always created. You cannot specify a creation policy on a Group.

Using the createComponentsFromDescriptors() method

***Note:** The `createComponentsFromDescriptors()` method is for MX containers. For Spark containers, use the `createDeferredContent()` method.*

You use the `createComponentsFromDescriptors()` method of an MX container to create all the children of a container at one time.

The `createComponentsFromDescriptors()` method has the following signature:

```
container.createComponentsFromDescriptors(recurse:Boolean):Boolean
```

The *recurse* argument determines whether Flex should recursively instantiate children of containers that are children of the top-level container. Set the parameter to `true` to instantiate children of the containers, or `false` to not instantiate the children. The default value is `true`.

On a single-view MX container, calling the `createComponentsFromDescriptors()` method instantiates all controls in that container, regardless of the value of the `creationPolicy` property.

In navigator containers, if you set the `creationPolicy` property to `all`, you do not have to call the `createComponentsFromDescriptors()` method, because the container creates all controls in all views of the container. If you set the `creationPolicy` property to `none` or `auto`, calling the `createComponentsFromDescriptors()` method creates only the current view’s controls and their descendents.

Another common usage is to set the navigator container’s `creationPolicy` property to `auto`. You can then call *navigator*`.getChildAt(n).createComponentsFromDescriptors()` to explicitly create the children of the *n*-th view.

Using the callLater() method

The `callLater()` method queues an operation to be performed for the next screen refresh, rather than in the current update. Without the `callLater()` method, you might try to access a property of a component that is not yet available. The `callLater()` method is most commonly used with the `creationComplete` event to ensure that a component has finished being created before Flex proceeds with a specified method call on that component.

All objects that inherit from the UIComponent class can open the `callLater()` method. It has the following signature:

```
callLater(method:Function, args:Array):void
```

The *method* argument is the function to call on the object. The *args* argument is an optional Array of arguments that you can pass to that function.

The following example defers the invocation of the `doSomething()` method, but when it is opened, Flex passes the Event object and the “Product Description” String in an Array to that function:

```
callLater(doSomething, [event, "Product Description"]);
...
private function doSomething(event:Event, title:String):void {
    ...
}
```

The following example uses a call to the `callLater()` method to ensure that new data is added to a DataGrid before Flex tries to put focus on the new row. Without the `callLater()` method, Flex might try to focus on a cell that does not exist and throw an error:

```
<?xml version="1.0"?>
<!-- layoutperformance/CallLaterAddItem.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    initialize="initData()">
    <fx:Script><![CDATA[
        import mx.collections.*;
        private var DGArray:Array = [
            {Artist:'Pavement', Album:'Charred Walls', Price:11.99},
            {Artist:'Pavement', Album:'Good For You', Price:11.99}];

        [Bindable]
        public var initDG:ArrayCollection;
        //Initialize initDG ArrayCollection variable from the Array.

        public function initData():void {
            initDG=new ArrayCollection(DGArray);
        }

        public function addNewItem():void {
            var o:Object;
            o = {Artist:'Pavement', Album:'Tradio', Price:11.99};
            initDG.addItem(o);
            callLater(focusNewRow);
        }
        public function focusNewRow():void {
            myGrid.editedItemPosition = {
                columnIndex:0,rowIndex:myGrid.dataProvider.length-1
            };
        }

    ]]></fx:Script>
    <s:VGroup>
        <mx:DataGrid id="myGrid" width="350" height="200" dataProvider="{initDG}"
editable="true">
            <mx:columns>
                <fx:Array>
                    <mx:DataGridColumn dataField="Album" />
                    <mx:DataGridColumn dataField="Price" />
                </fx:Array>
            </mx:columns>
        </mx:DataGrid>
        <s:Button id="b1" label="Add New Item" click="addNewItem()"/>
    </s:VGroup>

</s:Application>
```

Another use of the `callLater()` method is to create a recursive method. Because the function is called only after the next screen refresh (or frame), the `callLater()` method can be used to create animations or scroll text with methods that reference themselves.

The following example scrolls ticker symbols across the screen and lets users adjust the speed with an HSlider control:

```
<?xml version="1.0"?>
<!-- layoutperformance/CallLaterTicker.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <fx:Script><![CDATA[

        [Bindable]
        public var text:String = "SLAR:95.5....TIBA:42....RTF:34.15....AST:23.42";
        [Bindable]
        public var speed:Number = 5;
        public function initTicker():void {
            theText.move( this.width+10, 0 ); // Start the text on the right side.
            callLater(moveText);
        }
        public function moveText():void {
            var xpos:Number = theText.x;
            if( xpos-speed+theText.width < 0 ) {
                xpos = this.width+10; // Start the text on the right side.
            }
            xpos -= speed;
            theText.move(xpos,0);
            callLater(moveText);
        }
        public function changeSpeed():void {
            speed = speedSelector.value;
        }

    ]]></fx:Script>
    <s:Panel title="Ticker Sample" width="400" height="200">
        <s:VGroup>
                <mx:Canvas creationComplete="initTicker()"
                    horizontalScrollPolicy="off" backgroundColor="red" color="white"
                    width="400">
                <mx:Label id="theText" text="{text}" y="0"/>
            </mx:Canvas>
            <mx:HBox>
                <mx:Label text="Speed:"/>
                <mx:HSlider minimum="1" maximum="10" value="{speed}"
                    id="speedSelector" snapInterval="1" tickInterval="1"
                    change="changeSpeed()"/>
            </mx:HBox>
        </s:VGroup>
    </s:Panel>
</s:Application>
```

Ant tasks

The Adobe® Flex® Ant tasks provide a convenient way to build your Flex projects using an industry-standard build management tool. If you are already using Ant projects to build Flex applications, you can use the Flex Ant tasks to replace your `exec` or `java` commands that invoke the mxmlc and compc compilers. If you are not yet using Ant to build your Flex applications, you can take advantage of these custom tasks to quickly and easily set up complex build processes for your Flex applications.

The Ant tasks for Flex include two compiler tasks, `mxmlc` and `compc`. You can use these to compile Flex applications, modules, and component libraries. In addition, the Ant tasks include the `html-wrapper` task that lets you generate custom HTML wrappers and the supporting files for those wrappers, and an `asdoc` Ant task to generate ASDoc documentation.

The `mxmlc` and `compc` Ant tasks extend the `java` Ant task. As a result, you can use all the available attributes of the `java` Ant task in those Ant tasks. This includes `fork`, `maxmemory`, and `classpath`.

The Apache Ant Project

Setting up Flex Ant tasks

Installing the Flex Ant tasks is a simple process. You copy the flexTasks.jar file from a Flex directory to Ant's lib directory. For Adobe® Flex® Builder™, the flexTasks.jar file is located at *flash_builder_install*/sdks/4.6.0/ant/lib. For the SDK, the flexTasks.jar file is located at *sdk_install*/ant/lib.

Copy the flexTasks.jar file to Ant's lib directory (*ant_root*/lib). If you do not copy this file to Ant's lib directory, you must specify it by using Ant's `-lib` option on the command line when you make a project.

For Flash Builder, the ant directory also includes the source code for the Flex Ant tasks.

Using Flex Ant tasks

You can use the Flex Ant tasks in your existing projects or create new Ant projects that use them. There are three tasks that you can use in your Ant projects:

- `mxmlc` — Invokes the application compiler. You use this compiler to compile applications, modules, resource modules, and CSS SWF files.
- `compc` — Invokes the component compiler. You use this compiler to compile SWC files and Runtime Shared Libraries (RSLs).
- `html-wrapper` — Generates the HTML wrapper and supporting files for your application. By using this task, you can select the type of wrapper (with and without deep linking support, with and without Express Install, and with and without Player detection), as well as specify application settings such as the height, width, and background color.
- `asdoc` — Generates ASDoc output for the specified classes in your project.

To use the custom Flex Ant tasks in your Ant projects, you must add the flexTasks.jar file to your project's lib directory, and then point to that JAR file in the `taskdef` task. A `taskdef` task adds a new set of task definitions to your current project. You use it to add task definitions that are not part of the default Ant installation. In this case, you use the `taskdef` task to add the `mxmlc`, `compc`, and `html-wrapper` task definitions to your Ant installation. In addition, for most projects you set the value of the `FLEX_HOME` variable so that Ant can find your flex-config.xml file and so that you can add the frameworks directory to your source path.

Use the Flex tasks in Ant:

1 Add a new `taskdef` task to your project. In this task, specify the flexTasks.tasks file as the resource, and point to the flexTasks.jar file for the classpath. For example:

```
<taskdef resource="flexTasks.tasks" classpath="${basedir}/flexTasks/lib/flexTasks.jar"/>
```

2 Define the `FLEX_HOME` and `APP_ROOT` properties. Use these properties to point to your Flex SDK's root directory and application's root directory. Although not required, creating properties for these directories is a common practice because you will probably use them several times in your Ant tasks. For example:

```
<property name="FLEX_HOME" value="C:/flex/sdk"/>
<property name="APP_ROOT" value="myApps"/>
```

3 Write a target that uses the Flex Ant tasks. The following example defines the `main` target that uses the `mxmlc` task to compile the Main.mxml file:

```
<target name="main">
    <mxmlc file="${APP_ROOT}/Main.mxml" keep-generated-actionscript="true">
        <load-config filename="${FLEX_HOME}/frameworks/flex-config.xml"/>
        <source-path path-element="${FLEX_HOME}/frameworks"/>
    </mxmlc>
</target>
```

The following shows the complete example:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- mySimpleBuild.xml -->
<project name="My App Builder" basedir=".">
    <taskdef resource="flexTasks.tasks"
        classpath="${basedir}/flexTasks/lib/flexTasks.jar"/>
    <property name="FLEX_HOME" value="C:/flex/sdk"/>
    <property name="APP_ROOT" value="myApp"/>
    <target name="main">
        <mxmlc file="${APP_ROOT}/Main.mxml" keep-generated-actionscript="true">
            <load-config filename="${FLEX_HOME}/frameworks/flex-config.xml"/>
            <source-path path-element="${FLEX_HOME}/frameworks"/>
        </mxmlc>
    </target>
</project>
```

This example shows how to use different types of options for the `mxmlc` task. You can specify the value of the `keep-generated-actionscript` option as an attribute of the `mxmlc` task's tag because it does not take any child tags. To specify the values of the `load-config` and `source-path` options, you create child tags of the `mxmlc` task's tag. For more information on using options, see "Working with compiler options" on page 2345.

4 Execute the Ant project, as shown in the following example:

```
> ant -buildfile mySimpleBuild.xml main
```

If you did not copy the flexTasks.jar file to Ant's lib directory as described in "Setting up Flex Ant tasks" on page 2343, you must include the JAR file by using Ant's `-lib` option. For example:

```
> ant -lib c:/ant/lib/flexTasks.jar -buildfile mySimpleBuild.xml main
```

The output of these commands should be similar to the following:

```
Buildfile: mySimpleBuild.xml
main:
    [mxmlc] Loading configuration file C:\flex\sdk\frameworks\flex-config.xml
    [mxmlc] C:\myfiles\flex4\ant_tests\apps\Main.swf (150035 bytes)
BUILD SUCCESSFUL
Total time: 10 seconds
>
```

To embed fonts in your Flex ant tasks, you must be sure to include the font manager in your build file. For more information, see Embedding Fonts Using AS3 and Flex 4 Ant Tasks.

Working with compiler options

The compc and mxmlc compilers share a very similar set of options. As a result, the behavior of the `mxmlc` and `compc` Ant tasks are similar as well.

You can specify options for the `mxmlc` and `compc` Flex tasks in a number of ways:

- Task attributes
- Single argument options
- Multiple argument options
- Nested elements
- Implicit FileSets

Task attributes

The simplest method of specifying options for the Flex Ant tasks is to specify the name and value of command-line options as a task attribute. In the following example, the `file` and `keep-generated-actionscript` options are specified as attributes of the `mxmlc` task:

```
<mxmlc file="${APP_ROOT}/Main.mxml" keep-generated-actionscript="true">
```

Many mxmlc and compc options have aliases (alternative shorter names). The Flex Ant tasks support all documented aliases for these options.

Single argument options

Many compiler options must specify the value of one or more parameters. For example, the `load-config` option takes a parameter named `filename`.

To specify the option in an Ant task, you add a child tag with that option as the tag name. You set the values of the arguments by including an attribute in the tag whose name is the option name and whose value is the value of the argument.

The following example sets the values of the `load-config` and `source-path` options, which have arguments named `filename` and `path-element` respectively:

```
<mxmlc ... >
    <load-config filename="${FLEX_HOME}/frameworks/flex-config.xml"/>
    <source-path path-element="${FLEX_HOME}/frameworks"/>
</mxmlc>
```

The `source-path` option can take more than one `path-element` parameter. For more information, see “Repeatable options” on page 2346.

You can see which options take parameters by looking at the mxmlc command-line syntax. In the Flex bin directory, enter the following command:

```
mxmlc -help list advanced
```

The output includes all options for the mxmlc compiler. The syntax for the `load-config` option appears like the following:

```
-load-config <filename>
```

This indicates that the `load-config` option takes a single argument called `filename`.

Multiple argument options

Some compiler options, such as the `default-size` option, take more than one argument. The `default-size` option takes a `height` and a `width` argument. You set the values of options that take multiple arguments by using a nested element of the same name, with the attributes of the element corresponding to the arguments of the option as shown in the command-line compiler's online help.

For example, the online help for mxmlc shows the following syntax for the `default-size` option:

```
-default-size <width> <height>
```

To pass the option `-default-size 800 600` to the `mxmlc` task, use the following syntax:

```
<mxmlc ...>
    <default-size width="800" height="600"/>
</mxmlc>
```

Repeatable options

Some compiler options are repeatable. The online help shows their arguments in square brackets, followed by a bracketed ellipses, like this:

```
-compiler.source-path [path-element] [...]
```

You set the value of repeatable options by using multiple nested elements of the same name as the option, along with attributes of the same name as they appear in the online help.

The following example sets two values for the `compiler.source-path` option:

```
<mxmlc ...>
    <compiler.source-path path-element="src"/>
    <compiler.source-path path-element="../bar/src"/>
</mxmlc>
```

Nested elements

In some situations, options that are closely related are grouped together in a nested element of the main task element. For example, the command-line compiler options with the `compiler.fonts` and `metadata` prefixes can be grouped into nested elements. The `compiler.fonts` options use the element name `fonts` and the `metadata` options use the element name `metadata`.

The following example shows how to use the `metadata` nested element:

```
<mxmlc ...>
    <metadata description="foo app">
        <contributor name="Joe" />
        <contributor name="Nick" />
    </metadata>
</mxmlc>
```

In this example, you drop the `metadata` prefix when setting the `description` and `contributor` options as a nested element.

This is a uniformly applied rule with one exception: the `compiler.fonts.languages.language-range` option is set using a nested element with the name `language-range`, rather than `languages.language-range`.

Implicit FileSets

There are many examples in the Apache Ant project where tasks behave as implicit FileSets. For example, the `delete` task, while supporting additional attributes, supports all of the attributes (such as `dir` and `includes`) and nested elements (such as `include` and `exclude`) of a FileSet to specific the files to be deleted.

Some Flex Ant tasks allow nested attributes that are implicit FileSets. These nested attributes support all the attributes and nested elements of an Ant FileSet while adding additional functionality. These elements are usually used to specify repeatable arguments that take a filename as an argument.

The following example uses the implicit FileSet syntax with the `include-sources` nested element:

```
<include-sources dir="player/avmplus/core"
    includes="builtin.as, Date.as, Error.as, Math.as, RegExp.as, XML.as"/>
```

When a nested element in a Flex Ant task is an implicit FileSet, it supports one additional attribute: `append`. The reason for this is that some repeatable options for the Flex compilers have default values. When setting these options in a command line, you can append new values to the default value of the option, or replace the default value with the specified values. Setting the `append` value to `true` adds the new option to the list of existing options. Setting the `append` value to `false` replaces the existing options with the new option. By default, the value of the `append` attribute is `false` in implicit FileSets.

The following example sets the value of the `append` attribute to `true` and uses the Ant `include` element of an implicit FileSet to add multiple SWC files to the `include-libraries` option:

```
<compiler.include-libraries dir="${swf.output}" append="true">
    <include name="MyComponents.swc" />
    <include name="AcmeComponents.swc" />
    <include name="DharmaComponents.swc" />
</compiler.include-libraries>
```

The following options are implemented as implicit FileSets:

```
compiler.external-library-path
compiler.include-libraries
compiler.library-path
compiler.theme
compiler.include-sources (compc only)
```

The Flex Ant task's implicit FileSets are also different from the Ant project's implicit FileSets in that they support being empty, as in the following example:

```
<external-library-path/>
```

This is equivalent to using `external-library-path=` on the command line.

Using the mxmlc task

You use the `mxmlc` Flex Ant task to compile applications, modules, resource modules, and Cascading Style Sheets (CSS) SWF files. This task supports most mxmlc command-line compiler options, including aliases.

For more information on using the mxmlc command-line compiler, see “Using mxmlc, the application compiler” on page 2174.

Required attributes

The mxmlc task requires the file attribute. The file attribute specifies the MXML file to compile. This attribute does not have a command-line equivalent because it is the default option on the command line.

Unsupported options

The following mxmlc command-line compiler options are not supported by the mxmlc task:

- help
- version

Example

The following example mxmlc task explicitly defines the source-path and library-path options, in addition to other properties such as incremental and keep-generated-actionscript. This example also specifies an output location for the resulting SWF file. This example defines two targets: main and clean. The main target compiles the Main.mxml file into a SWF file. The clean target deletes the output of the main target.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- myMXMLCBuild.xml -->
<project name="My App Builder" basedir=".">
    <taskdef resource="flexTasks.tasks" classpath="${basedir}/flexTasks/lib/flexTasks.jar" />
    <property name="FLEX_HOME" value="C:/flex/sdk"/>
    <property name="APP_ROOT" value="apps"/>
    <property name="DEPLOY_DIR" value="c:/jrun4/servers/default/default-war"/>
    <target name="main">
        <mxmlc
            file="${APP_ROOT}/Main.mxml"
            output="${DEPLOY_DIR}/Main.swf"
            actionscript-file-encoding="UTF-8"
            keep-generated-actionscript="true"
            incremental="true">
            <!-- Get default compiler options. -->
            <load-config filename="${FLEX_HOME}/frameworks/flex-config.xml"/>

            <!-- List of path elements that form the roots of ActionScript
            class hierarchies. -->
            <source-path path-element="${FLEX_HOME}/frameworks"/>

            <!-- List of SWC files or directories that contain SWC files. -->
            <compiler.library-path dir="${FLEX_HOME}/frameworks" append="true">
                <include name="libs" />
                <include name="../bundles/{locale}" />
            </compiler.library-path>

            <!-- Set size of output SWF file. -->
            <default-size width="500" height="600" />
        </mxmlc>
    </target>
    <target name="clean">
        <delete dir="${APP_ROOT}/generated"/>
        <delete>
            <fileset dir="${DEPLOY_DIR}" includes="Main.swf"/>
        </delete>
    </target>
</project>
```

Using the compc task

You use the `compc` Flex Ant task to compile component SWC files. This task supports most compc command-line compiler options, including aliases. For more information on using the compc command-line compiler, see "Using compc, the component compiler" on page 2194.

Required attributes

The only required attribute for the `compc` task is the `output` attribute, which specifies the name of the SWC file that the `compc` task creates.

Special attributes

The `include-classes` attribute takes a space-delimited list of class names. For example:

```
<compc include-classes="custom.MyPanel custom.MyButton" ... >
    ...
</compc>
```

When using the `include-resource-bundles` attribute, you should not specify them as a comma or space-delimited list in a single entry. Instead, add a separate child tag for each resource bundle that you want to include, as the following example shows:

```
<compc output="${swf.output}/compc_rb.swc" locale="en_US">
    <include-resource-bundles bundle="ErrorLog"/>
    <include-resource-bundles bundle="LabelResource"/>
    <sp path-element="locale/{locale}"/>
</compc>
```

Unsupported options

The following compc command-line compiler options are not supported by the `compc` task:

- `help`
- `version`

Example

The following example `compc` task builds a new SWC file that contains two custom components and other assets. The components are added to the SWC file by using the `include-classes` attribute. The source files for the components are in a subdirectory called components. The other assets, including four images and a CSS file, are added to the SWC file by using the `include-file` element.

This example defines two targets: `main` and `clean`. The main target compiles the MyComps.swc file. The `clean` target deletes the output of the main target.

```
<?xml version="1.0" encoding="utf-8"?>
<project name="My Component Builder" basedir=".">
    <taskdef resource="flexTasks.tasks" classpath="${basedir}/flexTasks/lib/flexTasks.jar" />
    <property name="FLEX_HOME" value="C:/flex/sdk"/>
    <property name="DEPLOY_DIR" value="c:/jrun4/servers/default/default-war"/>
    <property name="COMPONENT_ROOT" value="components"/>
    <target name="main">
        <compc
            output="${DEPLOY_DIR}/MyComps.swc"
            include-classes="custom.MyButton custom.MyLabel">
            <source-path path-element="${basedir}/components"/>
            <include-file name="f1-1.jpg" path="assets/images/f1-1.jpg"/>
            <include-file name="f1-2.jpg" path="assets/images/f1-2.jpg"/>
            <include-file name="f1-3.jpg" path="assets/images/f1-3.jpg"/>
            <include-file name="f1-4.jpg" path="assets/images/f1-4.jpg"/>
            <include-file name="main.css" path="assets/css/main.css"/>
        </compc>
    </target>
    <target name="clean">
        <delete>
            <fileset dir="${DEPLOY_DIR}" includes="MyComps.swc"/>
        </delete>
    </target>
</project>
```

Using the html-wrapper task

The `html-wrapper` Ant task generates files that you deploy with your applications. An HTML wrapper consists of a generated HTML page and a JavaScript file that defines embed logic. The output can also include files that support features such as deep linking and Express Install.

The `html-wrapper` task outputs the index.html and swfobject.js files for your application. The swfobject.js file defines the SWFObject 2 logic that embeds SWF files in HTML.

If you enable deep linking support, the `html-wrapper` task also outputs the deep linking files such as historyFrame.html, history.css, and history.js. If you enable express installation, the `html-wrapper` task also outputs the playerProductInstall.swf file.

You typically deploy these files, along with your application's SWF file, to a web server. Users request the HTML wrapper, which embeds the SWF file. You can customize the output of the wrapper and its supporting files after it is generated by Ant.

For more information on the HTML wrapper, see “Creating a wrapper” on page 2552.

Supported attributes

The attributes of the `html-wrapper` task correspond to some of the arguments in the `swfobject.embedSWF()` method of the default HTML wrapper.

The following table describes the supported attributes of the `html-wrapper` task:

Attribute	Description
`application`	The name of the SWF object in the HTML wrapper. You use this name to refer to the SWF object in JavaScript or when using the ExternalInterface API. This value should not contain any spaces or special characters. This attribute sets the value of the `<embed>` tag's `name` attribute and the `<object>` tag's `id` attribute.
`bgcolor`	Specifies the background color of the application. Use this property to override the background color setting specified in the SWF file. This property does not affect the background color of the HTML page. This attribute sets the value of the `params.bgcolor` argument in the `embedSWF()` method. The default value is `white`.
`express-install=false|true`	Determines whether to include Express Install logic in the HTML wrapper. When set to `true`, the Ant task copies the playerProductInstall.swf file to the output directory and referenced in the wrapper file. If you set this option to `true`, the `version-detection` option is also assumed to be `true`. For more information, see "Using Express Install in the wrapper" on page 2558. The default value is `false`.
`file`	Sets the file name of the HTML output file. The default value is "index.html".
`height`	Defines the height, in pixels, of the SWF file. Adobe® Flash® Player makes a best guess to determine the height of the application if none is provided. This attribute sets the value of the third argument in the `embedSWF()` method. The default value is 400.
`history`	Set to `true` to include deep linking support (also referred to as *history management*) in the HTML wrapper. Set to `false` to exclude deep linking from the wrapper. When you set this attribute to true, Ant creates a history directory and stores the historyFrame.html, history.css, and history.js files in it. The default value is `false`. For more information on deep linking, see "Deep linking" on page 2022.
`output`	Sets the directory that Ant writes the generated files to. If you do not set the value of this option, Ant creates the wrapper files in the same directory as the build file.
`swf`	Sets the name of the SWF file that the HTML wrapper embeds (for example, Main). Do not include the *.swf extension; the extension is appended to the name for you. This attribute sets the value of the attributes.name and attributes.id arguments in the `embedSWF()` method. It also sets the value of the first argument in that method call. This SWF file does not have to exist when you generate the HTML wrapper. It is used by SWFObject 2 to point to the location of the SWF file at deployment time.
`title`	Sets the value of the `<title>` tag in the head of the HTML page. The default value is `Flex Application`.
`version-detection=true|false`	Determines whether to include version detection logic in the wrapper. Set this value to `false` to disable all Player version logic in the HTML wrapper. The default value is `true`.
`version-major`	Sets the value of the `swfVersionStr` variable in the HTML wrapper. The default value is 10. The value of this attribute only matters if you include version detection in your wrapper by setting the `template` attribute to `express-installation` or `client-side-detection`.

Attribute	Description
`version-minor`	Sets the value of the `swfVersionStr` variable in the HTML wrapper. The default value is 0. The value of this attribute only matters if you include version detection in your wrapper by setting the `template` attribute to `express-installation` or `client-side-detection`.
`version-revision`	Sets the value of the `swfVersionStr` variable in the HTML wrapper. The default value is 0. The value of this attribute only matters if you include version detection in your wrapper by setting the `template` attribute to `express-installation` or `client-side-detection`.
`width`	Defines the width, in pixels, of the SWF file. Flash Player makes a best guess to determine the width of the application if none is provided. This attribute sets the value of the fourth argument in the `embedSWF()` method. The default value is 400.

Required attributes

The `html-wrapper` task requires the `swf` attribute. If you specify only the `swf` attribute, the default wrapper will have the following settings:

```
title="Flex Application"
swfVersionStr = "10.0.0";
params.quality = "high";
params.bgcolor = "white";
params.allowscriptaccess = "sameDomain";
params.allowfullscreen = "true";
attributes.align = "middle";
height="400"
width="400"
```

Be sure to use the filename only and not the filename plus extension when specifying the value of the `swf` attribute. The `html-wrapper` task appends `.swf` to the end of its value before passing it to the `embedSWF()` method.

For example, do this:

```
swf="Main"
```

Do not do this:

```
swf="Main.swf"
```

Unsupported options

The `html-wrapper` task does not support all properties used by SWFObject 2 to embed a SWF file in an HTML wrapper. Parameters you cannot set include `quality`, `allowScriptAccess`, `classid`, `pluginspage`, and `type`.

Example

The following example project includes a wrapper target that uses the `html-wrapper` task to generate a wrapper with deep linking, Player detection, and Express Install logic. This target (`wrapper`) also sets the height and width of the SWF file. The project also includes a `clean` target that deletes all the files generated by the wrapper target.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- myWrapperBuild.xml -->
<project name="My Wrapper Builder" basedir=".">
    <taskdef resource="flexTasks.tasks" classpath="${basedir}/lib/flexTasks.jar"/>
    <property name="FLEX_HOME" value="C:/p4/flex/flex/sdk"/>
    <property name="APP_ROOT" value="c:/temp/ant/wrapper"/>
    <target name="wrapper">
        <html-wrapper
            title="Welcome to My Flex App"
            file="index.html"
            height="300"
            width="400"
            application="app"
            swf="Main"
            history="true"
            express-install="true"
            version-detection="true"
            output="${APP_ROOT}"/>
    </target>
    <target name="clean">
        <delete>
            <!-- Deletes playerProductInstall.swf -->
            <fileset dir="${APP_ROOT}"
                includes="playerProductInstall.swf"
                defaultexcludes="false"/>
            <!-- Deletes the swfobject.js file -->
            <fileset dir="${APP_ROOT}" includes="*.js" defaultexcludes="false"/>
            <!-- Deletes the previously-generated HTML wrapper file -->
            <fileset dir="${APP_ROOT}" includes="*.html" defaultexcludes="false"/>
            <!-- Deletes the history files -->
            <fileset dir="${APP_ROOT}/history" includes="*.*" defaultexcludes="false"/>
        </delete>
    </target>
</project>
```

Using the asdoc task

The Flex Ant tasks include a task to run the asdoc utility. This utility generates HTML documentation based on a defined set of tags that you can include in your ActionScript and MXML files.

For more information about using ASDoc, see “ASDoc” on page 2241.

Required attributes

The asdoc Ant task requires that you specify a target class or classes to generate ASDoc for. This must be either a list of one or more classes, a directory of classes, or a namespace. You specify these by using the `doc-classes`, `doc-sources`, or `doc-namespaces` attributes.

If you use the `doc-classes` or `doc-namespaces` attributes, you must also specify a `source-path` argument. If you use the doc-namespaces attribute, you must also specify a `namespace` attribute.

Adobe recommends that you specify a value for the `output` attribute. If you do not specify a value, Ant creates a directory called asdoc-output in the same directory that you launched the command from. Ant then stores the HTML output files in that new directory.

Unsupported options

All options of the asdoc utility are supported by the `asdoc` Ant task.

Example

The following example defines two targets, `doc` and `clean`. The `doc` target generates ASDoc for the Spark and MX button classes. The `clean` target deletes all the files generated by the `doc` target.

```
<?xml version="1.0" encoding="utf-8"?>
<project name="ASDoc Builder" basedir=".">
    <property name="FLEX_HOME" value="C:/p4/flex/flex/sdk"/>
    <property name="OUTPUT_DIR" value="C:/temp/ant/asdoc"/>
    <taskdef resource="flexTasks.tasks" classpath="${FLEX_HOME}/ant/lib/flexTasks.jar" />
    <target name="doc">
        <asdoc output="${OUTPUT_DIR}" lenient="true" failonerror="true">
            <doc-sources
                path-
element="${FLEX_HOME}/frameworks/projects/spark/src/spark/components/Button.as"/>
            <doc-sources
                path-
element="${FLEX_HOME}/frameworks/projects/framework/src/mx/controls/Button.as"/>
        </asdoc>
    </target>
    <target name="clean">
        <delete includeEmptyDirs="true">
            <fileset dir="${OUTPUT_DIR}" includes="**/*"/>
        </delete>
    </target>
</project>
```

You will have to change the values of the Flex home and output directory to match the locations of the directories on your file system.

To run this example, you can use the following Ant command:

```
ant clean doc
```

This example generates simple ASDoc output for the Spark and MX Button controls by using the `doc-sources` attribute. The output does not include all the parent classes that provide the inherited methods, properties, events, and other members of the Button controls.

To generate ASDoc that includes the parent classes of the Button controls, you can use an Ant task that uses the `doc-classes` attribute. When you do this, you must be sure to also define the `source-path` for the classes.

The following example generates ASDoc for the MX Button control. It includes the parent classes that this control inherits its members from.

```
<?xml version="1.0" encoding="utf-8"?>
<project name="ASDoc Builder" basedir=".">
    <property name="FLEX_HOME" value="C:/p4/flex/flex/sdk"/>
    <property name="OUTPUT_DIR" value="C:/temp/ant/asdoc"/>
    <taskdef resource="flexTasks.tasks" classpath="${FLEX_HOME}/ant/lib/flexTasks.jar" />
    <target name="doc">
        <asdoc output="${OUTPUT_DIR}" lenient="true" failonerror="true">
            <compiler.source-path
                path-element="${FLEX_HOME}/frameworks/projects/framework/src"/>
            <doc-classes class="mx.controls.Button"/>
        </asdoc>
    </target>
    <target name="clean">
        <delete includeEmptyDirs="true">
            <fileset dir="${OUTPUT_DIR}" includes="**/*"/>
        </delete>
    </target>
</project>
```

You can also define an `asdoc` Ant task that includes all components in a particular namespace by using the `doc-namespaces` attribute. When you want to document all classes in a namespace, you must also point to the manifest file for that namespace by using the `namespace` attribute.

The following example generates ASDoc for all components in the Spark namespace:

```
<?xml version="1.0" encoding="utf-8"?>
<project name="ASDoc Builder" basedir=".">
    <property name="FLEX_HOME" value="C:/p4/flex/flex/sdk"/>
    <property name="OUTPUT_DIR" value="C:/temp/ant/asdoc"/>
    <taskdef resource="flexTasks.tasks" classpath="${FLEX_HOME}/ant/lib/flexTasks.jar" />
    <target name="doc">
        <asdoc output="${OUTPUT_DIR}" lenient="true" failonerror="true">
            <compiler.source-path
                path-element="${FLEX_HOME}/frameworks/projects/spark/src"/>
            <doc-namespaces uri="library://ns.adobe.com/flex/spark"/>
            <namespace
                uri="library://ns.adobe.com/flex/spark"
                manifest="${FLEX_HOME}/frameworks/projects/spark/manifest.xml"/>
        </asdoc>
    </target>
    <target name="clean">
        <delete includeEmptyDirs="true">
            <fileset dir="${OUTPUT_DIR}" includes="**/*"/>
        </delete>
    </target>
</project>
```

In this example, only the members that are inherited from other classes in the Spark namespace are added to the ASDoc output.

The flex-config.xml file contains a list of predefined namespace URIs and the locations of their manifest files. As a result, if you use the `asdoc` Ant task to generate ASDoc for one of these namespaces, and not a custom namespace, then you are not required to define the location of the manifest file. This is because the `asdoc` Ant task reads in their definitions. It is, however, best practice to define the manifest file location for all namespaces.

Chapter 10: Custom components

Custom Flex components

Adobe® Flex® supports a component-based development model. You use the predefined components included with Flex to build your applications, and create components for your specific application requirements. You can create custom components by using MXML or ActionScript.

Flex Developer Mike Jones has written the following book about creating custom Flex components: Developing Flex 4 Components: Using ActionScript 3.0 and MXML to Extend Flex and AIR Applications.

About custom components

Defining your own custom components has several benefits. One advantage is that components let you divide your applications into modules that you can develop and maintain separately. By implementing commonly used logic within custom components, you can also build a suite of reusable components that you can share among multiple Flex applications.

Also, you can extend the Flex class hierarchy to base your custom components on the set of predefined Flex components. You can create custom versions of Flex visual controls, as well as custom versions of nonvisual components, such as validators, formatters, and effects.

You can build an entire Flex application in a single MXML file that contains both your MXML code and any supporting ActionScript code. However, as your application gets larger, your single file also grows in size and complexity. This type of application would soon become difficult to understand and debug, and very difficult for multiple developers to work on simultaneously. By breaking it up into components, you can simplify the architecture and divide the application among multiple developers.

Using modules in application development

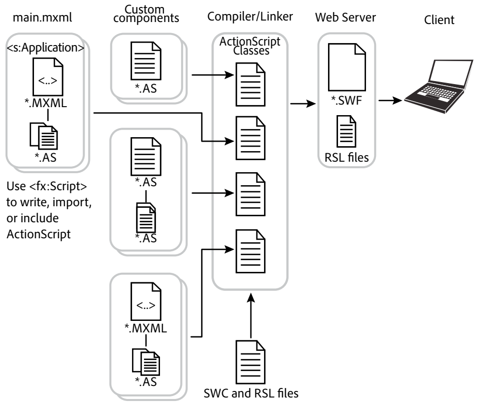
A common coding practice is to divide an application into functional units, or modules, where each module performs a discrete task. Dividing your application into modules provides you with many benefits, including the following:

Ease of development Different developers or development groups can develop and debug modules independently of each other.

Reusability You can reuse modules in different applications so that you do not have to duplicate your work.

Maintainability By developing your application in discrete modules, you can isolate and debug errors faster than you could if you developed your application in a single file.

In Flex, a module corresponds to a custom component, implemented either in MXML or in ActionScript. The following image shows an example of a Flex application divided into components:



This example shows the following relationships among the components:

- You define a main MXML file that contains the `<s:Application>` tag.
- In your main MXML file, you define an ActionScript block that uses the `<fx:Script>` tag. Inside the ActionScript block, you write ActionScript code, or include external logic defined by an ActionScript file. Typically, you use this area to write small amounts of ActionScript code. If you must write large amounts of ActionScript code, you should include an external file.
- The main MXML file uses MXML and ActionScript to reference components supplied with Flex, and to reference your custom components.
- Custom components can reference other custom components.

The Flex class hierarchy

Flex is implemented as an ActionScript class hierarchy. That class hierarchy contains component classes, manager classes, data-service classes, and classes for all other Flex features. For a complete description of the class hierarchy, see the ActionScript 3.0 Reference for the Adobe Flash Platform.

All visual components are derived from the UIComponent ActionScript class. Flex nonvisual components are also implemented as a class hierarchy in ActionScript. The most commonly used nonvisual classes are the Validator, Formatter, and Effect base classes.

You create custom components by extending the Flex class hierarchy using the MXML and ActionScript languages. Components inherit the properties, methods, events, styles, and effects of their superclasses.

Spark and MX components

Flex defines two sets of components: Spark and MX. The Spark components are new for Flex 4 and are defined in the spark.* packages. The MX components shipped in previous releases of Flex and are defined in the mx.* packages.

Spark and MX define some of the same components. For example, Spark defines a button control in the spark.components package, and MX defines a button control in the mx.controls package. When a component is available in both Spark and MX, Adobe recommends that you use the Spark component.

Spark and MX also define components that are unique. For example, Spark defines components to perform three dimensional effects. MX defines charting controls not included in Spark. Your applications often contains a mixture of Spark and MX components.

Customizing existing components

One reason for you to create a component is to customize an existing component for your application requirements. This customization could be as simple as setting the `label` property of a Button control to *Submit* to create a custom button for all of your forms.

You might also want to modify the behavior of a Flex component. For example, a VBox container lays out its children from the top of the container to the bottom in the order in which you define the children within the container. Instead, you might want to customize the VBox container to lay out its children from bottom to top.

Another reason to customize a Flex component is to add logic or behavior to it. For example, you might want to modify the TextInput control so that it supports a key combination to delete all the text entered into the control. Or, you might want to modify a component so that it dispatches a new event type when a user carries out an action.

To create your own components, you create subclasses from the UIComponent class, or any other class in the Flex component hierarchy. For example, if you want to create a component that behaves almost the same as a Button component does, you can extend the Button class instead of recreating all the functionality of the Button class from the base classes.

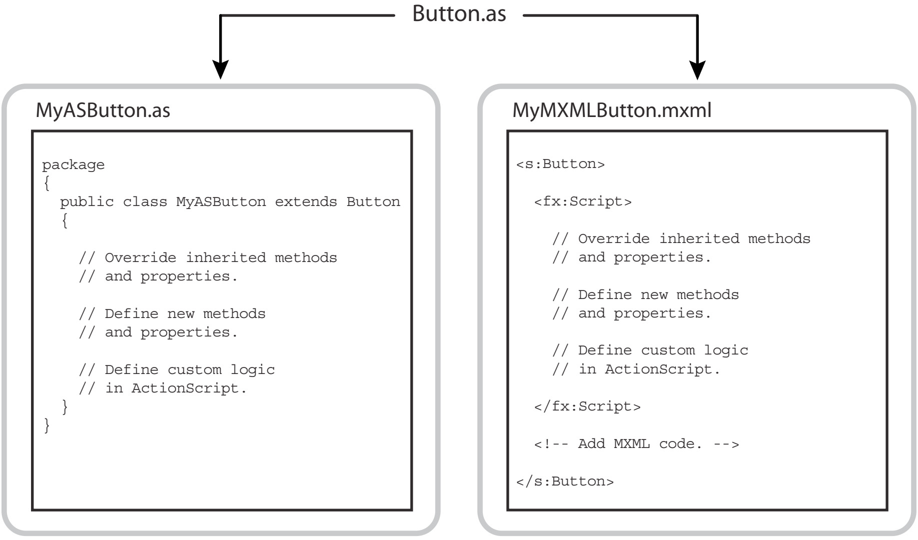
Depending on the modifications that you want to make, you can create a subclass of a Flex component in MXML or ActionScript.

The relationship between MXML components and ActionScript components

To create a custom component in ActionScript, you create a subclass from a class in the Flex class hierarchy. The name of your class (for example, MyASButton), must correspond to the name of the ActionScript file; for example, MyASButton.as. The subclass inherits all of the properties and methods of the superclass. In this example, you use the `<MyASButton>` tag to reference it in MXML.

When you create a custom component in MXML, the Flex compiler automatically creates an ActionScript class. The name of the MXML file (for example, MyMXMLButton.mxml) corresponds to the ActionScript class name. In this example, the ActionScript class is named MyMXMLButton, and you use the `<MyMXMLButton>` tag to reference it in MXML.

The following example shows two components based on the Flex Button component, one defined in ActionScript and the other in MXML:



```
package
{
  public class MyASButton extends Button
  {

    // Override inherited methods
    // and properties.

    // Define new methods
    // and properties.

    // Define custom logic
    // in ActionScript.
  }
}
```

```
<s:Button>

  <fx:Script>

    // Override inherited methods
    // and properties.

    // Define new methods
    // and properties.

    // Define custom logic
    // in ActionScript.

  </fx:Script>

  <!-- Add MXML code. -->

</s:Button>
```

Both implementations create a component as a subclass of the Button class and, therefore, inherit all of the public and protected properties, methods, and other elements of the Button class. Within each implementation, you can override inherited items, define new items, and add your custom logic.

***Note:** You cannot override an inherited property defined by a variable, but you can override a property defined by setter and getter methods. You can reset the value of an inherited property defined by a variable. You typically reset it in the constructor of the subclass for an ActionScript component, or in an event handler for an MXML component because MXML components cannot define a constructor.*

However, when you use MXML, the Flex compiler performs most of the overhead required to create a subclass of a component for you. This makes it much easier to create components in MXML than in ActionScript.

Deciding to create components in MXML or ActionScript

One of the first decisions that you must make when creating custom components is deciding whether to write them in MXML or in ActionScript. Ultimately, it is the requirements of your application that determine how you develop your custom component.

Some basic guidelines include the following:

- MXML components and ActionScript components both define new ActionScript classes.
- Almost anything that you can do in a custom ActionScript custom component, you can also do in a custom MXML component. However, for simple components, such as components that modify the behavior of an existing component or add a basic feature to an existing component, it is simpler and faster to create them in MXML.
- When your new component is a composite component that contains other components, and you can express the positions and sizes of those other components using one of the Flex containers, you should use MXML to define your component.
- To modify the behavior of the component, such as the way a container lays out its children, use ActionScript.
- To create a visual component by creating a subclass from UIComponent, use ActionScript.
- To create a nonvisual component, such as a formatter, validator, or effect, use ActionScript.
- To add logging support to your control, use ActionScript. For more information, see “Logging” on page 2222.

***Note:** The Adobe® Flash® Professional 8 authoring environment does not support ActionScript 3.0. Therefore, you should not use it to create ActionScript components for Flex. Instead, you should use Adobe® Flash® Builder™ or Adobe Flash Professional CS4 or later.*

For more information on custom MXML components, see “Simple MXML components” on page 2399. For more information on ActionScript components, see “Create simple visual components in ActionScript” on page 2433.

Creating new components

Your application might require you to create new components, rather than modifying existing ones. To create components, you typically create them in ActionScript by creating a subclass from the UIComponent class. This class contains the generic functionality of all Flex components. You then add the required functionality to your new component to meet your application requirements.

For more information, see “Create advanced MX visual components in ActionScript” on page 2475.

Creating custom components

You create custom components as either MXML or ActionScript files.

Creating MXML components

Flex supplies the Spark ComboBox control that you can use as part of a form that collects address information from a customer. In the form, you can include a ComboBox control to let the user select the state portion of the address from a list of the 50 states in the U.S. In an application that has multiple forms where a user can enter an address, it would be tedious to create and initialize multiple ComboBox controls with the same information about all 50 states.

Instead, you create an MXML component that contains a ComboBox control with all the 50 states defined within in it. Then, wherever you need to add a state selector to your application, you use your custom MXML component. The following example shows a possible definition for a custom ComboBox control:

```
<?xml version="1.0"?>
<!-- createcomps_intro\StateComboBox.mxml -->
<!-- Specify the root tag and namespace. -->
<s:ComboBox xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:dataProvider>
        <s:ArrayList>
            <fx:String>AK</fx:String>
            <fx:String>AL</fx:String>
            <!-- Add all other states. -->
        </s:ArrayList>
    </s:dataProvider>
</s:ComboBox>
```

This example shows the following:

1. The first line of the custom MXML component definition specifies the declaration of the XML version.
2. The first MXML tag of the component, called its *root* tag, specifies a Flex component or a custom component. MXML components correspond to ActionScript classes, therefore, the root tag specifies the superclass of the MXML component. In this example, the MXML component specifies the Flex ComboBox control as its superclass.
3. The `xmlns` properties in the root tag specifies the Flex XML namespaces. In this example, the `xmlns` property indicates that tags in the MX namespace use the prefix *mx:*.
4. The remaining lines of the component specify its definition.

The main application, or any other MXML component file, references the StateComboBox component, as the following example shows:

```
<?xml version="1.0"?>
<!-- createcomps_intro/IntroMyApplication.mxml -->
<!-- Include the namespace definition for your custom components. -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="*">
    <!-- Use the filename as the MXML tag name. -->
    <MyComp:StateComboBox/>
</s:Application>
```

The MXML tag name for a custom component is composed of two parts: the namespace prefix, in this case `MyComp`, and the tag name. The namespace prefix tells Flex where to look for the file that implements the custom component. The tag name corresponds to the filename of the component, in this case StateComboBox.mxml. Therefore, a file named StateComboBox.mxml defines a component with the tag name of `<`*namespace*`:StateComboBox>`.

As part of the `<s:Application>` tag, the main application file includes the following namespace definition: `xmlns:MyComp="*"`. This definition specifies that the component is in the same directory as the main application file, or in a directory included in the ActionScript source path. For more information on deploying MXML components, see "Simple MXML components" on page 2399.

The best practice is to put your custom components in a subdirectory of your application. That practice helps to ensure that you do not have duplicate component names because they have a different namespace. If you stored your component in the myComponents subdirectory of your application, you would specify the namespace definition as `xmlns:MyComp="myComponents.*"`.

The StateComboBox.mxml file specifies the ComboBox control as its root tag, so you can reference all of the properties of the ComboBox control in the MXML tag of your custom component, or in the ActionScript specified in an `<fx:Script>` tag. For example, the following example specifies the `ComboBox.maxChars` property and a listener for the `ComboBox.close` event for your custom control:

```
<?xml version="1.0"?>
<!-- createcomps_intro/MyApplicationProperties.mxml -->
<s:Application  xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myComponents.*">

    <fx:Script>
        <![CDATA[
            import flash.events.Event;
            private function handleCloseEvent(eventObj:Event):void {
                // ...
            }
        ]]>
    </fx:Script>
    <MyComp:StateComboBox maxChars="25"
        close="handleCloseEvent(event);"/>
</s:Application>
```

For more information on MXML components, see "Simple MXML components" on page 2399.

Creating ActionScript components

You create ActionScript components by defining ActionScript classes. You can create the following types of components in ActionScript:

User-interface, or visual, components User-interface components contain both processing logic and visual elements. You create custom user-interface components to modify existing behavior or add new functionality to the component. These components usually extend the Flex component hierarchy. You can extend from the UIComponent class, or any of the Flex components, such as Button, ComboBox, or DataGrid. Your custom ActionScript component inherits all of the methods, properties, events, styles, and effects of its superclass.

Nonvisual components Nonvisual components define nonvisual elements. Flex includes several types of nonvisual components that you can create, including formatters, validators, and effects. You create nonvisual components by creating a subclass from the Flex component hierarchy. For validators, you create subclasses of the Validator class; for formatters you create subclasses of the Formatter class; and for effects, you create subclasses of the Effect class.

For example, you can define a custom button component based on the Spark Button class, as the following example shows:

```
package myComponents
{
    // createcomps_intro/myComponents/MyButton.as
    import spark.components.Button;
    public class MyButton extends Button {

        // Define the constructor.
        public function MyButton() {
            // Call the constructor in the superclass.
            super();
            // Set the label property to "Submit".
            label="Submit";
        }
    }
}
```

In this example, you write your MyButton class to the MyButton.as file.

You must define your custom components within an ActionScript package. The package reflects the directory location of your component in the directory structure of your application. Typically, you put custom ActionScript components in directories that are in the ActionScript source path, subdirectories of your application, or for Adobe® LiveCycle™ Data Services ES, in the WEB-INF/flex/user_classes directory. In this example, the `package` statement specifies that the MyButton.as file is in the myComponents subdirectory of your Flex application.

In the MXML file that references the custom component, you define the namespace and reference it in an MXML file as the following example shows:

```
<?xml version="1.0"?>
<!-- createcomps_intro/MyApplicationASComponent.mxml -->
<!-- Include the namespace definition for your custom components. -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myComponents.*">
    <!-- Use the filename as the MXML tag name. -->
    <MyComp:MyButton/>
</s:Application>
```

In this example, you first define the `MyComp` namespace that specifies the location of your custom component in the application's directory structure. You then reference the component as an MXML tag using the namespace prefix.

For more information, see "Create simple visual components in ActionScript" on page 2433.

Deploying components

When you deploy your custom components as MXML or ActionScript files, you typically deploy them in the same directory structure as your application files, in a directory specified in the ActionScript source path, or for LiveCycle Data Services ES, in the WEB-INF/flex/user_classes directory.

For security reasons, you may decide not to deploy your custom components as source code files. Alternatively, you can deploy your components as SWC files or as part of a Runtime Shared Library (RSL).

A *SWC file* is an archive file for Flex components. SWC files make it easy to exchange components among Flex developers. You need only exchange a single file, rather than the MXML or ActionScript files and images and other resource files. In addition, the SWF file inside a SWC file is compiled, which means that the code is hidden from casual view.

SWC files can contain one or more components and are packaged and expanded with the PKZip archive format. You can open and examine a SWC file using WinZip, JAR, or another archiving tool. However, you should not manually change the contents of a SWC file, and you should not try to run the SWF file that is in a SWC file outside of a SWC file.

To create a SWC file, use the compc utility in the *flex_install_dir*/bin directory. The compc utility generates a SWC file from MXML component source files and/or ActionScript component source files. For more information on compc, see "Flex compilers" on page 2164.

One way to reduce the size of your application's SWF file is by externalizing shared assets into stand-alone files that can be separately downloaded and cached on the client. These shared assets are loaded by any number of applications at run time, but only need to be transferred to the client once. These shared files are known as Runtime Shared Libraries or RSLs.

For more information, including information on how to create an RSL file, see "Runtime Shared Libraries" on page 253.

Custom ActionScript components

You use ActionScript code to create ActionScript components for Adobe® Flex®, or to add logic to MXML components. ActionScript provides flow control and object manipulation features that are not available in MXML.

The summary of the general rules for using ActionScript code in custom components in this topic supplements the information in the ActionScript reference documentation. For additional information on ActionScript, see the following resources:

- *ActionScript 3.0 Reference for the Adobe Flash Platform*: Contains the API reference for ActionScript 3.0.
- *ActionScript 3.0 Developer's Guide*: Contains information on using ActionScript 3.0.

Using ActionScript

Before you start developing custom components, you should be familiar with basic ActionScript coding practices.

Using the package statement

You must define your ActionScript custom components within a package. The package reflects the directory location of your component within the directory structure of your application. To define the package structure, you include the package statement in your class definition, as the following example shows:

```
package myComponents
{
    // Class definition goes here.
}
```

Your `package` statement must wrap the entire class definition. If you write your ActionScript class file to the same directory as your other application files, you can leave the package name blank. However, as a best practice, you should store your components in a subdirectory, where the package name reflects the directory location. In this example, write your ActionScript class file to the directory myComponents, a subdirectory of your main application directory.

Formatters are a particular type of component. You might also create a subdirectory of your application's root directory called myFormatters for all of your custom formatter classes. Each formatter class would then define its `package` statement, as the following example shows:

```
package myFormatters
{
    // Formatter class definition goes here.
}
```

If you create a component that is shared among multiple applications, or a component that might be used with third-party components, assign a unique package name to avoid naming conflicts. For example, you might prefix your package name with your company name, as in:

```
package Acme.myFormatters
{
    // Formatter class definition goes here.
}
```

When you reference a custom component from an MXML file, specify a namespace definition for the component that corresponds to its directory location and package name, as the following example shows:

```
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myFormatters.*">

    <!-- Declare a formatter and specify formatting properties. -->
    <MyComp:SimpleFormatter id="upperFormat" formatString="upper"/>
        ...

</s:Application>
```

If a formatter class is in a subdirectory of myFormatters, such as myFormatters/dataFormatters, the package statement is as follows:

```
package myFormatters.dataFormatters
{
    // Formatter class definition goes here.
}
```

You then specify the namespace definition for the component, as the following example shows:

```
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myFormatters.dataFormatters.*">

    <!-- Declare a formatter and specify formatting properties. -->
    <MyComp:SimpleFormatter id="upperFormat" formatString="upper"/>
        ...

</s:Application>
```

Using the import statement

You use the import statement to import any classes that your class requires. Importing adds a reference to the class so that you can access classes defined by the import. Classes that you import must be located in the ActionScript source path for your application.

You import the classes referenced by your custom component as part of its implementation, as the following example shows:

```
package myComponents
{
    // Import necessary classes.
    import mx.core.Container;
    import mx.controls.Button;
    // Import all classes in the mx.events package
    import mx.events.*;

    // Class definition goes here.

    // You can now create an instance of a Container using this syntax:
    private var myContainer:Container = new Container();

}
```

There is a distinct difference between including and importing in ActionScript. *Including* is copying lines of code from one ActionScript file into another. Files that you include must be located relative to the file performing the include, or use an absolute path. *Importing* is adding a reference to a class file or package so that you can access objects and properties defined by external classes.

For more information on including and importing, see "Using ActionScript" on page 32.

Using the class statement

You use the class statement to define your class name, and to specify its superclass, as the following example shows:

```
package myComponents
{
    // Import necessary classes
    import mx.core.Container;
    import mx.controls.Button;
    // Import all classes in the mx.events package
    import mx.events.*;

    // Class definition goes here.
    public class MyButton extends Button {

        // Define properties, constructor, and methods.

    }
}
```

The class definition of your component must be prefixed by the `public` keyword, or it cannot be used as an MXML tag. A file that contains a class definition can have one, and only one, public class definition, although it can have additional internal class definitions. Place any internal class definitions at the bottom of your source file below the closing curly brace of the package definition.

In a single ActionScript file, you can define only one class in the package. To define more than one class in a file, define the additional classes outside of the package body.

***Note:** The class definition is one of the few ActionScript constructs that you cannot use in an `<fx:Script>` block in an MXML file.*

Defining the constructor

An ActionScript class must define a public constructor method, which initializes an instance of the class. The constructor has the following characteristics:

- No return type.
- Should be declared public.
- Might have optional arguments.
- Cannot have any required arguments if you use it as an MXML tag.
- Calls the `super()` method to invoke the superclass' constructor.

You call the super() method within your constructor to invoke the superclass' constructor to initialize the inherited items from the superclass. The `super()` method should be the first statement in your constructor; otherwise, the inherited parts of the superclass might not be properly constructed. In some cases, you might want to initialize your class first, and then call `super()`.

***Note:** If you do not define a constructor, the compiler inserts one for you and adds a call to `super()`. However, it is considered a best practice to write a constructor and to explicitly call `super()`, unless the class contains nothing but static members. If you define the constructor, but omit the call to `super()`, Flex automatically calls `super()` at the beginning of your constructor.*

In the following example, you define a constructor that uses `super()` to call the superclass' constructor:

```
package myComponents
{
    // Import necessary classes
    import mx.core.Container;
    import mx.controls.Button;
    // Import all classes in the mx.events package
    import mx.events.*;

    // Class definition goes here.
    public class MyButton extends Button {

        // Public constructor.
        public function MyButton()
        {
            // Call the constructor in the superclass.
            super();
        }
        // Define properties and methods.

    }
}
```

***Note:** You cannot define a constructor for an MXML component. For more information, see "About implementing IMXMLObject" on page 2431*

Defining properties as variables

Properties let you define data storage within your class. You can define your properties as public, which means that they can be accessed by users of the class. You can also define properties as private, which means that they are used internally by the class, as the following example shows:

```
public class MyButton extends Button {

    // Define private vars.
    private var currentFontSize:Number;

    // Define public vars.
    public var maxFontSize:Number = 15;
    public var minFontSize:Number = 5;
}
```

Users of the class can access the public variables but not the private variables, as the following example shows:

```
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myControls.*">

    <MyComp:MyButton label="Submit" maxFontSize="30"/>
</s:Application>
```

Although you can define your classes to use public properties, you may find it advantageous to define properties by using setter and getter methods. For more information, see "Defining methods" on page 2368.

***Note:** You cannot override an inherited property defined by a variable, but you can override a property defined by setter and getter methods. You can reset the value of an inherited property defined by a variable. You typically reset it in the constructor of the subclass for an ActionScript component, or in an event handler for an MXML component because MXML components cannot define a constructor.*

Defining properties as getters and setters

You can define properties for your components by using setter and getter methods. The advantage of getters and setters is that they isolate the variable from direct public access so that you can perform the following actions:

- Inspect and validate any data written to the property on a write
- Trigger events that are associated with the property when the property changes
- Calculate a return value on a read
- Allow a child class to override

To define getter and setter methods, precede the method name with the keyword get or set, followed by a space and the property name. The following example shows the declaration of a public property named `initialCount`, and the getter and setter methods that get and set the value of this property:

```
// Define internal private variable.
private var _initialCount:uint = 42;

// Define public getter.
public function get initialCount():uint {
    return _initialCount;
}

// Define public setter.
public function set initialCount(value:uint):void {
    _initialCount = value;
}
```

By convention, setters use the identifier `value` for the name of the argument.

The variable that stores the property's value cannot have the same name as the getter or setter. By convention, precede the name of the variables with one (_) or two underscores (__). In addition, Adobe recommends that you declare the variable as private or protected.

Users of the class can access the public property, as the following example shows:

```
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myControls.*" >

    <MyComp:MyButton label="Submit" initialCount="24"/>
</s:Application>
```

If the getter or setter overrides a getter or setter in a superclass, ensure that you include the `override` keyword, as the following example shows:

```
override public function get label():String {}
override public function set label(value:String):void {}
```

Defining methods

Methods define the operations that your class can perform. You define methods in the body of the class. Your methods can override a method of a superclass, or define new functionality for your components.

If the method adds new functionality, you define it using the `function` keyword, as the following example shows:

```
public function myMethod():void {
    // Method definition
}
```

If you define this method as a public method, users of the class can call it.

You can also define private methods, as the following example shows:

```
private function internalMethod():void {
    // Method definition
}
```

Private methods are for internal use by the class, and cannot be called by users of the class.

If the method overrides a method in a superclass, you must include the `override` keyword and the signature of the method must exactly match that of the superclass method, as the following example shows:

```
override protected function createChildren():void {
    // Method definition
}
```

Your methods may take required or optional arguments. To make any of the arguments optional, assign default values to them, as the following example shows:

```
override public validate(value:Object = null,
    supressEvents:Boolean = false):ValidationResultEvent {
    // Method definition
}
```

If the method takes a variable number of arguments, use the "..." syntax, as the following example shows:

```
function foo(n:Number, ... rest):void {
    // Method definition
}
```

Flex creates an Array called `rest` for the optional arguments. Therefore, you can determine the number of arguments passed to the method by using `rest.length`, and access the arguments by using `rest[i]`.

Using the super keyword in a method override

You use the super keyword in a method override to invoke the corresponding method of the superclass. The `super` keyword has the following syntax:

```
super.methodName([arg1, ..., argN])
```

This technique is useful when you create a subclass method that adds behavior to a superclass method but also invokes the superclass method to perform its original behavior.

***Note:** Although Flex automatically calls the `super()` method in a constructor to execute the superclass' constructor, you must call `super.methodName()` in a method override. Otherwise, the superclass' version of the method does not execute.*

Whether you call `super.`*myMethod*`()` within a method override depends on your application requirement, as follows:

- Typically, you extend the existing functionality of the superclass method, so the most common pattern is to call `super.`*myMethod*`()` first in your method override, and then add your logic.
- You might need to change something before the superclass method does its work. In this case, you might call `super.`*myMethod*`()` in the override after your logic.
- In some method overrides, you might not want to invoke the superclass method at all. Only call `super.`*myMethod*`()` if and when you want the superclass to do its work.
- Sometimes the superclass has an empty method that does nothing, which requires you to implement the functionality in the method. In this case, you should still call `super.`*myMethod*`()` because in a future version of Flex, that method might implement some functionality. For more information, see the documentation on each Flex class.

About the scope

Scoping is mostly a description of what the `this` keyword refers to at any given point in your application. In the main MXML application file, the file that contains the `<s:Application>` tag, the current scope is the Application object, and therefore the `this` keyword refers to the Application object.

In an ActionScript component, the scope is the component itself and not the application or other file that references the component. As a result, the `this` keyword inside the component refers to the component instance and not the Flex Application object.

Nonvisual ActionScript components do not have access to their parent application with the `parentDocument` property. However, you can access the top-level Application object by using the `mx.core.Application.application` property.

For more information on scope, see "Using ActionScript" on page 32.

Custom events

You can create custom events as part of defining MXML and ActionScript components. Custom events let you add functionality to your custom components to respond to user interactions, to trigger actions by your custom component, and to take advantage of data binding.

For more information on creating custom events for MXML components, see “Advanced MXML components” on page 2412. For information on creating custom events for ActionScript components, see “Create simple visual components in ActionScript” on page 2433.

About events

Adobe Flex applications are event-driven. Events let an application know when the user interacts with the interface, and also when important changes happen in the appearance or life cycle of a component, such as the creation of a component or its resizing. Events can be generated by user input devices, such as the mouse and keyboard, or by the asynchronous operations, such as the return of a web service call or the firing of a timer.

The core class of the Flex component architecture, mx.core.UIComponent, defines core events, such as `updateComplete`, `resize`, `move`, `creationComplete`, and others that are fundamental to all components. Subclasses of UIComponent inherit these events.

Custom components that extend existing Flex classes inherit all the events of the base class. Therefore, if you extend the Button class to create the MyButton class, you can use the `click` event and the events that all controls inherit, such as `mouseOver` or `initialize`, as the following example shows:

```
<?xml version="1.0"?>
<!-- createcomps_events/EventsMyApplication.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myComponents.*">
    <fx:Script>
        <![CDATA[
            import flash.events.Event;
            // Event listener for the click event.
            private function handleClick(eventObj:Event):void {
                // Define event listener.
            }
            // Event listener for the initialize event.
            private function handleInit(eventObj:Event):void {
                // Define event listener.
            }
        ]]>
    </fx:Script>
    <MyComp:MyButton
        click="handleClick(event);"
        initialize="handleInit(event);"/>
</s:Application>
```

In addition to using the events inherited from its superclasses, your custom components can define custom events. You use custom events to support data binding, to respond to user interactions, or to trigger actions by your component.

For more information on the Flex event mechanism, see “Events” on page 54.

Using an event object

When a Flex component dispatches an event, it creates an event object, where the properties of the event object contain information describing the event. An event listener takes this event object as an argument and accesses the properties of the object to determine information about the event.

The base class for all event objects is the flash.events.Event class. All event objects are instances of the Event class, or instances of a subclass of the Event class.

The following table describes the public properties of the Event class. The Event class implements these properties using getter methods.

Property	**Type**	**Description**
`type`	String	The name of the event; for example, `"click"` . The event constructor sets this property.
`target`	EventDispatcher	A reference to the component instance that dispatches the event. This property is set by the `dispatchEvent()` method; you cannot change this to a different object.
`currentTarget`	EventDispatcher	A reference to the component instance that is actively processing the Event object. The value of this property is different from the value of the `target` property during the event capture and bubbling phase. For more information, see "Events" on page 54.
`eventPhase`	uint	The current phase in the event flow. The property might contain the following values: • `EventPhase.CAPTURING_PHASE`: The capture phase • `EventPhase.AT_TARGET`: The target phase • `EventPhase.BUBBLING_PHASE`: The bubbling phase
`bubbles`	Boolean	Whether an event is a bubbling event. If the event can bubble, the value for this property is `true;` otherwise, it is `false`. You can optionally pass this property as a constructor argument to the Event class. By default, most event classes set this property to `false`. For more information, see "Events" on page 54.
`cancelable`	Boolean	Whether the event can be canceled. If the event can be canceled, the value for this value is `true;` otherwise, it is `false`. You can optionally pass this property as a constructor argument to the Event class. By default, most event classes set this property to `false`. For more information, see "Events" on page 54.

Dispatching custom events

Flex defines many of the most common events, such as the `click` event for the Button control; however, your application may require that you create events. In your custom Flex components, you can dispatch any of the predefined events inherited by the component from its superclass, and dispatch new events that you define within the component.

To dispatch a new event from your custom component, you must do the following:

1. (Optional) Create a subclass from the flash.events.Event class to create an event class that describes the event object. For more information, see "Creating a subclass from the Event class" on page 2371.
2. (Optional) Use the `[Event]` metadata tag to make the event public so that the MXML compiler recognizes it. For more information, see "Using the Event metadata tag" on page 2373.
3. Dispatch the event using the `dispatchEvent()` method. For more information, see "Dispatching an event" on page 2374.

Creating a subclass from the Event class

All events use an event object to transmit information about the event to the event listener, where the base class for all event objects is the flash.events.Event class. When you define a custom event, you can dispatch an event object of the Event type, or you can create a subclass of the Event class to dispatch an event object of a different type. You typically create a subclass of the Event class when your event requires you to add information to the event object, such as a new property to hold information that the event listener requires.

For example, the event objects associated with the Flex Tree control include a property named `node`, which identifies the node of the Tree control associated with the event. To support the `node` property, the Tree control dispatches event objects of type TreeEvent, a subclass of the Event class.

Within your subclass of the Event class, you can add properties, add methods, set the value of an inherited property, or override methods inherited from the Event class. For example, you might want to set the `bubbles` property to `true` to override the default setting of `false`, which is inherited from the Event class.

You are required to override the `Event.clone()` method in your subclass. The `clone()` method returns a cloned copy of the event object by setting the `type` property and any new properties in the clone. Typically, you define the `clone()` method to return an event instance created with the `new` operator.

Suppose that you want to pass information about the state of your component to the event listener as part of the event object. To do so, you create a subclass of the Event class to create an event, EnableChangeEvent, as the following example shows:

```
package myEvents
{
    //createcomps_events/myEvents/EnableChangeEvent.as
    import flash.events.Event;
    public class EnableChangeEvent extends Event
    {
        // Public constructor.
        public function EnableChangeEvent(type:String,
            isEnabled:Boolean=false) {
                // Call the constructor of the superclass.
                super(type);

                // Set the new property.
                this.isEnabled = isEnabled;
        }
        // Define static constant.
        public static const ENABLE_CHANGE:String = "enableChange";
        // Define a public variable to hold the state of the enable property.
        public var isEnabled:Boolean;
        // Override the inherited clone() method.
        override public function clone():Event {
            return new EnableChangeEvent(type, isEnabled);
        }
    }
}
```

In this example, your custom class defines a public constructor that takes two arguments:

- A String value that contains the value of the `type` property of the Event object.
- An optional Boolean value that contains the state of the component’s `isEnabled` property. By convention, all constructor arguments for class properties, except for the `type` argument, are optional.

  From within the body of your constructor, you call the `super()` method to initialize the base class properties.

Using the Event metadata tag

You use the `[Event]` metadata tag to define events dispatched by a component so that the Flex compiler can recognize them as MXML tag attributes in an MXML file. You add the `[Event]` metadata tag in one of the following locations:

- ActionScript components

  Above the class definition, but within the package definition, so that the events are bound to the class and not a particular member of the class.

- MXML components

  In the `<fx:Metadata>` tag of an MXML file.

The `Event` metadata keyword has the following syntax:

```
[Event(name="eventName", type="package.eventType")]
```

The *eventName* argument specifies the name of the event. The *eventType* argument specifies the class name, including the package, that defines the event object.

The following example identifies the `enableChange` event as an event that an ActionScript component can dispatch:

```
[Event(name="enableChange", type="myEvents.EnableChangeEvent")]
public class MyComponent extends TextArea
{
    ...
}
```

The following example shows the `[Event]` metadata tag within the `<fx:Metadata>` tag of an MXML file:

```
<?xml version="1.0"?>
<!-- createcomps_events\myComponents\MyButton.mxml -->
<s:Button xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    click="dispatchEvent(new EnableChangeEvent('enableChange'));">
    <fx:Script>
        <![CDATA[
            import myEvents.EnableChangeEvent;
        ]]>
    </fx:Script>
    <fx:Metadata>
        [Event(name="enableChange", type="myEvents.EnableChangeEvent")]
    </fx:Metadata>
</s:Button>
```

Once you define the event using the `[Event]` metadata tag, you can refer to the event in an MXML file, as the following example shows:

```
<?xml version="1.0"?>
<!-- createcomps_events/MainEventApp.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myComponents.*" >
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import myEvents.EnableChangeEvent;
            public function
                enableChangeListener(eventObj:EnableChangeEvent):void {
                    // Handle event.
                    myTA2.text='got event';
            }
        ]]>
    </fx:Script>
    <MyComp:MyButton enableChange="myTA.text='got event';" />
    <mx:TextArea id="myTA" />
    <MyComp:MyButton enableChange="enableChangeListener(event);" />
    <mx:TextArea id="myTA2" />
</s:Application>
```

If you do not identify an event with the `[Event]` metadata tag, the compiler generates an error if you try to use the event name in MXML. The metadata for events is inherited from the superclass, however, so you do not need to tag events that are already defined with the `[Event]` metadata tag in the superclass.

Dispatching an event

You use the dispatchEvent() method to dispatch an event. The `dispatchEvent()` method has the following signature:

```
public dispatchEvent(event:Event):Boolean
```

This method requires an argument of the Event type, which is the event object. The `dispatchEvent()` method initializes the `target` property of the event object with a reference to the component dispatching the event.

You can create an event object and dispatch the event in a single statement, as the following example shows:

```
dispatchEvent(new Event("click"));
```

You can also create an event object, initialize it, and then dispatch it, as the following example shows:

```
var eventObj:EnableChangeEvent = new EnableChangeEvent("enableChange");
eventObj.isEnabled=true;
dispatchEvent(eventObj);
```

For complete examples that create and dispatch custom events, see “Advanced MXML components” on page 2412 and “Create simple visual components in ActionScript” on page 2433.

Creating static constants for the Event.type property

The constructor of an event class typically takes a single required argument that specifies the value of the event object’s `type` property. In the previous section, you passed the string `enableChange` to the constructor, as the following example shows:

```
// Define event object, initialize it, then dispatch it.
var eventObj:EnableChangeEvent = new EnableChangeEvent("enableChange");
dispatchEvent(eventObj);
```

The Flex compiler does not examine the string passed to the constructor to determine if it is valid. Therefore, the following code compiles, even though `enableChangeAgain` might not be a valid value for the `type` property:

```
var eventObj:EnableChangeEvent =
    new EnableChangeEvent("enableChangeAgain");
```

Because the compiler does not check the value of the `type` property, the only time that your application can determine if `enableChangeAgain` is valid is at run time.

However, to ensure that the value of the `type` property is valid at compile time, Flex event classes define static constants for the possible values for the `type` property. For example, the Flex EffectEvent class defines the following static constant:

```
// Define static constant for event type.
public static const EFFECT_END:String = "effectEnd";
```

To create an instance of an EffectEvent class, you use the following constructor:

```
var eventObj:EffectEvent = new EffectEvent(EffectEvent.EFFECT_END);
```

If you incorrectly reference the constant in the constructor, the compiler generates a syntax error because it cannot locate the associated constant. For example, the following constructor generates a syntax error at compile time because `MY_EFFECT_END` is not a predefined constant of the EffectEvent class:

```
var eventObj:EffectEvent = new EffectEvent(EffectEvent.MY_EFFECT_END);
```

You can use this technique when you define your event classes. The following example modifies the definition of the EnableChangeEventConst class to include a static constant for the `type` property:

```
package myEvents
{
    //createcomps_events/myEvents/EnableChangeEventConst.as
    import flash.events.Event;
    public class EnableChangeEventConst extends Event
    {
        // Public constructor.
        public function EnableChangeEventConst(type:String,
            isEnabled:Boolean=false) {
                // Call the constructor of the superclass.
                super(type);

                // Set the new property.
                this.isEnabled = isEnabled;
        }
        // Define static constant.
        public static const ENABLE_CHANGE:String = "myEnable";

        // Define a public variable to hold the state of the enable property.
        public var isEnabled:Boolean;
        // Override the inherited clone() method.
        override public function clone():Event {
            return new EnableChangeEvent(type, isEnabled);
        }
    }
}
```

Now you create an instance of the class by using the static constant, as the following example shows for the MyButtonConst custom component:

```
<?xml version="1.0"?>
<!-- createcomps_events\myComponents\MyButtonConst.mxml -->
<s:Button xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    click="dispatchEvent(new EnableChangeEventConst(EnableChangeEventConst.ENABLE_CHANGE));">
    <fx:Script>
        <![CDATA[
            import myEvents.EnableChangeEventConst;
        ]]>
    </fx:Script>
    <fx:Metadata>
        [Event(name="myEnable", type="myEvents.EnableChangeEventConst")]
    </fx:Metadata>
</s:Button>
```

This technique does not preclude you from passing a string to the constructor.

Metadata tags in custom components

You insert metadata tags into your MXML and ActionScript files to provide information to the Adobe® Flex® compiler. Metadata tags do not get compiled into executable code, but provide information to control how portions of your code get compiled.

For more information about additional metadata tags that you use when creating an application, such as the `[Embed]` metadata tag, see "Embedding assets" on page 1699.

About metadata tags

Metadata tags provide information to the compiler that describes how your components are used in an application. For example, you might create a component that defines a new event. To make that event known to the Flex compiler so that you can reference it in MXML, you insert the `[Event]` metadata tag into your component, as the following ActionScript class definition shows:

```
[Event(name="enableChanged", type="flash.events.Event")]
class ModalText extends TextArea {
    ...
}
```

In this example, the `[Event]` metadata tag specifies the event name and the class that defines the type of the event object dispatched by the event. After you identify the event to the compiler, you can reference it in MXML, as the following example shows:

```
<?xml version="1.0"?>
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx" xmlns:MyComp="*">

    <fx:Script>
        <![CDATA[
            function handleEnableChangeEvent(eventObj:Event):void {
                ...
            }
        ]]>
    </fx:Script>

    <MyComp:ModalText enableChanged="handleEnableChangeEvent(event);"/>
</s:Application>
```

If you omit the `[Event]` metadata tag from your class definition, Flex issues a syntax error when it compiles your MXML file. The error message indicates that Flex does not recognize the `enableChanged` property.

The Flex compiler recognizes component metadata statements in your ActionScript class files and MXML files. The metadata tags define component attributes, data binding properties, events, and other properties of the component. Flex interprets these statements during compilation; they are never interpreted during run time.

Metadata statements are associated with a class declaration, an individual data field, or a method. They are bound to the next line in the file. When you define a component property or method, add the metadata tag on the line before the property or method declaration.

Metadata tags in ActionScript

In an ActionScript file, when you define component events or other aspects of a component that affect more than a single property, you add the metadata tag outside the class definition so that the metadata is bound to the entire class, as the following example shows:

```
// Add the [Event] metadata tag outside of the class file.
[Event(name="enableChange", type="flash.events.Event")]
public class ModalText extends TextArea {

    ...

    // Define class properties/methods
    private var _enableTA:Boolean;

    // Add the [Inspectable] metadata tag before the individual property.
    [Inspectable(defaultValue="false")]
    public function set enableTA(val:Boolean):void {
        _enableTA = val;
        this.enabled = val;

        // Define event object, initialize it, then dispatch it.
        var eventObj:Event = new Event("enableChange");
        dispatchEvent(eventObj);
    }
}
```

In this example, you add the [Event] metadata tag before the class definition to indicate that the class dispatches an event named enableChanged. You also include the [Inspectable] metadata tag to indicate the default value of the property for Adobe® Flash® Builder™. For more information on using this tag, see “Inspectable metadata tag” on page 2386.

Metadata tags in MXML

In an MXML file, you insert the metadata tags either in an <fx:Script> block along with your ActionScript code, or in an <fx:Metadata> block, as the following example shows:

```
<?xml version="1.0"?>
<!-- TextAreaEnabled.mxml -->
<mx:TextArea xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Metadata>
        [Event(name="enableChange", type="flash.events.Event")]
    </fx:Metadata>

    <fx:Script>
        <![CDATA[

            // Import Event class.
            import flash.events.Event;

            // Define class properties and methods.
            private var _enableTA:Boolean;

            // Add the [Inspectable] metadata tag before the individual property.
            [Inspectable(defaultValue="false")]
            public function set enableTA(val:Boolean):void {
                _enableTA = val;
                this.enabled = val;

                // Define event object, initialize it, then dispatch it.
                var eventObj:Event = new Event("enableChange");
                dispatchEvent(eventObj);
            }
        ]]>
    </fx:Script>
</mx:TextArea>
```

A key difference between the <fx:Metadata> and <fx:Script> tags is that text within the <fx:Metadata> tag is inserted before the generated class declaration, but text within <fx:Script> tag is inserted in the body of the generated class declaration. Therefore, metadata tags like [Event] and [Effect] must go in an <fx:Metadata> tag, but the [Bindable] and [Embed] metadata tags must go in an <fx:Script> tag.

Metadata tags

The following table describes the metadata tags that you can use in ActionScript class files:

Tag	Description
`[Alternative]`	Specifies a replacement class for an existing class, and a version number that indicates when the replacement occurred. For more information, see "Alternative metadata tag" on page 2380.
`[ArrayElementType]`	Defines the allowed data type of each element of an Array. For more information, see "ArrayElementType metadata tag" on page 2380.
`[Bindable]`	Identifies a property that you can use as the source of a data binding expression. For more information, see "Bindable metadata tag" on page 2381.
`[DefaultProperty]`	Defines the name of the default property of the component when you use the component in an MXML file. For more information, see "DefaultProperty metadata tag" on page 2383.
`[Deprecated]`	Marks a class or class element as deprecated so that the compiler can recognize it and issue a warning when the element is used in an application. For more information, see "Deprecated metadata tag" on page 2383.
`[Effect]`	Defines the MXML property name for the effect. For more information, see "Effect metadata tag" on page 2384.
`[Embed]`	Imports JPEG, GIF, PNG, SVG, and SWF files at compile time. Also imports image assets from SWC files. This is functionally equivalent to the MXML `@Embed` syntax, as described in "Embedding assets" on page 1699.
`[Event]`	Defines the MXML property for an event and the data type of the event object that a component emits. For more information, see "Event metadata tag" on page 2384.
`[Exclude]`	Omits an inherited class element from the Flash Builder tag inspector. The syntax is as follows: `[Exclude(name="label", kind="property")]` Where `kind` can be `property`, `method`, `event`, or `style`.
`[ExcludeClass]`	Omits the class from the Flash Builder tag inspector. This is equivalent to the `@private` tag in ASDoc when applied to a class.
`[HostComponent]`	Specifies the host component for a Spark skin class. For more information, see "HostComponent metadata tag" on page 2385
`[IconFile]`	Identifies the filename for the icon that represents the component in the Insert bar of Adobe Flash Builder. For more information, see "IconFile metadata tag" on page 2386.
`[Inspectable]`	Defines an attribute exposed to component users in the attribute hints and Tag inspector of Flash Builder. Also limits allowable values of the property. For more information, see "Inspectable metadata tag" on page 2386.
`[InstanceType]`	Specifies the allowed data type of a property of type IDeferredInstance. For more information, see "InstanceType metadata tag" on page 2387.
`[NonCommittingChangeEvent]`	Identifies an event as an interim trigger. For more information, see "NonCommittingChangeEvent metadata tag" on page 2388.
`[RemoteClass]`	Maps the ActionScript object to a Java object. For more information on using the `[RemoteClass]` metadata tag, see "RemoteClass metadata tag" on page 2388.
`[RichTextContent]`	Indicate that the value of a property in MXML should always be interpreted by the compiler as a String. For more information, see "RichTextContent metadata tag" on page 2389.

Tag	Description
`[SkinPart]`	Define a property of a component that corresponds to a skin part. For more information, see "SkinPart metadata tag" on page 2389.
`[SkinState]`	Defines the view states that a component's skin must support. For more information, see "SkinState metadata tag" on page 2390.
`[Style]`	Defines the MXML property for a style property for the component. For more information on using the `[Style]` metadata tag, see "Style metadata tag" on page 2390.
`[SWF]`	Specifies attributes of the application when you write the main application file in ActionScript. For more information, see "SWF metadata tag" on page 2392.
`[Transient]`	Identifies a property that should be omitted from data that is sent to the server when an ActionScript object is mapped to a Java object using `[RemoteClass]`. For more information, see "Transient metadata tag" on page 2392.

Alternative metadata tag

If you want to replace one class with another, mark the class to be replaced with the `[Alternative]` metadata tag. The `[Alternative]` metadata tag specifies the replacement class, and a version number that indicates when the replacement occurred.

The `[Alternative]` metadata tag is not the same a the `[Deprecated]` metadata tag. When a class is deprecated, it might not work in a future release. A class marked by the `[Alternative]` metadata tag is still supported, but it indicates that there is an alternate to the class. For example, the MX Button class is marked with the `[Alternative]` metadata tag to indicate that you should use the Spark Button class instead.

Insert the `[Alternative]` metadata tag before the class definition of the class to be replaced. The `[Alternative]` metadata tag has the following syntax:

```
[Alternative(replacement="packageAndClassName", since="versionNum")]
```

The `replacement` option specifies the package and class name of the alternate class, and the `since` option specifies a version number.

ArrayElementType metadata tag

When you define an Array variable in ActionScript, you specify `Array` as the data type of the variable. However, you cannot specify the data type of the elements of the Array.

To allow the Flex MXML compiler to perform type checking on Array elements, you can use the `[ArrayElementType]` metadata tag to specify the allowed data type of the Array elements, as the following example shows:

```
public class MyTypedArrayComponent extends VBox {

    [ArrayElementType("String")]
    public var newStringProperty:Array;

    [ArrayElementType("Number")]
    public var newNumberProperty:Array;
    ...
}
```

***Note:** The MXML compiler checks for proper usage of the Array only in MXML code; it does not check Array usage in ActionScript code.*

In this example, you specify String as the allowed data type of the Array elements. If a user attempts to assign elements of a data type other than String to the Array in an MXML file, the compiler issues a syntax error, as the following example shows:

```
<MyComp:MyTypedArrayComponent>
    <MyComp:newStringProperty>
        <fx:Number>94062</fx:Number>
        <fx:Number>14850</fx:Number>
        <fx:Number>53402</fx:Number>
    </MyComp:newStringProperty>
</MyComp:MyTypedArrayComponent>
```

In this example, you try to use Number objects to initialize the Array, so the compiler issues an error.

You can also specify Array properties as tag attributes, rather than using child tags, as the following example shows:

```
<MyComp:MyTypedArrayComponent newNumberProperty="[abc,def]"/>
```

This MXML code generates an error because Flex cannot convert the Strings "`abc`" and "`def`" to a Number.

You insert the `[ArrayElementType]` metadata tag before the variable definition. The tag has the following syntax:

```
[ArrayElementType("elementType")]
```

The following table describes the property of the `[ArrayElementType]` metadata tag:

Property	Type	Description
`elementType`	String	Specifies the data type of the Array elements, and can be one of the ActionScript data types, such as String, Number, class, or interface. You must specify the type as a fully qualified class name, including the package.

Bindable metadata tag

When a property is the source of a data binding expression, Flex automatically copies the value of the source property to any destination property when the source property changes. To signal to Flex to perform the copy, you must use the `[Bindable]` metadata tag to register the property with Flex, and the source property must dispatch an event.

The `[Bindable]` metadata tag has the following syntax:

```
[Bindable]
[Bindable(event="eventname")]
```

If you omit the event name, Flex automatically creates an event named `propertyChange`.

For more information on data binding and on this metadata tag, see “Data binding” on page 299.

Working with bindable property chains

When you specify a property as the source of a data binding, Flex monitors not only that property for changes, but also the chain of properties leading up to it. The entire chain of properties, including the destination property, is called a *bindable property chain*. In the following example, `firstName.text` is a bindable property chain that includes both a `firstName` object and its `text` property:

```
<first>{firstName.text}</first>
```

You should raise an event when any named property in a bindable property chain changes. If the property is marked with the `[Bindable]` metadata tag, the Flex compiler generates the event for you.

The following example uses the `[Bindable]` metadata tag for a variable and a getter property. The example also shows how to call the `dispatchEvent()` function.

```
[Bindable]
public var minFontSize:Number = 5;

[Bindable("textChanged")]
public function get text():String {
     return myText;
}

public function set text(t : String):void {
     myText = t;
    dispatchEvent( new Event( "textChanged" ) );}
```

If you omit the event name in the `[Bindable]` metadata tag, the Flex compiler automatically generates and dispatches an event named `propertyChange` so that the property can be used as the source of a data binding expression.

You should also provide the compiler with specific information about an object by casting the object to a known type. In the following example, the `myList` List control contains Customer objects, so the `selectedItem` property is cast to a Customer object:

```
<fx:Model id="selectedCustomer">
    <customer>
        <name>{Customer(myList.selectedItem).name}</name>
        <address>{Customer(myList.selectedItem).address}</address>
        ...
    </customer>
</fx:Model>
```

There are some situations in which binding does not execute automatically as expected. Binding does not execute automatically when you change an entire item of a `dataProvider` property, as the following example shows:

```
dataProvider[i] = newItem
```

Binding also does not execute automatically for subproperties of properties that have `[Bindable]` metadata, as the following example shows:

```
...
[Bindable]
var temp;
// Binding is triggered:
temp = new Object();
// Binding is not triggered, because label not a bindable property
// of Object:
temp.label = foo;
...
```

In this code example, the problem with `{temp.label}` is that temp is an Object. You can solve this problem in one of the following ways:

- Preinitialize the Object.
- Assign an ObjectProxy to `temp`; all of an ObjectProxy's properties are bindable.
- Make `temp` a strongly typed object with a `label` property that is bindable.

Binding also does not execute automatically when you are binding data to a property that Flash Player updates automatically, such as the `mouseX` property.

The executeBindings() method of the UIComponent class executes all the bindings for which a UIComponent object is the destination. All containers and controls, as well as the Repeater component, extend the UIComponent class. The executeChildBindings() method of the Container and Repeater classes executes all of the bindings for which the child UIComponent components of a Container or Repeater class are destinations. All containers extend the Container class.

These methods give you a way to execute bindings that do not occur as expected. By adding one line of code, such as a call to executeChildBindings() method, you can update the user interface after making a change that does not cause bindings to execute. However, you should only use the executeBindings() method when you are sure that bindings do not execute automatically.

DefaultProperty metadata tag

The [DefaultProperty] metadata tag defines the name of the default property of the component when you use the component in an MXML file.

The [DefaultProperty] metadata tag has the following syntax:

```
[DefaultProperty("propertyName")]
```

The *propertyName* property specifies the name of the default property.

You can use the [DefaultProperty] metadata tag in your ActionScript component to define a single default property. For more information and an example, see “Creating a default property” on page 2439.

Deprecated metadata tag

A class or class element marked as deprecated is one which is considered obsolete, and whose use is discouraged in the current release. While the class or class element still works, its use can generate compiler warnings.

The mxmlc command-line compiler supports the show-deprecation-warnings compiler option, which, when true, configures the compiler to issue deprecation warnings when your application uses deprecated elements. The default value is true.

Insert the [Deprecated] metadata tag before a property, method, or class definition to mark that element as deprecated. The [Deprecated] metadata tag has the following options for its syntax when used with a class, property or method:

```
[Deprecated("string_describing_deprecation")]
[Deprecated(message="string_describing_deprecation")]
[Deprecated(replacement="string_specifying_replacement")]
[Deprecated(replacement="string_specifying_replacement", since="version_of_replacement")]
```

The following uses the [Deprecated] metadata tag to mark the dataProvider property as obsolete:

```
[Deprecated(replacement="MenuBarItem.data")]
public function set dataProvider(value:Object):void
{
    ...
}
```

The [Event], [Effect] and [Style] metadata tags also support deprecation. These tags support the following options for syntax:

```
[Event(... , deprecatedMessage="string_describing_deprecation")]
[Event(... , deprecatedReplacement="change2")]
[Event(... , deprecatedReplacement="string_specifying_replacement",
deprecatedSince="version_of_replacement")]
```

These metadata tags support the `deprecatedReplacement` and `deprecatedSince` attributes to mark the event, effect, or style as deprecated.

Effect metadata tag

The `[Effect]` metadata tag defines the name of the MXML property that you use to assign an effect to a component and the event that triggers the effect. If you define a custom effect, you can use the `[Effect]` metadata tag to specify that property to the Flex compiler.

For more information on defining custom effects, see "Custom effects" on page 2525.

An effect is paired with a trigger that invokes the effect. A *trigger* is an event, such as a mouse click on a component, a component getting focus, or a component becoming visible. An *effect* is a visible or audible change to the component that occurs over a period of time.

You insert the `[Effect]` metadata tag before the class definition in an ActionScript file or in the `<fx:Metadata>` block in an MXML file. The `[Effect]` metadata tag has the following syntax:

```
[Effect(name="eventNameEffect", event="eventName")]
```

The following table describes the properties of the `[Effect]` metadata tag:

Property	Type	Description
`eventNameEffect`	String	Specifies the name of the effect.
`eventName`	String	Specifies the name of the event that triggers the effect.

The `[Effect]` metadata tag is often paired with an `[Event]` metadata tag, where the `[Event]` metadata tag defines the event corresponding to the effect's trigger. By convention, the name of the effect is the event name with the suffix `Effect`, as the following example of an ActionScript file shows:

```
// Define event corresponding to the effect trigger.
[Event(name="darken", type="flash.events.Event")]
// Define the effect.
[Effect(name="darkenEffect", event="darken")]
class ModalText extends TextArea {
    ...
}
```

In an MXML file, you can define the event and effect in an `<fx:Metadata>` block, as the following example shows:

```
<fx:Metadata>
    [Event(name="darken", type="flash.events.Event")]
    [Effect(name="darkenEffect", event="darken")]
</fx:Metadata>
```

Event metadata tag

Use the `[Event]` metadata tag to define the MXML property for an event and the data type of the event object that a component emits. You insert the [Event] metadata tag before the class definition in an ActionScript file, or in the `<fx:Metadata>` block in an MXML file.

For more information on defining custom events, see "Custom events" on page 2369.

The `[Event]` metadata tag has the following syntax:

```
[Event(name="eventName", type="package.eventType")]
```

The following table describes the properties of the `[Event]` metadata tag:

Property	Type	Description
eventName	String	Specifies the name of the event.
eventType	String	Specifies the package and class that defines the data type of the event object. It is either the base event class, Event, or a subclass of the Event class. You must include the package in the class name.

The following example identifies the `myClickEvent` event as an event that the component can dispatch:

```
[Event(name="myClickEvent", type="flash.events.Event")]
```

If you do not identify an event in the class file with the `[Event]` metadata tag, the MXML compiler generates an error if you try to use the event name in MXML. Any component can register an event listener for the event in ActionScript by using the `addEventListener()` method, even if you omit the `[Event]` metadata tag.

The following example identifies the `myClickEvent` event as an event that an ActionScript component can dispatch:

```
[Event(name="myEnableEvent", type="flash.events.Event")]
public class MyComponent extends UIComponent
{
    ...
}
```

The following example shows the `[Event]` metadata tag in the `<fx:Metadata>` tag in an MXML file:

```
<?xml version="1.0"?>
<!-- TextAreaEnabled.mxml -->
<mx:TextArea xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Metadata>
        [Event(name="myEnableEvent", type="flash.events.Event")]
    </fx:Metadata>

    ....

</mx:TextArea>
```

HostComponent metadata tag

Use the `[HostComponent]` metadata tag to identify the host component of a Spark skin class. The `[HostComponent]` metadata tag has the following syntax:

```
<Metadata>
    [HostComponent(componentName)]
</Metadata>
```

For example:

```
<Metadata>
    [HostComponent("spark.components.Button")]
</Metadata>
```

As a result of this metadata, Flex creates the property `hostComponent` on the skin class. You can then use this property to access public members of the host component's instance from within the skin. For example, in a Button skin, you can access the Button's style properties.

For more information, see "Spark Skinning" on page 1602.

IconFile metadata tag

Use the [IconFile] metadata tag to identify the filename for the icon that represents the component in the Insert bar of Flash Builder.

The [IconFile] metadata tag has the following syntax:

```
[IconFile("fileName")]
```

The fileName property specifies a PNG, GIF, or JPEG file that contains the icon, as the following example shows:

```
[IconFile("MyButton.png")]
public class MyButton extends Button
{
    ...
}
```

Inspectable metadata tag

The [Inspectable] metadata tag defines information about an attribute of your component that you expose in code hints and in the Property inspector area of Flash Builder. The [Inspectable] metadata tag is not required for either code hints or the Property inspector. The following rules determine how Flash Builder displays this information:

- All public properties in components appear in code hints and in the Flash Builder Property inspector. If you have extra information about the property that you want to add, such as enumeration values or that a String property represents a file path, add the [Inspectable] metadata tag with that information.
- Code hints for components and the information in the Property inspector come from the same data. Therefore, if the attribute appears in one, it should appear in the other.
- Code hints for ActionScript components do not require metadata to work correctly so that you always see the appropriate code hints, depending the current scope. Flash Builder uses the public, protected, private, and static keywords, plus the current scope, to determine which ActionScript code hints to show.

The [Inspectable] metadata tag must immediately precede the property's variable declaration or the setter and getter methods to be bound to that property. The [Inspectable] metadata tag has the following syntaxes:

```
[Inspectable(attribute=value[,attribute=value,...])]
property_declaration name:type;
[Inspectable(attribute=value[,attribute=value,...])]
setter_getter_declarations;
```

The following table describes the properties of the [Inspectable] metadata tag:

Property	Type	Description
category	String	Groups the property into a specific subcategory in the Property inspector of the Flash Builder user interface. The default category is "Other". Specify a value of "Common", "Effects", "Events", "Layout Constraints", "Size", "Styles", "Text", or "Other".
defaultValue	String or Number	Sets the initial value in the editor that appears in the Property inspector when you modify the attribute. The default value is determined from the property definition.
enumeration	String	Specifies a comma-delimited list of legal values for the property. Only these values are allowed; for example, item1,item2,item3. Notice the lack of a space character between items so that Flex Builder does not interpret a space as a part of a valid value. This information appears as code hints and in the Property inspector. If you define a Boolean variable, Flash Builder automatically shows true and false without you having to specifying them using enumeration.

Property	Type	Description
environment	String	Specifies which inspectable properties should not be allowed (environment=none), which are used only for Flash Builder (environment=Flash), and which are used only by Flex and not Flash Builder (environment=MXML).
format	String	Determines the type of editor that appears in the Property inspector when you modify the attribute. You can use this property when the data type of the attribute is not specific to its function. For example, for a property of type Number, you can specify format="Color" to cause Flash Builder to open a color editor when you modify the attribute. Common values for the format property include "Length", "Color", "Time", "EmbeddedFile", and "File".
listOffset	Number	Specifies the default index into a List value.
name	String	Specifies the display name for the property; for example, FontWidth. If not specified, use the property's name, such as _fontWidth.
type	String	Specifies the type specifier. If omitted, use the property's type. The following values are valid: • Array • Boolean • Color • Font Name • List • Number • Object • String If the property is an Array, you must list the valid values for the Array.
variable	String	Specifies the variable to which this parameter is bound.
verbose	Number	Indicates that this inspectable property should be displayed in the Flash Builder user interface only when the user indicates that verbose properties should be included. If this property is not specified, Flash Builder assumes that the property should be displayed.

The following example defines the myProp parameter as inspectable:

```
[Inspectable(defaultValue=true, verbose=1, category="Other")]
public var myProp:Boolean;
```

InstanceType metadata tag

The [InstanceType] metadata tag specifies the allowed data type of a property of type IDeferredInstance, as the following example shows:

```
// Define a deferred property for the top component.
[InstanceType("mx.controls.Label")]
public var topRow:IDeferredInstance;
```

The compiler validates that users assign values only of the specified type to the property. In this example, if the component user sets the topRow property to a value of a type other than mx.controls.Label, the compiler issues an error message.

You use the `[InstanceType]` metadata tag when creating template components. For more information, see "Template components" on page 2507.

The `[InstanceType]` metadata tag has the following syntax:

```
[InstanceType("package.className")]
```

You must specify a fully qualified package and class name.

NonCommittingChangeEvent metadata tag

The `[NonCommittingChangeEvent]` metadata tag identifies an event as an interim trigger, which means that the event should not invoke Flex data validators on the property. You use this tag for properties that might change often, but which you do not want to validate on every change.

An example of this is if you tied a validator to the `text` property of a TextInput control. The `text` property changes on every keystroke, but you do not want to validate the property until the user presses the Enter key or changes focus away from the field. The `NonCommittingChangeEvent` tag lets you dispatch a change event, but that does not trigger validation.

You insert the `[NonCommittingChangeEvent]` metadata tag before an ActionScript property definition or before a setter or getter method. The `[NonCommittingChangeEvent]` metadata tag has the following syntax:

```
[NonCommittingChangeEvent("event_name")]
```

In the following example, the component dispatches the `change` event every time the user enters a keystroke, but the `change` event does not trigger data binding or data validators. When the user completes data entry by pressing the Enter key, the component broadcasts the `valueCommit` event to trigger any data bindings and data validators:

```
[Event(name="change", type="flash.events.Event")]
class MyText extends UIComponent {
    ...

    [Bindable(event="valueCommit")]
    [NonCommittingChangeEvent("change")]
    function get text():String {
        return getText();
    }
    function set text(t):void {
        setText(t);
        // Dispatch events.
    }
}
```

RemoteClass metadata tag

Use the `[RemoteClass]` metadata tag to register the class with Flex so that Flex preserves type information when a class instance is serialized by using Action Message Format (AMF). You insert the `[RemoteClass]` metadata tag before an ActionScript class definition.

The `[RemoteClass]` metadata tag has the following syntax:

```
[RemoteClass]
```

You can also use this tag to represent a server-side Java object in a client application. You use the `[RemoteClass(alias=" ")]` metadata tag to create an ActionScript object that maps directly to the Java object. You specify the fully qualified class name of the Java class as the value of `alias`. For more information, see Accessing Server-Side Data with Flex.

RichTextContent metadata tag

If a property is typed as a String, the compiler automatically tries to convert its value in MXML to a String. If the property is of a type such as *, Object, or Array, the compiler by default attempts to convert the value to an appropriate data type. Use the `[RichTextContent]` metadata tag to indicate that the value of a property in MXML should always be interpreted by the compiler as a String.

For example, the `content` property of the spark.components.TextArea and spark.primitives.RichText classes is typed as Object. However, these classes use the `[RichTextContent]` metadata tag to indicate that the value of the property in MXML should always be interpreted as a String.

Shown below are two examples that set the `content` property of the RichText class:

```
<!-- Without [RichTextContent] metadata, interpret the value as type Number. -->
<s:RichText>
    <s:content>1</s:content>
</s:RichText>

<!-- Without [RichTextContent] metadata, interpret the value as type Array. -->
<s:RichText>
    <s:content>[1]</s:content>
</s:RichText>
```

Data binding syntax, { }, and @ functions, such as `@Resource` and `@Embed`, are supported by properties that use the `[RichTextContent]` metadata tag.

You insert the `[RichTextContent]` metadata tag a property before a property definition in ActionScript. The `[RichTextContent]` metadata tag has the following syntax:

```
[RichTextContent]
```

SkinPart metadata tag

Components can uses skins made up of skin parts. Use the `[SkinPart]` metadata tag to define a property of a component that corresponds to a skin part. Users of the component do not set the skin part properties directly. The component's skin sets the skin part properties.

Insert the `[SkinPart]` metadata tag before any property that corresponds to a skin part. The `[SkinPart]` metadata tag has the following syntax:

```
[SkinPart(type="package.className", required="true_false")]
/**
* Optional ASDoc comment.
*/
Property definition
```

The `type` and `required` attributes are optional. The `type` attribute specifies the data type of the skin part, which determines whether the part is static or dynamic. The default value of `type` is determined by the data type of the property.

The `required` attribute specifies if the skin class must define the skin part. The default value of the `required` attribute is `false`.

SkinPart metadata is inherited by subclasses of the component.

For more information, see “Spark Skinning” on page 1602.

Static skin parts

Static skin parts are created once by an instance of a component, and are defined as shown below:

```
[SkinPart]
/**
* ASDoc comment for thumb.
*/
public var thumb:spark.components.Button;
```

The data type for static parts is the data type of the part property. In this example above, the type is Button. Therefore, static skin parts typically omit the `type` attribute of the `[SkinPart]` metadata tag.

Dynamic skin parts

Some components create multiple instances of a skin part. For example, the Spark ButtonBar control can create any number of buttons. Dynamic skin parts can be created multiple times by a component. The data type of a dynamic skin part property is always IFactory, but the metadata tag can optionally define the data type of the skin part by using the `type` property.

For example from the spark.components.ButtonBar class:

```
[SkinPart(required="false", type="mx.core.IVisualElement")]
/**
* A skin part that defines the first button.
*/
public var firstButton:IFactory;
```

Because the data type of the skin part is IFactory, it is a dynamic skin part. Each instance of the skin part is of type mx.core.IVisualElement.

SkinState metadata tag

The `[SkinState]` metadata tag defines the view states that a component's skin must support. The tag goes outside the component's class definition, and inside the package definition. The tag is inherited, but can be overridden in a subclass.

The SkinState tag has the following ActionScript syntax:

```
[SkinState("stateName")]
```

The following example defines two skin states for a component:

```
package spark.components.supportCl asses
{
    /**
    *  Optional ASDoc comment. */
    [SkinState("n ormal")]

    /**
    *  Optional ASDoc comment. */
    [SkinState("disabled")]

    public class MyClass {}
```

For more information, see "Spark Skinning" on page 1602.

Style metadata tag

Use the `[Style]` metadata tag to define the MXML tag attribute for a style property for the component. You insert the `[Style]` metadata tag before the class definition in an ActionScript file, or in the `<fx:Metadata>` block in an MXML file.

The `[Style]` metadata tag has the following syntax:

```
[Style(name="style_name"[,property="value",...])]
```

The following table describes the properties for the `[Style]` metadata tag:

Option	Type	Description
`name`	String	(Required) Specifies the name of the style.
`arrayType`	String	If `type` is `Array`, `arrayType` specifies the data type of the Array elements. If the data type is not an ActionScript type such as Number or Date, use a qualified class name in the form *packageName.className*.
`enumeration`	String	Specifies an enumerated list of possible values for the style property.
`format`	String	Specifies the units of the property. For example, if you specify `type` as `"Number"` , you might specify `format="Length"` if the style defines a length measured in pixels. Or, if you specify `type="uint"`, you might set `format="Color"` if the style defines an RGB color. The possible values are `Boolean`, `Color`, `Number`, `Length`, `uint`, `Time`, `File`, `EmbeddedFile`, `int`, `ICollectionView`, `Array`, `Class`, `String`, and `Object`.
`inherit`	String	Specifies whether the property is inheriting. Valid values are `yes` and `no`. This property refers to CSS inheritance, not object-oriented inheritance. All subclasses automatically use object-oriented inheritance to inherit the style property definitions of their superclasses. Some style properties are inherited using CSS inheritance. If you set an inheritable style property on a parent container, its children inherit that style property. For example, if you define `fontFamily` as Times for a Panel container, all children of that container will also use Times for `fontFamily`, unless they override that property. If you set a noninheritable style, such as `textDecoration`, on a parent container, only the parent container and not its children use that style. For more information on inheritable style properties, see “About style inheritance” on page 1526.
`states`	String	For skin properties, specifies that you can use the style to specify a stateful skin for multiple states of the component. For example, the definition of the `Slider.thumbSkin` style uses the following `[Style]` metadata tag: `[Style(name="thumbSkin", type="Class", inherit="no", states="disabled, down, over, up")]` This line specifies that you can use the `Slider.thumbSkin` style to specify a stateful skin for the disabled, down, over, and up states of the Slider control. For more information, see “Skinning MX components” on page 1655.
`theme`	String	If the style is only valid for a specific theme, specifies the name of the theme. For example, some styles on Flex components are only valid if you are using the Spark or Halo theme. For more information, see “About themes” on page 1561
`type`	String	Specifies the data type of the value that you write to the style property. If the type is not an ActionScript type such as Number or Date, use a qualified class name in the form *packageName.className*.

The following example shows the definition of the `textSelectedColor` style property:

```
[Style(name="textSelectedColor",type="Number",format="Color",inherit="yes")]
```

The next example shows the definition of the `verticalAlign` style property:

```
[Style(name="verticalAlign", type="String", enumeration="bottom,middle,top", inherit="no")]
```

For more information on the `[Style]` metadata tag, see “Custom style properties” on page 2501.

SWF metadata tag

Use the `[SWF]` metadata tag to specify attributes of the application when you write the main application file in ActionScript. Typically, you set these attributes by using the `<s:Application>` tag when you write the main application file in MXML.

The `[SWF]` tag has the following syntax:

```
[SWF(option="value"[,option="value",...])]
```

You can specify several options the `[SWF]` metadata tag. The following table describes these options:

Option	Type	Description
`frameRate`	Number	Specifies the frame rate of the application, in frames per second. The default value is 24.
`height`	Number	The height of the application, in pixels.
`heightPercent`	Number	The height of the application, as a percentage of the browser window. Include the percent sign (`%`) in the value.
`pageTitle`	String	Specifies a String that appears in the title bar of the browser. This property provides the same functionality as the HTML `<title>` tag.
`scriptRecursionLimit`	Number	Specifies the maximum depth of Flash Player or AIR call stack before Flash Player or AIR stops. This is essentially the stack overflow limit. The default value is 1000.
`scriptTimeLimit`	Number	Specifies the maximum duration, in seconds, that an ActionScript event listener can execute before Flash Player or AIR assumes that it has stopped processing and aborts it. The default value is 60 seconds, which is also the maximum allowable value that you can set.
`width`	Number	The width of the application, in pixels.
`widthPercent`	Number	The width of the application, as a percentage of the browser window. Include the percent sign (`%`) in the value.

For more information on these options, see "Specifying options of the Application container" on page 402.

Transient metadata tag

Use the `[Transient]` metadata tag to identifies a property that should be omitted from data that is sent to the server when an ActionScript object is mapped to a Java object using the `[RemoteClass]` metadata tag.

The `[Transient]` metadata tag has the following syntax:

```
[Transient]
public var count:Number = 5;
```

Component compilation

When you compile an application, you create a SWF file that a user can download and play. You can also compile any custom components that you create as part of the application.

When you create a component, you save it to a location that the Adobe® Flex® compiler can access. You can save your components as MXML and ActionScript files, as SWC files, or as Runtime Shared Libraries (RSLs). You have several options when you compile the components.

About compiling

You compile a custom component so that you can use it as part of your application. You can compile the component when you compile the entire application, or you can compile it separately so that you can link it into the application at a later time.

Flex component file types

When you create a Flex component, you can distribute it in one of several different file formats, as the following table shows:

File format	Extension	Description
MXML	.mxml	A component implemented as an MXML file.
ActionScript	.as	A component implemented as an ActionScript class.
SWC	.swc	A component implemented as an MXML or ActionScript file, and then packaged as a SWC file. A SWC file contains components that you package and reuse among multiple applications. The SWC file is then compiled into your application when you create the application's SWF file.
RSL	.swc	A component implemented as an MXML or ActionScript file, and then deployed as an RSL. An RSL is a stand-alone file that is downloaded separately from your application's SWF file, and cached on the client computer for use with multiple application SWF files.

You must take into consideration the file format and file location when you compile an application that uses the component.

About compiling with Flex SDK

Adobe Flex includes two compilers: mxmlc and compc. You use the mxmlc compiler to compile MXML, ActionScript, SWC, and RSL files into a single SWF file. After your application is compiled and deployed on your web or application server, a user can make an HTTP request to download and play the SWF file on their computer.

You use the compc compiler to compile components, classes, and other files into SWC files or into RSLs.

You can use the compc and mxmlc compilers from Adobe Flash Builder or from a command line. For more information on using the compilers, see "Flex compilers" on page 2164.

The most basic example of using the mxmlc compiler is one in which the MXML file has no external dependencies (such as components in a SWC file or ActionScript classes). In this case, you open mxmlc and point it to your MXML file:

```
$ mxmlc c:/myfiles/app.mxml
```

The default option is the target file to compile into a SWF file, and it must have a value. If you use a space-separated list as part of the options, you can terminate the list with a double hyphen before adding the target file, as in the following example:

```
$ mxmlc -option arg1 arg2 arg3 -- target_file.mxml
```

About case sensitivity during a compilation

The Flex compilers use a case-sensitive file lookup on all file systems. On case-insensitive file systems, such as the Macintosh and Windows file systems, the Flex compiler generates a case-mismatch error when you use a component with the incorrect case. On case-sensitive file systems, such as the UNIX file system, the Flex compiler generates a component-not-found error when you use a component with the incorrect case.

About the ActionScript source path

Typically, you put component files in directories that are in the ActionScript source path. These include your application's root directory, its subdirectories, and any directory that you specify to the compiler. To specify a directory, you use the `source-path` option to the mxmlc compiler, or the Project Properties dialog box in Flash Builder.

The following rules can help you organize your custom components:

- An application can access MXML and ActionScript components in the same directory and in its subdirectories.
- An ActionScript component in a subdirectory of the main application directory must define a fully qualified package name that is relative to the location of the application's root directory. For example, if you define a custom component in the dir1/dir2/myControls/PieChart.as file, its fully qualified package name must be dir1.dir2.myControls, assuming dir1 is an immediate subdirectory of the main application directory.
- An MXML component does not include a package name definition. However, you must declare a namespace definition in the file that references the MXML component that corresponds to the directory location of the MXML component, either in a subdirectory of the application's root directory or in a subdirectory of the source path. For more information, see "Simple MXML components" on page 2399.
- An application can access MXML and ActionScript components in the directories included in the ActionScript source path. The component search order in the source path is based on the order of the directories listed in the source path.
- An ActionScript component in a subdirectory of a directory included in the source path must define a fully qualified package name that is relative to the location of the source path directory. For example, if you define a custom component in the file dir1/dir2/myControls/PieChart.as, and dir1 is included in the ActionScript source path, its fully qualified package name must be dir1.dir2.myControls.
- The `<fx:Script>` tag in the main MXML file, and in dependent MXML component files, can reference components located in the ActionScript source path.

Compiling components with Flex SDK

How you compile an application with Adobe Flex SDK is based on how you distribute your custom components that are distributed as MXML, ActionScript, SWC, and RSL files.

Distributing components as MXML and ActionScript files

When you compile an application with Flex SDK, you define where the MXML and ActionScript files for your custom components exist in the directory structure of your application, or in the directory structure of components shared by multiple applications.

For example, you can create a component for use by a single application. In that case, you store it in the directory structure of the application, usually in a subdirectory under the directory that contains the main file of the application. The component is then compiled with the entire application into the resultant SWF file.

You can also create a component that is shared among multiple applications as an MXML or ActionScript file. In that case, store the component in a location that is included in the ActionScript source path of the application. When Flex compiles the application, it also compiles the components included in the application's ActionScript source path.

You specify the directory location of the shared components by using one of the following methods:

Flash Builder Open the Project Properties dialog box, and then select Flex Build Path to set the ActionScript source path.

mxmlc compiler Use the `source-path` option to the mxmlc compiler to specify the directory location of your shared MXML and ActionScript files.

Distributing components as SWC files

A SWC file is an archive file of Flex components. SWC files make it easy to exchange components among Flex developers. You need to exchange only a single file, rather than the MXML or ActionScript files, images, and other resource files. In addition, the SWF file inside a SWC file is compiled, which means that the code is hidden from casual view. Finally, compiling a component as a SWC file can make namespace allocation an easier process.

SWC files can contain one or more components and are packaged and expanded with the PKZIP archive format. You can open and examine a SWC file by using WinZip, JAR, or another archiving tool. However, do not manually change the contents of a SWC file, and do not try to run the SWF file that is in a SWC file outside of the SWC file.

When you compile your application, you specify the directory location of the SWC files by using one of the following methods:

Flash Builder Open the Project Properties dialog box, and then select Flex Build Path to set the library directories that contain the SWC files.

mxmlc compiler Set the `library-classpath` option to the mxmlc compiler to specify the directory location of your SWC files.

One of the advantages of distributing components as SWC files is that you can define a global style sheet, named defaults.css, in the SWC file. The defaults.css file defines the default style settings for all of the components defined in the SWC file. For more information, see "Applying styles from a defaults.css file" on page 2409.

For more information about SWC files, see "Flex compilers" on page 2164, and Basic workflow to develop an application with Flex.

Distributing components as RSLs

One way to reduce the size of your application's SWF file is by externalizing shared assets into stand-alone files that can be separately downloaded and cached on the client. These shared assets are loaded by any number of applications at run time, but must be transferred to the client only once. These shared files are known as Runtime Shared Libraries (RSLs).

If you have multiple applications but those applications share a core set of components or classes, your users download those assets only once as an RSL. The applications that share the assets in the RSL use the same cached RSL as the source for the libraries as long as they are in the same domain. By using an RSL, you can reduce the resulting file size for your applications. The benefits increase as the number of applications that use the RSL increases. If you only have one application, putting components into RSLs does not reduce the aggregate download size, and may increase it.

When you compile your application, you specify the directory location of an RSL file by using one of the following methods:

Flash Builder Open the Project Properties dialog box, and then select Flex Build Path to set the library directories that contain the SWC files.

mxmlc compiler Set the `external-library-path` option to the mxmlc compiler to specify the location of the RSL file at compile time. Set the `runtime-shared-libraries` option to the mxmlc compiler to specify the relative location of the RSL file when the application is deployed.

For more information, including information on how to create an RSL file, see "Runtime Shared Libraries" on page 253.

Example: Compiling a custom formatter component

The example in this section uses a custom formatter component that is defined as an ActionScript file. The name of the formatter is MySimpleFormatter, and it is defined in the file MySimpleFormatter.as. For more information on creating customer formatter components, see "Custom formatters" on page 2513.

The process for compiling an MXML file is the same as for an ActionScript file. For an example of deploying an MXML file, see "Simple MXML components" on page 2399.

Distributing a component as an ActionScript file

When you distribute a component defined as an ActionScript file, you can store it within the same directory structure as your application files or in a directory specified in the ActionScript source path.

The MXML tag name for a custom component consists of two parts: the namespace prefix and the tag name. The namespace prefix tells Flex where to look for the file that implements the custom component. The tag name corresponds to the filename of the component, in this case MySimpleFormatter.as. Therefore, the file MySimpleFormatter.as defines a component with the tag name of `<`*namespace*`:MySimpleFormatter>`.

The main application MXML file defines the namespace prefix used to reference the component in the `<s:Application>` tag. When you deploy your formatter as an ActionScript file, you refer to it in one of the following ways:

1 If you store the formatter component in the same directory as the application file, or in a directory that the ActionScript source path (not a subdirectory) specifies, you define the formatter by using an empty `package` statement, as the following example shows:

```
package
{
    //Import base Formatter class.
    import mx.formatters.Formatter

    public class MySimpleFormatter extends Formatter {
        ...
    }
}
```

You can refer to it as the following example shows. In the following code, the local namespace (*) is mapped to the prefix MyComp.

```
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="*">

    <MyComp:MySimpleFormatter/>

</s:Application>
```

If the same file exists in the ActionScript source path directory and the application directory, Flex uses the file in the application directory.

2 If you store the formatter component in a subdirectory of the directory that contains the application file, you specify that directory as part of the package statement, as the following example shows:

```
package myComponents.formatters
{
    //Import base Formatter class
    import mx.formatters.Formatter

    public class MySimpleFormatter extends Formatter {
        ...
    }
}
```

In this example, the MySimpleFormatter.as file is located in the myComponents/formatter subdirectory of the main application directory. You map the myComponents.formatters namespace to the MyComp prefix, as the following example shows:

```
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myComponents.formatters.*">

    <MyComp:MySimpleFormatter/>

</s:Application>
```

If multiple files with the same name exist under an ActionScript source path subdirectory and the application subdirectory, Flex uses the file under the application subdirectory.

3 If you store the formatter component in a subdirectory of the ActionScript source path directory, you specify that subdirectory as part of the package statement, as the following example shows:

```
package flexSharedRoot.custom.components
{
    //Import base Formatter class.
    import mx.formatters.Formatter

    public class MySimpleFormatter extends Formatter {
        ...
    }
}
```

You then use a namespace that specifies the subdirectory. The following code declares a component that is in the flexSharedRoot/custom/components directory:

```
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="flexSharedRoot.custom.components.*"/>

    <MyComp:MySimpleFormatter/>

</s:Application>
```

If the same file exists in the ActionScript source path directory and the application directory, Flex uses the file in the application file directory.

Distributing a component as a SWC file

To create a SWC file, use the compc compiler in the *flex_install_dir*/bin directory. The compc compiler generates a SWC file from MXML component source files and/or ActionScript component source files.

In this example, you create a SWC file for a custom formatter component that you defined by using the following package and class definition:

```
package myComponents.formatters
{
    //Import base Formatter class.
    import mx.formatters.Formatter

    public class MySimpleFormatter extends Formatter {
        ...
    }
}
```

In this example, the MySimpleFormatter.as file is in the directory c:\flex\myComponentsForSWCs\myComponents\formatters.

You use the following compc command from the *flex_install_dir*/bin directory to create the SWC file for this component:

```
.\compc -source-path c:\flex\myComponentsForSWCs\
    -include-classes myComponents.formatters.MySimpleFormatter
    -o c:\flex\mainApp\MyFormatterSWC.swc
```

In this example, you use the following options of the compc compiler:

Option name	Description
`-source-path`	Specifies the base directory location of the MySimpleFormatter.as file. It does not include the directories that the component's package statement defines.
`-include-classes`	Specifies classes to include in the SWC file. You provide the class name (MyComponents.formatters.MySimpleFormatter) not the filename of the source code. All classes specified with this option must be in the compiler's source path, which is specified in the `source-path` compiler option. You can use packaged and unpackaged classes. To use components in namespaces, use the `include-namespaces` option. If the components are in packages, use dot (.) notation rather than slashes to separate package levels.
`-o`	Specifies the name and directory location of the output SWC file. In this example, the directory is c:\flex\mainApp, the directory that contains your main application.

In your main application file, you specify the component's namespace, as the following example shows:

```
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myComponents.formatters.*">

    <MyComp:MyFormatter/>

</s:Application>
```

When you distribute SWC files, ensure that the corresponding ActionScript file is not in the directory structure of the application or in the ActionScript source path. Otherwise, Flex might use the ActionScript file, rather than the SWC file.

When you use mxmlc to compile the main application, ensure that the c:\flex\mainApp directory is included in the library path; otherwise, mxmlc cannot locate the SWC file.

For more information about SWC files, see "Flex compilers" on page 2164, and Build projects.

Distributing a component as an RSL file

You create an RSL by using the compc tool, and then pass the library's location to the compiler when you compile your application. For more information, including an example, see "Runtime Shared Libraries" on page 253.

Simple MXML components

Applications for Adobe® Flex® typically consist of multiple MXML and ActionScript files, and each MXML file is a separate MXML component. MXML components let you encapsulate functionality in a reusable component, extend an existing Flex component by adding new functionality to it, and reference the MXML component by using an MXML tag.

For information on advanced techniques for creating MXML components, see "Advanced MXML components" on page 2412.

About MXML components

In typical applications, you do not code the entire application within a single source code file. Such an implementation makes it difficult for multiple developers to work on the project simultaneously, makes it difficult to debug, and discourages code reuse.

Instead, you develop applications by using multiple MXML and ActionScript files. This architecture promotes a modular design, code reuse, and lets multiple developers contribute to the implementation.

MXML components are MXML files that you reference by using MXML tags from within other MXML files. One of the main uses of MXML components is to extend the functionality of an existing Flex component.

For example, Flex supplies a ComboBox control that you can use as part of a form that collects address information from a customer. You can use a ComboBox to let the user select the State portion of the address from a list of the 50 states in the U.S. In an application that has multiple locations where a user can enter an address, it would be tedious to create and initialize multiple ComboBox controls with the information about all 50 states.

Instead, you create an MXML component that contains a ComboBox control with all 50 states defined within it. Then, wherever you must add a state selector to your application, you use your custom MXML component.

Creating MXML components

An application that uses MXML components includes a main MXML application file, which contains the `<s:Application>` root tag, and references one or more components that are defined in separate MXML and ActionScript files. Each MXML component extends an existing Flex component, or another MXML component.

You create an MXML component in an MXML file where the component's filename becomes its MXML tag name. For example, a file named StateComboBox.mxml defines a component with the tag name of `<StateComboBox>`.

The root tag of an MXML component is a component tag, either a Flex component or another MXML component. The root tag specifies the namespace definitions for the component. For example, the following MXML component extends the standard Flex ComboBox control.

```
<?xml version="1.0"?>
<!-- createcomps_mxml/StateComboBox.mxml -->
<s:ComboBox xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:dataProvider>
        <s:ArrayList>
            <fx:String>AK</fx:String>
            <fx:String>AL</fx:String>
            <!-- Add all other states. -->
        </s:ArrayList>
    </s:dataProvider>
</s:ComboBox>
```

As part of its implementation, a custom MXML component can reference another custom MXML component.

The main application, or any other MXML component file, references the StateComboBox component, as the following example shows:

```
<?xml version="1.0"?>
<!-- createcomps_mxml/MXMLMyApplication.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="*">
    <MyComp:StateComboBox/>
</s:Application>
```

In this example, the main application file includes a new namespace definition of `xmlns:MyComp="*"` as part of the `<s:Application>` tag. This namespace definition specifies the location of the MXML component. In this case, it specifies that the component is in the same directory as the main application file, or if you are using Adobe® LiveCycle™ Data Services ES, in the WEB-INF/flex/user-classes directory.

As a best practice, store your components in a subdirectory. For example, you can write this file to the myComponents directory, a subdirectory of your main application directory. For more information on the namespace, see “Developing applications in MXML” on page 4.

The StateComboBox.mxml file specifies the ComboBox control as its root tag, so you can reference all of the properties of the ComboBox control within the MXML tag of your custom component, or in the ActionScript specified within an `<fx:Script>` tag. For example, the following code specifies the `maxChars` property and a listener for the `close` event for your custom control:

```
<?xml version="1.0"?>
<!-- createcomps_mxml/MyApplicationProps.mxml-->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:local="*">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import flash.events.Event;
            private function handleCloseEvent(eventObj:Event):void {
                myTA.text="foo";
            }
        ]]>
    </fx:Script>
    <local:StateComboBox maxChars="25"
        close="handleCloseEvent(event);"/>
    <mx:TextArea id="myTA" />
</s:Application>
```

Limitation on the default property of the root tag

Many Flex components define a single default property. The *default property* is the MXML tag property that is implicit for content inside of the MXML tag if you do not explicitly specify a property. For example, consider the following MXML tag definition:

```
<s:SomeTag>
    anything here
</s:SomeTag>
```

If this tag defines a default property named `default_property`, the preceding tag definition is equivalent to the following code:

```
<s:SomeTag>
    <s:default_property>
        anything here
    </s:default_property>
</s:SomeTag>
```

However, the default property mechanism does not work for root tags of MXML components. In this situation, you must use child tags to define the default property, as the following example shows:

```
<?xml version="1.0"?>
<s:SomeTag xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/halo">
    <s:default_property>
        anything here
    </s:default_property>
</s:SomeTag>
```

MXML components and ActionScript classes

When you create a custom MXML component, you define a new ActionScript class where the class name corresponds to the filename of the MXML component. Your new class is a subclass of the component's root tag, and therefore inherits all of the properties and methods of the root tag. However, because you are defining the component in MXML, many of the intricacies of creating an ActionScript class are hidden from you.

For example, in "Creating MXML components" on page 2399, you defined the component StateComboBox.mxml by using the `<s:ComboBox>` tag as its root tag. Therefore, StateComboBox.mxml defines a subclass of the ComboBox class.

Creating composite MXML components

A composite MXML component is a component that contains multiple component definitions within it. To create a composite component, you specify a container as its root tag, and then add components as children of the container.

For example, the following component contains an address form created by specifying a Form container as the root tag of the component, and then defining several children of the Form container. One of the `<mx:FormItem>` tags contains a reference to the `<MyComp:StateComboBox>` tag that you created in "Creating MXML components" on page 2399:

```
<?xml version="1.0"?>
<!-- createcomps_mxml/AddressForm.mxml -->
<s:Form xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="*">
    <s:FormItem label="NameField">
        <s:TextInput/>
    </s:FormItem>
    <s:FormItem label="Street">
        <s:TextInput/>
    </s:FormItem>
    <s:FormItem label="City" >
        <s:TextInput/>
    </s:FormItem>
    <s:FormItem label="State" >
        <MyComp:StateComboBox/>
    </s:FormItem>
</s:Form>
```

The following application file references the AddressForm component in the `<AddressForm>` tag:

```
<?xml version="1.0"?>
<!-- createcomps_mxml/MyApplicationAddressForm.mxml-->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="*" >
    <MyComp:AddressForm/>
</s:Application>
```

If you include child tags of the root container tag in an MXML component file, you cannot add child tags when you use the component as a custom tag in another MXML file. If you define an empty container in an MXML file, you can add child tags when you use the component as a custom tag.

***Note:** The restriction on child tags refers to the child tags that correspond to visual components. Visual components are subclasses of the UIComponent component. You can always insert tags for nonvisual components, such as ActionScript blocks, styles, effects, formatters, validators, and other types of nonvisual components, regardless of how you define your custom component.*

The following example defines an empty Form container in an MXML component:

```
<?xml version="1.0"?>
<!-- createcomps_mxml/EmptyForm.mxml -->
<s:Form xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
/>
```

This component defines no children of the Form container; therefore, you can add children when you use it in another MXML file, as the following example shows:

```
<?xml version="1.0"?>
<!-- mxml/MainEmptyForm.mxml-->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="*">
    <MyComp:EmptyForm>
        <s:FormItem label="Name">
            <s:TextInput/>
        </s:FormItem>
    </MyComp:EmptyForm>
</s:Application>
```

The AddressForm.mxml file specifies the Form container as its root tag. Because you define a container as the root tag of the MXML component, you are creating a subclass of that container, and you can reference all of the properties and methods of the root tag when using your MXML component. Therefore, in the main application, you can reference all of the properties of the Form container in the MXML tag that corresponds to your custom component, or in any ActionScript code in the main application. However, you cannot reference properties of the children of the Form container.

For example, the following example sets the `fontSize` property and a listener for the `creationComplete` event for your custom control, but you cannot specify properties for the child CheckBox or TextInput controls of the Form container:

```
<?xml version="1.0"?>
<!-- createcomps_mxml/MainEmptyFormProps.mxml-->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="*">
    <fx:Script>
        <![CDATA[
            import mx.events.FlexEvent;
            private function handleCreationCompleteEvent(event:FlexEvent):void {
                // Handle creationComplete event.
            }
        ]]>
    </fx:Script>
    <MyComp:AddressForm fontSize="15"
        creationComplete="handleCreationCompleteEvent(event);"/>
</s:Application>
```

To configure the children of a custom MXML component, you define new properties in the MXML component, and then use those new properties to pass configuration information to the component children. For more information, see “Advanced MXML components” on page 2412.

Scoping in custom components

Scoping is mostly a description of what the `this` keyword refers to at any given point in your application. In an `<fx:Script>` tag in an MXML file, the `this` keyword always refers to the current scope. In the main application file, the file that contains the `<s:Application>` tag, the current scope is the Application object; therefore, the `this` keyword refers to the Application object.

In an MXML component, Flex executes in the context of the custom component. The current scope is defined by the root tag of the file. So, the `this` keyword refers not to the Application object, but to the object defined by the root tag of the MXML file.

For more information on scoping, see “Using ActionScript” on page 32.

The root tag of an MXML component cannot contain an `id` property. Therefore, if you refer to the object defined by the root tag in the body of the component, you must use the `this` keyword, as the following example shows:

```
<?xml version="1.0"?>
<!-- createcomps_mxml/myComponents/StateComboBoxThis.mxml -->
<s:ComboBox xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    close="handleCloseEvent(event);">
    <fx:Script>
        <![CDATA[
            import flash.events.Event;
            // Define a property to hold the current index.
            public var stateIndex:Number;
            private function handleCloseEvent(eventObj:Event):void {
                stateIndex = this.selectedIndex;
            }
        ]]>
    </fx:Script>
    <s:dataProvider>
        <s:ArrayList>
            <fx:String>AK</fx:String>
            <fx:String>AL</fx:String>
        </s:ArrayList>
    </s:dataProvider>
</s:ComboBox>
```

This example defines an event listener for the ComboBox control that updates the `stateIndex` property when the ComboBox control closes.

Applying styles to your custom component

Along with skins, styles define the look and feel of your Flex applications. You can use styles to change the appearance of a single component, or apply them across all components.

When working with custom components, you have several options for how you use styles. You can define your custom components so that they contain no style information at all. That design allows the application developer who is using your component to apply styles to match the rest of their application. For example, if you define a custom component to display text, the application developer can style it to ensure that the font, font size, and font style of your component match the rest of the application.

Alternatively, you might develop a component that you want to deploy with a built-in look so that it is not necessary for application developers to apply any additional styles to it. This type of component might be useful for applications that require a header or footer with a fixed look, while the body of the application has more flexibility in its look.

Or you might develop a custom component by using a combination of these approaches. This type of design lets application developers set some styles, but not others.

For general information on Flex styles, see "Styles and themes" on page 1492. For information on creating custom styles, see "Custom style properties" on page 2501.

Applying styles from the custom component

You can choose to define styles within your MXML component so that the component has the same appearance whenever it is used, and application developers do not have to worry about applying styles to it.

In the definition of your custom component, you define styles by using one or both of the following mechanisms:

- Tag properties
- Class selectors

The following custom component defines a style by using a tag property of the ComboBox control:

```
<?xml version="1.0"?>
<!-- createcomps_mxml/myComponents/StateComboBoxWithStyleProps.mxml -->
<s:ComboBox xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"

    fontWeight="bold"
    fontSize="15">
    <s:dataProvider>
        <s:ArrayList>
            <fx:String>AK</fx:String>
            <fx:String>AL</fx:String>
        </s:ArrayList>
    </s:dataProvider>
</s:ComboBox>
```

Alternatively, you can define these styles by using a class selector style declaration, as the following example shows:

```
<?xml version="1.0"?>
<!-- createcomps_mxml/myComponents/StateComboBoxWithStyleClassSel.mxml -->
<s:ComboBox xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    styleName="myCBStyle">
    <fx:Style>
        .myCBStyle {
            fontWeight : bold;
            fontSize : 15;
            }
    </fx:Style>
    <s:dataProvider>
        <s:ArrayList>
            <fx:String>AK</fx:String>
            <fx:String>AL</fx:String>
        </s:ArrayList>
    </s:dataProvider>
</s:ComboBox>
```

***Note:** You cannot define a type selector in an MXML component. If you define a type selector, a compiler error occurs.*

Application developers can apply additional styles to the component. For example, if your component defines styles for the open duration and font size, application developers can still specify font color or other styles. The following example uses StateComboBoxWithStyleProps.mxml in an application and specifies the font color style for the control:

```
<?xml version="1.0"?>
<!-- mxml/MainStyleWithPropsAddColor.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myComponents.*">
    <MyComp:StateComboBoxWithStyleProps color="red"/>

</s:Application>
```

Applying styles from the referencing file

When you reference an MXML component, the referencing file can specify style definitions to the MXML component by using the following mechanisms:

- Tag properties
- Class selectors
- Type selectors

The styles that application developers can apply correspond to the styles supported by the root tag of the MXML component. The following example uses a tag property to set a style for the custom MXML component:

```
<?xml version="1.0"?>
<!-- createcomps_mxml/MainStyleWithPropsOverrideOpenDur.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myComponents.*">
    <MyComp:StateComboBoxWithStyleProps
        fontSize="12"/>
</s:Application>
```

When you specify styles as tag attributes, those styles override any conflicting styles set in the definition of the MXML component.

You can use a class selector to define styles. Often you use a class selector to apply styles to specific instances of a control, as the following example shows:

```
<?xml version="1.0"?>
<!-- createcomps_mxml/MainStyleOverrideUsingClassSel.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myComponents.*">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Style>
        .myStateComboBox {
            color : green;
        }
    </fx:Style>
    <MyComp:StateComboBoxWithStyleProps
        styleName="myStateComboBox"/>
    <s:ComboBox>
        <s:dataProvider>
            <s:ArrayList>
                <fx:String>AK</fx:String>
                <fx:String>AL</fx:String>
            </s:ArrayList>
        </s:dataProvider>
    </s:ComboBox>
</s:Application>
```

In this example, you use the `styleName` property in the tag definition of an MXML component to apply styles to a specific instance of the MXML component. However, those styles are not applied to the ComboBox control defined in the main application file, nor would they be applied to any other instances of StateComboBox.mxml unless you also specify the `styleName` property as part of defining those instances of the MXML component.

When you specify any styles by using a class selector, those styles override all styles that you set by using a class selector in the MXML file. Those styles do not override styles that you set by using tag properties in the MXML file.

You can also use a type selector to define styles. A type selector applies styles to all instances of a component, as the following example shows:

```
<?xml version="1.0"?>
<!-- createcomps_mxml/MainStyleOverrideUsingTypeSel.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myComponents.*">
    <fx:Style>
        @namespace "myComponents.*";
        StateComboBoxWithStyleProps {
            color : red;
        }
    </fx:Style>
    <MyComp:StateComboBoxWithStyleProps/>
</s:Application>
```

In this example, the type selector specifies the `color` style for all instances of the StateComboBox control in the application. Notice that with type selectors, you also have to include a namespace definition for the component in the `<fx:Style>` tag.

When you specify any styles by using a type selector, those styles override all styles that you set by using a class selector in the MXML file. Those styles do not override styles that you set by using tag properties in the MXML file.

Applying a type selector to the root tag of a custom component

All custom components contain a root tag that specifies the superclass of the component. In the case of StateComboBox.mxml, the root tag is `<s:ComboBox>`. If you define a type selector for the ComboBox control, or for a superclass of the ComboBox control, in your main application file, that style definition is also applied to any custom component that uses a ComboBox control as its root tag, as the following example shows:

```
<?xml version="1.0"?>
<!-- createcomps_mxml/MainStyleOverrideUsingCBTypeSel.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myComponents.*">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Style>
        @namespace s "library://ns.adobe.com/flex/spark";
        s|ComboBox {
            fontSize: 15;
            color: red;
        }
    </fx:Style>
    <MyComp:StateComboBoxWithStyleProps/>
    <s:ComboBox>
        <s:dataProvider>
            <s:ArrayList>
                <fx:String>AK</fx:String>
                <fx:String>AL</fx:String>
            </s:ArrayList>
        </s:dataProvider>
    </s:ComboBox>
</s:Application>
```

In this example, all ComboBox controls and all StateComboBox.mxml controls have a `fontSize` of 15 points and red text.

If you define a type selector for a superclass of the custom control and for the custom control itself, Flex ignores any conflicting settings from the type selector for the superclass, as the following example shows:

```
<?xml version="1.0"?>
<!-- mxml/MainStyleOverrideUsingCBTypeSelConflict.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myComponents.*">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Style>
        @namespace s "library://ns.adobe.com/flex/spark";
        @namespace "myComponents.*";
        s|ComboBox {
            color: red;
            fontSize: 15;
        }
        StateComboBoxWithStyleProps {
            color: green;
        }
    </fx:Style>
    <MyComp:StateComboBoxWithStyleProps/>
    <s:ComboBox>
        <s:dataProvider>
            <s:ArrayList>
                <fx:String>AK</fx:String>
                <fx:String>AL</fx:String>
            </s:ArrayList>
        </s:dataProvider>
    </s:ComboBox>
</s:Application>
```

In this example, the StateComboBox control uses green text, and the values for the `fontSize` style specified in the type selector for the ComboBox control.

Applying styles from a defaults.css file

Flex includes a global style sheet, named defaults.css, inside the framework.swc file in the /frameworks/libs directory. This global style sheet contains style definitions for the global class selector and type selectors for most Flex components. Flex implicitly loads the defaults.css file and applies it to all Flex applications during compilation.

One of the most common ways for you to distribute your custom MXML and ActionScript components is to create a SWC file. A SWC file is an archive file of Flex components that make it easy to exchange components among Flex developers. You need to exchange only a single file, rather than the MXML or ActionScript files, images, and other resource files. The SWF file inside a SWC file is compiled, which means that the code is hidden from casual view.

For more information about SWC files, see "Flex compilers" on page 2164 and Build projects.

A SWC file can contain a local style sheet, named defaults.css, that contains the default style settings for the custom components defined within the SWC file. When Flex compiles your application, it automatically applies the local defaults.css to the components in your SWC file. In this way, you can override the global defaults.css style sheet with the local version in your SWC file.

The only requirements on the local version are:

- You can include only a single style sheet in the SWC file.
- The file must be named defaults.css.

- The file must be in the top-most directory of the SWC file.

For example, you define a custom ComboBox control, named StateComboBox.mxml, as the following example shows:

```
<?xml version="1.0"?>
<!-- createcomps_mxml/StateComboBox.mxml -->
<s:ComboBox xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:dataProvider>
        <s:ArrayList>
            <fx:String>AK</fx:String>
            <fx:String>AL</fx:String>
            <!-- Add all other states. -->
        </s:ArrayList>
    </s:dataProvider>
</s:ComboBox>
```

Notice that this control does not define any style settings.

Then you create a defaults.css file in the same directory to define the default style settings for the custom component, as the following example shows:

```
@namespace "*";
StateComboBox
{
    arrowButtonWidth: 40;
    cornerRadius: 10;
    fontSize: "14";
    fontWeight: "bold";
    color: red;
    leading: 0;
    paddingLeft: 10;
    paddingRight: 10;
}
```

To create the SWC file, you run the compc command-line compiler from the directory that contains the defaults.css and StateComboBox.mxml files. Use the `include-file` option to specify the style sheet, as the following example shows:

```
flex_install_dir\bin\compc -source-path .
    -include-classes StateComboBox
    -include-file defaults.css defaults.css
    -o MyComponentsSWC.swc
```

This example creates a SWC file named MyComponentsSWC.swc.

***Note:** You can also use the `include-stylesheet` option to include the style sheet if the style sheet references assets that must be compiled, such as programmatic skins or other class files. For more information, see "Flex compilers" on page 2164.*

Then you write an application, named CreateCompsDefaultCSSApplication.mxml, that uses the StateComboBox control, as the following example shows:

```
<?xml version="1.0"?>
<!-- defaultCSS_app/CreateCompsDefaultCSSApplication.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="*">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <s:Label text="Custom MXML component using defaults.css from SWC file."/>
    <MyComp:StateComboBox/>

    <s:Label text="Default ComboBox control using the default defaults.css file."/>
    <s:ComboBox>
        <s:dataProvider>
            <s:ArrayList>
                <fx:String>AK</fx:String>
                <fx:String>AL</fx:String>
            </s:ArrayList>
        </s:dataProvider>
    </s:ComboBox>
</s:Application>
```

Notice that you include a namespace definition for the StateComboBox control in CreateCompsDefaultCSSApplication.mxml to reference the component. Because the MXML component is in the top-most directory of the SWC file, its package name is blank, and you reference it by using a namespace definition of `xmlns:MyComp="*"`.

To compile an application that uses MyComponentsSWC.swc, copy MyComponentsSWC.swc to the directory that contains the application. Then add the SWC file to the Library Path in Adobe® Flash® Builder™, or use the `-library-path` option to the mxmlc command-line compiler, as the following example shows:

```
flex_install_dir\bin\mxmlc
    -file-specs CreateCompsDefaultCSSApplication.mxml
    --library-path+=.
```

In the previous example, the defaults.css file and the component file were in the same directory. Typically, you place components in a directory structure, where the package name of the component reflects the directory location of the component in the SWC file.

In the next example, you put the StateComboBox.mxml file in the myComponents subdirectory of the SWC file, where the subdirectory corresponds to the package name of the component. However, defaults.css must still be in the top-level directory of the SWC file, regardless of the directory structure of the SWC file. You compile this SWC file by using the following command line:

```
flex_install_dir\bin\compc -source-path .
    -include-classes myComponents.StateComboBox
    -include-file defaults.css defaults.css
    -o MyComponentsSWC.swc
```

To use the StateComboBox.mxml component in your application, you define CreateCompsDefaultCSSApplication.mxml as the following example shows:

```
<?xml version="1.0"?>
<!-- defaultCSS_app/CreateCompsDefaultCSSApplicationSubDir.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myComponents.*">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <s:Label text="Custom MXML component using defaults.css from SWC file."/>
    <MyComp:StateComboBox/>

    <s:Label text="Default ComboBox control using the default defaults.css file."/>
    <s:ComboBox>
        <s:dataProvider>
            <s:ArrayList>
                <fx:String>AK</fx:String>
                <fx:String>AL</fx:String>
            </s:ArrayList>
        </s:dataProvider>
    </s:ComboBox>
</s:Application>
```

Notice that the namespace definition for the StateComboBox control in CreateCompsDefaultCSSApplication.mxml includes `myComponents.*` to match the directory structure, and package name, of the component in the SWC file.

You can modify and test your defaults.css file without having to recreate the SWC file by using the `-defaultscssfiles--` option to the compiler. The CSS files added by the `-defaults-css-files` option have a higher precedence than those in SWC files, so that they can override a corresponding definition in a SWC file.

When you are done modifying the defaults.css file, recreate the SWC file with the updated defaults.css file.

Advanced MXML components

One of the common goals of creating MXML components is to create configurable and reusable components. For example, you might want to create MXML components that take properties, dispatch events, define new style properties, have custom skins, or use other customizations.

For information about how to create and deploy simple MXML components, including how to apply styles and skins to your MXML components, see “Simple MXML components” on page 2399.

About reusable MXML components

One design consideration when you create custom MXML components is reusability. That is, do you want to create a component that is tightly coupled to your application, or one that is reusable in multiple applications?

A tightly coupled component is written for a specific application, and is often dependent on the application’s structure, variable names, or other details. If you change the application, you will probably need to modify the component to reflect that change, and it will also be difficult to use the component in another application without rewriting it.

Another possibility is to design a loosely coupled component for reuse. A loosely coupled component has a well-defined interface that specifies how to pass information to the component, and how the component passes back results to the application.

With loosely coupled components, you typically define properties of the component to let users pass information to it. These properties, defined by using variables or setter and getter methods, specify the data types of parameter values. For more information about defining component properties, see "Adding custom properties and methods to a component" on page 2413.

The best practice for defining components that return information to the main application is to design the component to dispatch an event that contains the return data. In that way, the main application can define an event listener to handle the event and take the appropriate action. For more information on dispatching events, see "Working with events" on page 2424.

Adding custom properties and methods to a component

MXML components provide you with a simple way to create ActionScript classes. When defining classes, you use class properties to store information and class methods to define class functionality. When creating MXML components, you can also add properties and methods to the components to make them configurable. By allowing the user to pass information to the components, you can create a reusable component that you can use in multiple locations throughout your application, or in multiple applications.

Defining properties and methods in MXML components

You can define methods for your MXML components in ActionScript, and properties in ActionScript or MXML. The Adobe Flex compiler converts the MXML component into an ActionScript class, so there is no performance difference between defining a property in MXML and defining it in ActionScript.

Defining properties and methods in ActionScript

With ActionScript, you define properties and methods by using the same syntax that you use in an ActionScript class. For more information on using ActionScript to define properties and methods, see "Custom ActionScript components" on page 2363.

When using ActionScript, you place a property or method definition within an `<fx:Script>` block. The `<fx:Script>` tag must be an immediate child tag of the root tag of the MXML file. A public variable declaration or a set function in an `<fx:Script>` tag becomes a property of the component. A public ActionScript function in an `<fx:Script>` tag becomes a method of the component.

In the following example, the component defines two data providers to populate the ComboBox control, and a function to use as the event listener for the `creationComplete` event. This function sets the data provider of the ComboBox based on the value of the `shortNames` property. By default, the `shortNames` property is set to `true`, to display two-letter names.

```
<?xml version="1.0"?>
<!-- mxmlAdvanced/myComponents/StateComboBoxPropAS.mxml -->
<s:ComboBox xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    creationComplete="setNameLength();">
    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayList;
            // Define public variables.
            public var shortNames:Boolean = true;

            // Define private variables.
            private var stateArrayShort:ArrayList = new ArrayList(["AK", "AL"]);
            private var stateArrayLong:ArrayList = new ArrayList(["Arkansas", "Alaska"]);
            // Define listener method.
            public function setNameLength():void {
                if (shortNames) {
                    dataProvider=stateArrayShort; }
                else {
                    dataProvider=stateArrayLong; }
            }
        ]]>
    </fx:Script>
</s:ComboBox>
```

The following MXML application file uses the `<MyComp:StateComboBoxPropAS>` tag to configure the control to display long state names:

```
<?xml version="1.0"?>
<!-- mxmlAdvanced/MainPropAS.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myComponents.*">
    <MyComp:StateComboBoxPropAS shortNames="true"/>

</s:Application>
```

The following example modifies the component to add a method that lets you change the display of the state name at run time. This public method takes a single argument that specifies the value of the `shortNames` property.

```
<?xml version="1.0"?>
<!-- mxmlAdvanced/myComponents/StateComboBoxPropMethod.mxml -->
<s:ComboBox xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    creationComplete="setNameLength();">
    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayList;
            // Define public variables.
            public var shortNames:Boolean = true;

            // Define private variables.
            private var stateArrayShort:ArrayList = new ArrayList(["AK", "AL"]);
            private var stateArrayLong:ArrayList = new ArrayList(["Arkansas", "Alaska"]);
            public function setNameLength():void {
                if (shortNames) {
                    this.dataProvider=stateArrayShort; }
                else {
                    this.dataProvider=stateArrayLong; }
            }

            public function setShortName(val:Boolean):void {
                shortNames=val;
                if (val) {
                    dataProvider=stateArrayShort; }
                else {
                    dataProvider=stateArrayLong; }
            }
        ]]>
    </fx:Script>
</s:ComboBox>
```

You might use this new method with the `click` event of a Button control to change the display from long names to short names, as the following example shows:

```
<?xml version="1.0"?>
<!-- mxmlAdvanced/MainPropWithMethod.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myComponents.*">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <MyComp:StateComboBoxPropMethod id="myCB"
        shortNames="false"/>
    <s:Button label="Use Short Names"
        click="myCB.setShortName(true);"/>
</s:Application>
```

Defining properties in MXML

In MXML, you can use an MXML tag to define a property of any type, as long as the type refers to an ActionScript class name. For example, you can use the `<fx:String>`, `<fx:Number>`, and `<fx:Boolean>` tags to define properties in your MXML components that take String, Number, or Boolean values, respectively. When using one of these tags, you must specify an `id`, which becomes the property name.

Optionally, you can specify an initial value in the body of the tag, or you can use the `source` property to specify the contents of an external URL or file as the initial property value. If you use the `source` property, the body of the tag must be empty. The initial value can be static data or a binding expression.

The following examples show initial properties set as static data and binding expressions. Values are set in the tag bodies and in the `source` properties.

```
<!-- Boolean property examples: -->
<fx:Boolean id="myBooleanProperty">true</fx:Boolean>
<fx:Boolean id="passwordStatus">{passwordExpired}</fx:Boolean>

<!-- Number property examples: -->
<fx:Number id="myNumberProperty">15</fx:Number>
<fx:Number id="minutes">{numHours * 60}</fx:Number>

<!-- String property examples: -->
<fx:String id="myStringProperty">Welcome, {CustomerName}.</fx:String>
<fx:String id="myStringProperty1" source="./file"/>
```

All properties defined by using the `<fx:String>`, `<fx:Number>`, and `<fx:Boolean>` tags are public. This means that the component user can access these properties.

The following example modifies the example in "Defining properties and methods in ActionScript" on page 2413 to define the `shortNames` property by using an MXML tag, rather than an ActionScript variable definition:

```
<?xml version="1.0"?>
<!-- mxmlAdvanced/myComponents/StateComboBoxPropMXML.mxml -->
<s:ComboBox xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    creationComplete="setNameLength();">
    <fx:Declarations>
        <!-- Control display of state names. -->
        <fx:Boolean id="shortNames">true</fx:Boolean>
    </fx:Declarations>
    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayList;
            // Define private variables.
            private var stateArrayShort:ArrayList = new ArrayList(["AK", "AL"]);
            private var stateArrayLong:ArrayList = new ArrayList(["Arkansas", "Alaska"]);

            // Define listener method.
            public function setNameLength():void {
                if (shortNames) {
                    dataProvider=stateArrayShort; }
                else {
                    dataProvider=stateArrayLong; }
            }
        ]]>
    </fx:Script>
</s:ComboBox>
```

In the preceding example, you implement the StateComboBox.mxml file by using the `<fx:Boolean>` tag to add a new property, `shortNames`, with a default value of `true`. This property controls whether the ComboBox control displays state names that use a two-letter format, or the entire state name.

Defining properties by using setters and getters

You can define properties for your MXML components by using setter and getter methods. The advantage of getters and setters is that they isolate the variable from direct public access so that you can perform the following tasks:

- Inspect and validate any data written to the property on a write operation
- Trigger events that are associated with the property when the property changes
- Calculate a return value on a read operation

For more information, see "Custom ActionScript components" on page 2363.

In the following example, the StateComboBoxGetSet.mxml component contains several new properties and methods:

```
<?xml version="1.0"?>
<!-- mxmlAdvanced/myComponents/StateComboBoxSetGet.mxml -->
<s:ComboBox xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayList;

            // Define private variables.
            private var stateArrayShort:ArrayList = new ArrayList(["AK", "AL"]);
            private var stateArrayLong:ArrayList = new ArrayList(["Arkansas", "Alaska"]);
            // Variable holding the display setting.
            private var __shortNames:Boolean = true;

            // Set method.
            public function set shortNames(val:Boolean):void {
                // Call method to set the dataProvider
                // based on the name length.
                __shortNames = val;
                if (__shortNames) {
                    this.dataProvider=stateArrayShort; }
                else {
                    this.dataProvider=stateArrayLong; }
            }
            // Get method.
            public function get shortNames():Boolean{
                return __shortNames;
            }
        ]]>
    </fx:Script>
</s:ComboBox>
```

In this example, you create a StateComboBoxGetSet.mxml control that takes a `shortNames` property defined by using ActionScript setter and getter methods. One advantage to using setter and getter methods to define a property is that the component can recognize changes to the property at run time. For example, you can give your users the option of displaying short state names or long state names from the application. The setter method modifies the component at run time in response to the user's selection.

You can also define events to be dispatched when a property changes. This enables you to signal the change so that an event listener can recognize the change. For more information on events, see "Working with events" on page 2424.

You can call a component's custom methods and access its properties in ActionScript just as you would any instance method or component property, as the following application shows:

```
<?xml version="1.0"?>
<!-- mxmlAdvanced/MainPropSetGet.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myComponents.*">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <MyComp:StateComboBoxSetGet id="myStateCB"
        shortNames="true"/>
    <s:Button label="Toggle Short Names"
        click="myStateCB.shortNames=!myStateCB.shortNames;"/>
</s:Application>
```

In this example, selecting the button toggles the display format of the state name between the short and long formats.

Defining inspectable properties

You should precede the variable or set function with the `[Inspectable]` metadata tag if you plan to use the component in an authoring tool such as Adobe Flash Builder™. The `[Inspectable]` metadata tag must immediately precede the property's variable declaration or the setter and getter methods to be bound to that property, as the following example shows:

```
<fx:Script>
    <![CDATA[

        // Define public variables.
        [Inspectable(defaultValue=true)]
        public var shortNames:Boolean = true;

    ]]>
</fx:Script>
```

For more information on the `[Inspectable]` metadata tag, see "Metadata tags in custom components" on page 2376.

Supporting data binding in custom properties

The Flex data binding mechanism provides a syntax for automatically copying the value of a property of one object to a property of another object at run time. The following example shows a Text control that gets its data from Slider control's `value` property. The property name inside the curly braces ({ }) is a binding expression that copies the value of the source property, `mySlider.value`, to the destination property, the Text control's `text` property, as the following example shows:

```
<mx:Slider id="mySlider"/>
<mx:Text text="{mySlider.value}"/>
```

Data binding is usually triggered whenever the value of the source property changes.

Properties that you define in your custom controls can also take advantage of data binding. You can automatically use any property defined by using an MXML tag, such as `<fx:Boolean>`, and any ActionScript property defined as a variable or defined by using setter and getter methods as the destination of a binding expression.

For example, "Defining properties by using setters and getters" on page 2417 defined the `shortNames` property of StateComboBoxGetSet.mxml by using setter and getter methods. With no modification to that component, you can use `shortNames` as the destination of a binding expression, as the following example shows:

```
<MyComp:StateComboBoxSetGet shortNames="{some_prop}"/>
```

However, you can also write your component to use the `shortNames` property as the source of a binding expression, as the following example shows for the component StateComboBoxGetSetBinding.mxml:

```
<?xml version="1.0"?>
<!-- mxmlAdvanced/MainPropSetGetBinding.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myComponents.*">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <MyComp:StateComboBoxSetGetBinding id="myStateCB"
        shortNames="false"/>

    <s:TextArea
        text="The value of shortNames is {myStateCB.shortNames}"/>
    <s:Button label="Toggle Short Names"
        click="myStateCB.shortNames=!myStateCB.shortNames;"/>
</s:Application>
```

When a property is the source of a data binding expression, any changes to the property must signal an update to the destination property. The way to signal that change is to dispatch an event, as the following example shows:

```
<?xml version="1.0"?>
<!-- mxmlAdvanced/myComponents/StateComboBoxSetGetBinding.mxml -->
<s:ComboBox xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayList;
            import flash.events.Event;
            // Define private variables.
            private var stateArrayShort:ArrayList = new ArrayList(["AK", "AL"]);
            private var stateArrayLong:ArrayList = new ArrayList(["Arkansas", "Alaska"]);
            private var __shortNames:Boolean = true;

            public function set shortNames(val:Boolean):void {
                __shortNames = val;
                if (__shortNames) {
                    dataProvider=stateArrayShort; }
                else {
                    dataProvider=stateArrayLong; }
                    // Create and dispatch event.
                    dispatchEvent(new Event("changeShortNames"));
            }
            // Include the [Bindable] metadata tag.
            [Bindable(event="changeShortNames")]
            public function get shortNames():Boolean {
                return __shortNames;
            }
        ]]>
    </fx:Script>
</s:ComboBox>
```

Use a property as the source of a data binding expression

1 Define the property as a variable, or by using setter and getter methods.

You must define a setter method and a getter method if you use the `[Bindable]` tag with the property.

2 Insert the `[Bindable]` metadata tag before the property definition, or before either the setter or getter method, and optionally specify the name of the event dispatched by the property when it changes.

If you omit the event name specification from the `[Bindable]` metadata tag, Flex automatically generates and dispatches an event named `propertyChange`. If the property value remains the same on a write, Flex does not dispatch the event or update the property.

Alternatively, you can place the `[Bindable]` metadata before a public class definition. This makes all public properties that you defined as variables, and all public properties that you defined by using both a setter and a getter method, usable as the source of a binding expression.

***Note:** When you use the `[Bindable]` metadata tag before a public class definition, it only applies to public properties; it does not apply to private or protected properties, or to properties defined in any other namespace. You must insert the `[Bindable]` metadata tag before a nonpublic property to make it usable as the source for a data binding expression.*

3 Add a call to the `dispatchEvent()` method to dispatch the event when you define the event name in the `[Bindable]` metadata tag.

For more information on using the `[Bindable]` tag, see “Bindable metadata tag” on page 2381.

Passing references to properties of MXML components

One of the ways that you can make a component reusable is to design it so that users can pass values to the component by using public properties of the component. For information on how to define properties for MXML components by using MXML and ActionScript, and how to pass values to those properties, see “Supporting data binding in custom properties” on page 2418.

Rather than passing a value to a component, you can pass a reference to it. The reference could be to the calling component, to another component, or to a property of a component.

Accessing the Application object

The Application object is the top-level object in a Flex application. Often, you must reference properties or objects of the Application object from your custom component. Use the mx.core.FlexGlobals.topLevelApplication static property to reference the application object.

You can also use the parentDocument property to reference the next object up in the document chain of a Flex application. The `parentDocument` property is inherited by all components from the UIComponent class. For an MXML component, the `parentDocument` property references the Object corresponding to the component that referenced the MXML component.

For more information on the `mx.core.FlexGlobals.topLevelApplication` static property and the `parentDocument` property, see “Application containers” on page 393.

Even if the calling file does not pass a reference to the Application object, you can always access it from your MXML component. For example, the following application contains a custom component called StateComboBoxDirectRef. In this example, StateComboBoxDirectRef is designed to write the index of the selected item in the ComboBox to the TextArea control:

```
<?xml version="1.0"?>
<!-- mxmlAdvanced/MainDirectRef.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myComponents.*">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <s:TextArea id="myTAMain"/>
    <MyComp:StateComboBoxDirectRef/>
</s:Application>
```

The simplest way to write StateComboBoxDirectRef.mxml is to use the `mx.core.FlexGlobals.topLevelApplication` static property to write the index directly to the TextArea control, as the following example shows:

```
<?xml version="1.0"?>
<!-- mxmlAdvanced/myComponents/StateComboBoxDirectRef.mxml -->
<s:ComboBox xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    close="handleCloseEvent(event);">
    <fx:Script>
        <![CDATA[

            import flash.events.Event;
            import mx.core.FlexGlobals;

            public function handleCloseEvent(eventObj:Event):void {
                mx.core.FlexGlobals.topLevelApplication.myTAMain.text=
                    String(this.selectedIndex);
            }
        ]]>
    </fx:Script>

    <s:dataProvider>
        <s:ArrayList>
            <fx:String>AK</fx:String>
            <fx:String>AL</fx:String>
        </s:ArrayList>
    </s:dataProvider>
</s:ComboBox>
```

In the previous example, you use the `close` event of the ComboBox control to write the `selectedIndex` directly to the TextArea control in the main application. You must cast the value of `selectedIndex` to a String because the `text` property of the TextArea control is of type String.

You could make the custom component slightly more reusable by using the `parentDocument` property to reference the TextArea control, rather than the `mx.core.FlexGlobals.topLevelApplication` static property. By using the `parentDocument` property, you can call the custom component from any other MXML component that contains a TextArea control named myTAMain, as the following example shows:

```
<?xml version="1.0"?>
<!-- mxmlAdvanced/myComponents/StateComboBoxDirectRefParentObj.mxml -->
<s:ComboBox xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    close="handleCloseEvent(event);">
    <fx:Script>
        <![CDATA[

            import flash.events.Event;

            public function handleCloseEvent(eventObj:Event):void {
                parentDocument.myTAMain.text=String(selectedIndex);
            }
        ]]>
    </fx:Script>

    <s:dataProvider>
        <s:ArrayList>
            <fx:String>AK</fx:String>
            <fx:String>AL</fx:String>
        </s:ArrayList>
    </s:dataProvider>
</s:ComboBox>
```

Although these examples work, they require that the TextArea control has a predefined `id` property, and that MXML component knows that `id`. In this case, the custom component is an example of a tightly coupled component. That is, the component is written for a specific application and application structure, and it is not easily reused in another application.

Passing a reference to the component

A loosely coupled component is a highly reusable component that you can easily use in different places in one application, or in different applications. To make the component from "Supporting data binding in custom properties" on page 2418 reusable, you can pass a reference to the TextArea control to the custom component, as the following example shows:

```
<?xml version="1.0"?>
<!-- mxmlAdvanced/MainPassRefToTA.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myComponents.*">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <s:TextArea id="myTAMain" />
    <MyComp:StateComboBoxPassRefToTA outputTA="{myTAMain}" />
</s:Application>
```

The custom component does not have to know anything about the main application, other than that it writes its results back to a TextArea control, as the following example shows:

```
<?xml version="1.0"?>
<!-- mxmlAdvanced/myComponents/StateComboBoxPassRefToTA.mxml -->
<s:ComboBox xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    close="handleCloseEvent(event);">
    <fx:Script>
        <![CDATA[
            import flash.events.Event;
            import spark.components.TextArea;

            // Define a variable of type mx.controls.TextArea.
            public var outputTA:TextArea;

            public function handleCloseEvent(eventObj:Event):void {
                outputTA.text=String(this.selectedIndex);
            }
        ]]>
    </fx:Script>

    <s:dataProvider>
        <s:ArrayList>
            <fx:String>AK</fx:String>
            <fx:String>AL</fx:String>
        </s:ArrayList>
    </s:dataProvider>
</s:ComboBox>
```

In this example, you use the Flex data binding syntax to pass the reference to the TextArea control to your custom component. Now, you can use StateComboBoxPassRefToTA.mxml anywhere in an application. The only requirement is that the calling component must pass a reference to a TextArea control to the component.

Passing a reference to the calling component

In “Passing a reference to the component” on page 2422, you passed a reference to a single component to the custom MXML component. This allowed the MXML component to access only a single component in the main application.

One type of reference that you can pass to your component is a reference to the calling component. With a reference to the calling component, your custom MXML file can access any properties or object in the calling component.

To pass a reference to the calling component to a custom MXML component, you create a property in the custom MXML component to represent the calling component. Then, from the calling component, you pass the reference, as the following example shows:

```
<?xml version="1.0"?>
<!-- mxmlAdvanced/CallingComponent.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myComponents.*">
    <s:layout>
        <s:VerticalLayout horizontalAlign="left"/>
    </s:layout>
    <!-- Use the caller property to pass a reference to the
        calling component to DestinationComp. -->
    <s:Label text="Enter text"/>
    <s:TextInput id="text1" text="Hello"/>
    <s:Label text="Input text automatically copied to MXML component."/>
    <MyComp:DestinationComp caller="{this}"/>
</s:Application>
```

In the definition of DestinationComp.mxml, you define the `caller` property, and specify as its data type the name of the file of the calling MXML file, as the following example shows:

```
<?xml version="1.0"?>
<!-- mxmlAdvanced/myComponents/DestinationComp.mxml -->
<s:VGroup xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Script>
        <![CDATA[
            // Define variable to reference calling file.
            [Bindable]
            public var caller:CallingComponent;
        ]]>
    </fx:Script>

    <s:TextInput id="mytext"
        text="{caller.text1.text}"/>
</s:VGroup>
```

Remember, an MXML component corresponds to an ActionScript class, where the ActionScript class name is the filename of the MXML component. Therefore, the MXML component defines a new data type. You can then create a variable whose data type is that of the calling file.

With the reference to the calling file, your MXML component can access any property of the calling file, and you can bind the value of the TextInput control in CallingComp.mxml to the TextInput control in StateComboBox.mxml. Creating a property of type CallingComp provides strong typing benefits and ensures that binding works correctly.

Working with events

Flex applications are event-driven. Events let a programmer know when the user interacts with the interface, and also when important changes happen in the appearance or life cycle of a component, such as the creation or destruction of a component or its resizing. You can handle events that your custom components generate and add your own event types to your custom components.

Handling events from simple MXML components

Simple MXML components are those that contain a single root tag that is not a container. In this topic, the StateComboBox.mxml component is a simple component because it contains a definition only for the ComboBox control.

You have two choices for handling events that a simple component dispatches: handle the events within the definition of your MXML component, or allow the file that references the component to handle them.

The following example uses the StateComboBox.mxml component, and defines the event listener for the component's `close` event in the main application:

```
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="*">

    <fx:Script>
        <![CDATA[
            import flash.events.Event;

            public function handleCloseEvent(eventObj:Event):void {
                ...
            }
        ]]>
    </fx:Script>

    <MyComp:StateComboBox rowCount="5" close="handleCloseEvent(event);"/>

</s:Application>
```

In this example, if the MXML component dispatches a `close` event, the event listener in the calling MXML file handles it.

Alternatively, you could define the event listener within the StateComboBox.mxml component, as the following example shows:

```
<?xml version="1.0"?>
<!-- StateComboBox.mxml -->
<s:ComboBox xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    close="handleCloseEvent(event);">

    <fx:Script>
        <![CDATA[

            import flash.events.Event;

            public function handleCloseEvent(eventObj:Event):void {
                ...
            }
        ]]>
    </fx:Script>

    <s:dataProvider>
        <s:ArrayList>
            <fx:String>AK</fx:String>
            <fx:String>AL</fx:String>
        </s:ArrayList>
    </s:dataProvider>
</s:ComboBox>
```

With simple MXML components, you can define event listeners in both places, and both event listeners process the event. However, the event listeners defined within the component execute before any listeners defined in the application.

Creating custom events

All MXML components can dispatch events, either those inherited by the components from their superclasses, or new events that you define within your components. When you are developing MXML components, you can add your own event types.

In this example, you define a new component called TextAreaEnabled.mxml that uses a `<s:TextArea>` tag as its root tag. This component also defines a new property called `enableTA` that users set to `true` to enable text input or to `false` to disable input.

The setter method dispatches a new event type, called `enableChanged`, when the value of the `enableTA` variable changes. The `[Event]` metadata tag identifies the event to the MXML compiler so that the file referencing the component can use the new property. For more information on using the `[Event]` metadata keyword, see “Metadata tags in custom components” on page 2376.

The syntax for the `[Event]` metadata tag is as follows:

```
<fx:Metadata>
    [Event(name="eventName", type="eventType")]
</fx:Metadata>
```

You dispatch new event types by using the `dispatchEvent()` method, as the following example shows:

```
<?xml version="1.0"?>
<!-- mxmlAdvanced/myComponents/TextAreaEnabled.mxml -->
<s:TextArea xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx" >
    <fx:Metadata>
        [Event(name="enableChanged", type="flash.events.Event")]
    </fx:Metadata>
    <fx:Script>
        <![CDATA[
            import flash.events.Event;
            // Define private variable to hold the enabled state.
            private var __enableTA:Boolean;
            // Define a setter method for the private variable.
            public function set enableTA(val:Boolean):void {
                __enableTA = val;
                enabled = val;

                // Define event object, initialize it, then dispatch it.
                dispatchEvent(new Event("enableChanged"));
            }
            // Define a getter method for the private variable.
            public function get enableTA():Boolean {
               return __enableTA;
            }
        ]]>
    </fx:Script>
</s:TextArea>
```

The following main application includes TextAreaEnabled.mxml and defines an event listener for the `enableChanged` event:

```
<?xml version="1.0"?>
<!-- mxmlAdvanced/MainTextAreaEnable.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myComponents.*">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import flash.events.Event;
            import myComponents.TextAreaEnabled;

            public function handleEnableChangeEvent(eventObj:Event):void {
                var tempTA:TextAreaEnabled =
                    eventObj.currentTarget as TextAreaEnabled;
                if (tempTA.enableTA) {
                    myButton.label="Click to disable";
                    }
                else {
                    myButton.label="Click to enable";
                    }
            }
        ]]>
    </fx:Script>
    <MyComp:TextAreaEnabled id="myTA" enableTA="false"
        enableChanged="handleEnableChangeEvent(event);" />

    <s:Button id="myButton" label="Click to enable"
        click="myTA.enableTA=!myTA.enableTA;" />
</s:Application>
```

If you do not use the `[Event]` metadata tag in the custom component file to define the `enableChanged` event, the MXML compiler generates an error message when you reference the event name in an MXML file. Any component can register an event listener for the event in ActionScript using the `addEventListener()` method, even if you omit the `[Event]` metadata tag.

You can also create and dispatch events that use an event object of a type other than that defined by the Event class. For example, you might want to create an event object that contains new properties so that you can pass those properties back to the referencing file. To do so, you create a subclass of the Event class to define your new event object. For information on creating custom event classes, see “Custom events” on page 2369.

Handling events from composite components

Composite components are components that use a container for the root tag, and define child components in that container. You handle events generated by the root container in the same way as you handle events generated by simple MXML components. That is, you can handle the event within the MXML component, within the referencing file, or both. For more information, see “Handling events from simple MXML components” on page 2425.

To handle an event that a child of the root container dispatches, you can handle it in the MXML component in the same way as you handle an event from the root container. However, if a child component of the root container dispatches an event, and you want that event to be dispatched to the referencing file, you must add logic to your custom component to propagate the event.

For example, you can define a component that uses an `<mx:Form>` tag as the root tag, and include within it a ComboBox control. Any event that the Form container dispatches, such a `scroll` event, is dispatched to the referencing file of the custom component. However, the `close` event of the ComboBox control is dispatched only within the custom MXML component.

To propagate the `close` event outside of the custom component, you define an event listener for it in the MXML component that redispatches it, as the following example shows:

```
<?xml version="1.0"?>
<!-- mxmlAdvanced/myComponents/AddressForm.mxml -->
<s:Form xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:local="*">
    <fx:Metadata>
        [Event(name="close", type="flash.events.Event")]
    </fx:Metadata>
    <fx:Script>
        <![CDATA[
            import flash.events.Event;
            // Redispatch event.
            private function handleCloseEventInternal(eventObj:Event):void {
                dispatchEvent(eventObj);
            }
        ]]>
    </fx:Script>
    <s:FormItem label="Name">
        <s:TextInput id="name1" />
    </s:FormItem>
    <s:FormItem label="Street">
        <s:TextInput id="street" />
    </s:FormItem>
    <s:FormItem label="City" >
        <s:TextInput id="city" />
    </s:FormItem>
    <s:FormItem label="State" >
        <s:ComboBox close="handleCloseEventInternal(event);">
            <s:dataProvider>
                <s:ArrayList>
                    <fx:String>AK</fx:String>
                    <fx:String>AL</fx:String>
                </s:ArrayList>
            </s:dataProvider>
        </s:ComboBox>
    </s:FormItem>
</s:Form>
```

In this example, you propagate the event to the calling file. You could, alternatively, create an event type and new event object as part the propagation. For more information on the `[Event]` metadata tag, see “Metadata tags in custom components” on page 2376.

You can handle the `close` event in your main application, as the following example shows:

```
<?xml version="1.0"?>
<!-- mxmlAdvanced/MainAddressFormHandleEvent.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myComponents.*"
    height="600">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[

            import flash.events.Event;

            private function handleCloseEvent(eventObj:Event):void {
                myTAClose.text=eventObj.type;
            }
            private function handleMouseDown(eventObj:Event):void {
                myTA.text=eventObj.type;
            }
        ]]>
    </fx:Script>
    <s:TextArea id="myTA" />
    <s:TextArea id="myTAClose" />
    <MyComp:AddressForm mouseDown="handleMouseDown(event);"
        close="handleCloseEvent(event);"/>
</s:Application>
```

About interfaces

Interfaces are a type of class that you design to act as an outline for your components. When you write an interface, you provide only the names of public methods rather than any implementation. For example, if you define two methods in an interface and then implement that interface, the implementing class must provide implementations of those two methods.

Interfaces in ActionScript can declare methods and properties only by using setter and getter methods; they cannot specify constants. The benefit of interfaces is that you can define a contract that all classes that implement that interface must follow. Also, if your class implements an interface, instances of that class can also be cast to that interface.

Custom MXML components can implement interfaces just as other ActionScript classes can. To do this, you use the `implements` attribute. All MXML tags support this attribute.

The following code is an example of a simple interface that declares several methods:

```
// The following is in a file named SuperBox.as.
interface SuperBox {
    function selectSuperItem():String;
    function removeSuperItem():Boolean;
    function addSuperItem():Boolean;
}
```

A class that implements the SuperBox interface uses the `implements` attribute to point to its interface and must provide an implementation of the methods. The following example of a custom ComboBox component implements the SuperBox interface:

```
<?xml version="1.0"?>
<!-- StateComboBox.mxml -->
<s:ComboBox xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    implements="SuperBox">
    <fx:Script>
        <![CDATA[
            public function selectSuperItem():String {
                return "Super Item was selected";
            }
            public function removeSuperItem():Boolean {
                return true;
            }
            public function addSuperItem():Boolean {
                return true;
            }
        ]]>
    </fx:Script>
    <s:dataProvider>
        <s:ArrayList>
            <fx:String>AK</fx:String>
            <fx:String>AL</fx:String>
        </s:ArrayList>
    </s:dataProvider>
</s:ComboBox>
```

You can implement multiple interfaces by separating them with commas, as the following example shows:

```
<s:ComboBox ... implements="SuperBox, SuperBorder, SuperData">
```

All methods that you declare in an interface are considered public. If you define an interface and then implement that interface, but do not implement all of its methods, the MXML compiler throws an error.

Methods that are implemented in the custom component must have the same return type as their corresponding methods in the interface. If no return type is specified in the interface, the implementing methods can declare any return type.

About implementing IMXMLObject

You cannot define a constructor for an MXML component. If you do, the Flex compiler issues an error message that specifies that you defined a duplicate function.

For many types of Flex components, you can use an event listener instead of a constructor. For example, depending on what you want to do, you can write an event listener for the `preinitialize`, `initialize`, or `creationComplete` event to replace the constructor.

These events are all defined by the UIComponent class, and inherited by all of its subclasses. If you create an MXML component that is not a subclass of UIComponent, you cannot take advantage of these events. You can instead implement the IMXMLObject interface in your MXML component, and then implement the `IMXMLObject.initialized()` method, as the following example shows:

```
<?xml version="1.0"?>
<!-- mxmlAdvanced/myComponents/ObjectComp.mxml -->
<fx:Object xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    implements="mx.core.IMXMLObject">
    <fx:Script>
        <![CDATA[

            // Implement the IMXMLObject.initialized() method.
            public function initialized(document:Object, id:String):void {
                trace("initialized, x = " + x);
            }
        ]]>
    </fx:Script>
    <fx:Declarations>
        <fx:Number id="y"/>
        <fx:Number id="z"/>
        <fx:Number id="x"/>
    </fx:Declarations>
</fx:Object>
```

Flex calls the `IMXMLObject.initialized()` method after it initializes the properties of the component. The following example uses this component:

```
<?xml version="1.0"?>
<!-- mxmlAdvanced/MainInitObject.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myComponents.*"
    creationComplete="initApp();">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            public function initApp():void {
                myTA.text="myFC.x = " + String(myFC.x);
            }
        ]]>
    </fx:Script>
    <fx:Declarations>
        <MyComp:ObjectComp id="myFC" x="1" y="2" z="3"/>
    </fx:Declarations>
    <s:TextArea id="myTA"/>
</s:Application>
```

Because Flex calls the `IMXMLObject.initialized()` method after it initializes the properties of the component, the `trace()` function in the implementation of the `IMXMLObject.initialized()` method outputs the following:

```
initialized, x = 1
```

Create simple visual components in ActionScript

You define custom ActionScript components to extend the Adobe® Flex® component library. For example, you can create a customized Button, Tree, or DataGrid component as an ActionScript component.

For information on creating advanced components in ActionScript, see “Create advanced Spark visual components in ActionScript” on page 2451 and “Create advanced MX visual components in ActionScript” on page 2475.

About ActionScript components

You create reusable components by using ActionScript, and reference these components in your Flex applications as MXML tags. Components created in ActionScript can contain graphical elements, define custom business logic, or extend existing Flex components.

Flex components are implemented as a class hierarchy in ActionScript. Each component in your application is an instance of an ActionScript class. All Flex visual components are derived from the ActionScript UIComponent class. To create your own components, you can create a subclass from the UIComponent class or from any of its subclasses. For a complete description of the class hierarchy, see the ActionScript 3.0 Reference for the Adobe Flash Platform.

The class you choose to use as the superclass of your custom component depends on what you are trying to accomplish. For example, you might require a custom button control. You could create a subclass of the UIComponent class, and then recreate all of the functionality built into the Flex Button class. A better and faster way to create your custom button component is to create a subclass of the Flex Button class, and then modify it in your custom class.

Simple components are subclasses of existing Flex components that modify the behavior of the component, or add new functionality to it. For example, you might add a new event type to a Button control, or modify the default styles or skins of a DataGrid control.

You can also create advanced ActionScript components. Advanced ActionScript components might have one of the following requirements:

- Modify the appearance of a control or the layout functionality of a container
- Encapsulate one or more components into a composite component
- Subclass UIComponent to create components

For information on creating advanced ActionScript components, see “Create advanced MX visual components in ActionScript” on page 2475.

Example: Creating a simple component

When you define a simple component, you do not create a component yourself, but instead modify the behavior of an existing component. In this section, you create a customized TextArea control by extending the spark.components.TextArea component. This component adds an event listener for the keyDown event to the TextArea control. The `KeyDown` event deletes all the text in the control when a user presses the Control+Alt+Z key combination.

```
package myComponents
{
    // createcomps_as/myComponents/DeleteTextArea.as
    import spark.components.TextArea;
    import flash.events.KeyboardEvent;

    public class DeleteTextArea extends TextArea {

        // Constructor
        public function DeleteTextArea() {
            // Call super().
            super();
            // Add event listener for keyDown event.
            addEventListener("keyDown", myKeyDown);
        }
        // Define private keyDown event handler.
        private function myKeyDown(eventObj:KeyboardEvent):void {
            // Check to see if Ctrl+Alt+Z pressed. Keycode is 90.
            if (eventObj.ctrlKey && eventObj.keyCode == 90)
                text = "";
        }
    }
}
```

The filename for this component is DeleteTextArea.as, and its location is the myComponents subdirectory of the application, as specified by the `package` statement. For more information on using the `package` statement and specifying the directory location of your components, see "Custom ActionScript components" on page 2363.

You can now use your new TextArea control in an application, as the following example shows:

```
<?xml version="1.0"?>
<!-- createcomps_as/MainDeleteTextArea.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myComponents.*">

    <MyComp:DeleteTextArea/>
</s:Application>
```

Note: *Your class must be specified as* `public` *for you to be able to access it by using an MXML tag.*

In this example, you first define the `MyComp` namespace to specify the location of your custom component. You then reference the component as an MXML tag by using the namespace prefix.

You can specify any inherited properties of the superclass in MXML, as the following example shows:

```
<?xml version="1.0"?>
<!-- createcomps_as/MainDeleteTextAreaProps.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myComponents.*">

    <MyComp:DeleteTextArea
        maxChars="50"
        text="My Message"/>
</s:Application>
```

You do not have to change the name of your custom component when you create a subclass of a Flex class. In the previous example, you could have named your custom component TextArea, and written it to the TextArea.as file in the myComponents directory, as the following example shows:

```
package myComponents
{
    import spark.components.TextArea;
    import flash.events.KeyboardEvent;

    public class TextArea extends TextArea {
        ...
    }
}
```

You can now use your custom TextArea control, and the standard TextArea control, in an application. To differentiate between the two controls, you use the namespace prefix, as the following example shows:

```
<?xml version="1.0"?>
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myComponents.*" >
    <MyComp:TextArea/>
    <s:TextArea/>
</s:Application>
```

Adding properties and methods to a component

To make your custom components reusable, you design them so that users can pass information to them. You do this by adding public properties and methods to your components, and by making the components accessible in MXML.

Defining public properties in ActionScript

You can use one of the following methods to add public properties to your ActionScript components:

- Define public variables
- Define public getter and setter methods

Accessing public properties in MXML

All public properties defined in your component are accessible in MXML by using MXML tag properties. For example, you might allow the user to pass a value to your component, as the following example shows:

```
<MyComp:MyCustomComponent prop1="3"/>
```

To create a component that takes tag attributes in MXML, you define a public variable with the same name as the tag attribute in your class definition:

```
public class MyCustomComponent extends TextArea {

    // Define an uninitialized variable.
    public var prop1:Number;

    // Define and initialize a variable.
    public var prop2:Number=5;
    ...
}
```

You can also use public getter and setter methods to define a property, as the following example shows:

```
public class MyCustomComponent extends TextArea {

    private var _prop1:Number;

    public function get prop1():Number {
        // Method body.
        // Typically the last line returns the value of the private variable.
        return _prop1;
    }

    public function set prop1(value:Number):void {
        // Typically sets the private variable to the argument.
        _prop1=value;
        // Define any other logic, such as dispatching an event.
    }
}
```

You can define and initialize a private variable, as the following example shows:

```
private var _prop2:Number=5;
```

When you specify a value to the property in MXML, Flex automatically calls the setter method. If you do not set the property in MXML, Flex sets it to its initial value, if you specified one, or to the type's default value, which is `NaN` for a variable of type Number.

Defining public properties as variables

In the following example, you use the Control+Alt+I key combination to extend the TextArea control to let the user increase the font size by one point, or use the Control+Alt+M key combination to decrease the font size by one point:

```
package myComponents
{
    // createcomps_as/myComponents/TextAreaFontControl.as
    import spark.components.TextArea;
    import flash.events.KeyboardEvent;
    import flash.events.Event;

    public class TextAreaFontControl extends TextArea
    {
        // Constructor
        public function TextAreaFontControl() {
            super();
            // Add event listeners.
            addEventListener("keyDown", myKeyDown);
            addEventListener("creationComplete", myCreationComplete);
        }
        // Define private var for current font size.
        private var currentFontSize:Number;
        // Define a public property for the minimum font size.
        public var minFontSize:Number = 5;
        // Define a public property for the maximum font size.
        public var maxFontSize:Number = 15;

        // Initialization event handler for getting default font size.
        private function myCreationComplete(eventObj:Event):void {
            // Get current font size
```

```
             currentFontSize = getStyle('fontSize');
        }
        // keyDown event handler.
        private function myKeyDown(eventObj:KeyboardEvent):void {
            // Was Ctrl key pressed?
            if (eventObj.ctrlKey)
            {
                switch (eventObj.keyCode) {
                    // Was Ctrl+Alt+I pressed?
                    case 73 :
                        if (currentFontSize < maxFontSize) {
                            currentFontSize = currentFontSize + 1;
                            setStyle('fontSize', currentFontSize);
                        }
                        break;
                    // Was Ctrl+Alt+ pressed?
                    case 77 :
                        if (currentFontSize > minFontSize) {
                            currentFontSize = currentFontSize - 1;
                            setStyle('fontSize', currentFontSize);
                        }
                        break;
                    default :
                        break;
                }
            }
        }
    }
}
```

Notice that the call to the `getStyle()` method is in the event listener for the `creationComplete` event. You must wait until component creation is complete before calling `getStyle()` to ensure that Flex has set all inherited styles. However, you can call `setStyle()` in the component constructor to set styles.

This example uses variables to define public properties to control the maximum font size, `maxFontSize`, and minimum font size, `minFontSize`, of the control. Users can set these properties in MXML, as the following example shows:

```
<?xml version="1.0"?>
<!-- createcomps_as/MainTextAreaFontControl.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myComponents.*">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <MyComp:TextAreaFontControl id="myTAFS"
        minFontSize="8"
        maxFontSize="50"/>

    <s:Button
        label="Get Font Size"
        click="myTA.text=String(myTAFS.getStyle('fontSize'));"/>
    <s:TextArea id="myTA"/>
</s:Application>
```

Defining public properties by using getter and setter methods

There are no restrictions on using public variables to define public properties, However, Adobe recommends that you use getter and setter methods so that you can control user interaction with your component, as described in “Defining properties as getters and setters” on page 2367.

The following example code defines a component named TextAreaFontControlGetSet that replaces the public property definition for the `maxFontSize` property shown in “Defining public properties as variables” on page 2436:

```
package myComponents
{
    // createcomps_as/myComponents/TextAreaFontControlGetSet.as
    import spark.components.TextArea;
    import flash.events.KeyboardEvent;
    import flash.events.Event;

    public class TextAreaFontControlGetSet extends TextArea
    {
        public function TextAreaFontControlGetSet()
        {
            super();
            addEventListener("keyDown", myKeyDown);
            addEventListener("creationComplete", myCreationComplete);
        }
        private var currentFontSize:Number;
        public var minFontSize:Number = 5;
        // Define private variable for maxFontSize.
        private var _maxFontSize:Number = 15;

        // Define public getter method.
        public function get maxFontSize():Number {
            return _maxFontSize;
        }

        // Define public setter method.
        public function set maxFontSize(value:Number):void {
            if (value <= 30) {
                _maxFontSize = value;
            } else _maxFontSize = 30;
        }

        private function myCreationComplete(eventObj:Event):void {
            // Get current font size
             currentFontSize = getStyle('fontSize');
        }
        // keyDown event handler.
        private function myKeyDown(eventObj:KeyboardEvent):void {
            // Was Ctrl key pressed?
            if (eventObj.ctrlKey)
            {
                switch (eventObj.keyCode) {
                    // Was Ctrl+Alt+I pressed?
                    case 73 :
                        if (currentFontSize < maxFontSize) {
                            currentFontSize = currentFontSize + 1;
                            setStyle('fontSize', currentFontSize);
                        }
                        break;
                    // Was Ctrl+Alt+M pressed?
                    case 77 :
                        if (currentFontSize > minFontSize) {
                            currentFontSize = currentFontSize - 1;
                            setStyle('fontSize', currentFontSize);
                        }
                        break;
                    default :
                        break;
                }
            }
        }
    }
}
```

In this example, the setter method checks that the specified font size is less than the predefined limit of 30 pixels. If the font size is greater than the limit, it sets it to the limit.

Creating a default property

You can define a default property for your ActionScript components by using the `[DefaultProperty]` metadata tag. You can then use the default property in MXML as the child tag of the component tag without specifying the property name. For more information on using the default property, including an example, see "Defining public properties as variables" on page 2436.

You can use the `[DefaultProperty]` metadata tag in your ActionScript component to define a single default property, as the following example shows:

```
package myComponents
{
    // createcomps_as/myComponents/TextAreaDefaultProp.as
    import spark.components.TextArea;
    // Define the default property.
    [DefaultProperty("defaultText")]
    public class TextAreaDefaultProp extends TextArea {

        public function TextAreaDefaultProp()
        {
            super();
        }
        // Define a setter method to set the text property
        // to the value of the default property.
        public function set defaultText(value:String):void {
            if (value!=null)
            text=value;
        }
        public function get defaultText():String {
            return text;
        }
    }
}
```

In this example, you add a new property to the TextArea control, called `defaultText`, and specify it as the default property of the control. The setter method for `defaultText` just sets the value of the `text` property of the control. You can then use the default property in MXML, as the following example shows:

```
<?xml version="1.0"?>
<!-- createcomps_as/MainTextAreaDefaultProp.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myComponents.*">

    <MyComp:TextAreaDefaultProp>Hello</MyComp:TextAreaDefaultProp>
</s:Application>
```

The one place where Flex prohibits the use of a default property is when you use the ActionScript class as the root tag of an MXML component. In this situation, you must use child tags to define the property, as the following example shows:

```
<?xml version="1.0"?>
<!-- as/myComponents/TextAreaDefaultPropMXML.mxml -->
<MyComp:TextAreaDefaultProp xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myComponents.*">
        <MyComp:defaultText>Hello</MyComp:defaultText>

</MyComp:TextAreaDefaultProp>
```

Making properties accessible in Flash Builder

You can make your property definitions accessible in Adobe Flex Builder by adding the `[Inspectable]` metadata tag to the property definition. For example, if you are using Flash Builder, you can insert the `[Inspectable]` metadata tag to define the property as user-editable (or *inspectable*), as the following example shows:

```
[Inspectable]
var prop1:Number;
```

You can also use the `[Inspectable]` metadata tag with setter and getter methods. For more information, see "Metadata tags in custom components" on page 2376.

Using data binding with custom properties

Data binding defines a syntax for automatically copying the value of a property of one object, the *source* property, to a property of another object, the *destination* property, at run time. Data binding is usually triggered when the value of the source property changes.

The following example shows a Text control that gets its data from a HSlider control's `value` property. The property name inside the curly braces ({ }) specifies a binding expression that copies the value of the source property, `mySlider.value`, into the destination property, the Text control's `text` property.

```
<mx:HSlider id="mySlider"/>
<mx:Text text="{mySlider.value}"/>
```

The current value of the HSlider control appears in the Text control when you stop moving the slider. To get continuous updates as you move the slider, set the `HSlider.liveDragging` property to `true`.

Using properties as the destination of a binding expression

Properties in your custom components can take advantage of data binding. Any property defined as a variable or defined by using a setter and getter method can automatically be used as the destination of a binding expression.

For example, in the section "Defining public properties in ActionScript" on page 2435, you created a class with the public property `maxFontSize`. You can use the `maxFontSize` property as the destination of a binding expression, as the following example shows:

```
<?xml version="1.0"?>
<!-- createcomps_as/MainTextAreaFontControlBindingDest.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myComponents.*" >
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <MyComp:TextAreaFontControl id="myTA"
        maxFontSize="{Number(myTI.text)}"/>
    <s:Label text="Enter max font size."/>
    <s:TextInput id="myTI" text="25"/>
</s:Application>
```

In this example, any value that the user enters into the TextInput control is automatically copied to the `maxFontSize` property.

Using properties as the source of a data binding expression

When a property is the source of a data binding expression, Flex automatically copies the value of the source property to any destination property when the source property changes. However, in order to signal to Flex to perform the copy, you must register the property with Flex and the source property must dispatch an event.

To register a property as a source for data bindings, you use the `[Bindable]` metadata tag. You can use this tag in three places:

- Before a class definition, in order to make all public properties defined as variables usable as the source of a binding expression. You can also do this by using setter and getter methods, in which case you use the `[Bindable]` tag before the getter method.
- Before a property that a variable defines, in order to make that specific property support binding
- Before a getter method for a property implemented by using setter and getter methods

Note: *When you use the* `[Bindable]` *metadata tag before a public class definition, it applies only to public properties; it does not apply to private or protected properties, or to properties defined in any other namespace. You must insert the* `[Bindable]` *metadata tag before a nonpublic property to make it usable as the source for a data binding expression.*

For more information on the `[Bindable]` metadata tag, see "Metadata tags in custom components" on page 2376.

The following example modifies the component in the section "Defining public properties in ActionScript" on page 2435 to make the `maxFontSize` and `minFontSize` properties usable as the source for data bindings:

```
    // Define public properties for tracking font size.
    [Bindable]
    public var maxFontSize:Number = 15;
    [Bindable]
    public var minFontSize:Number = 5;
```

If you omit the event name from the `[Bindable]` metadata tag, Flex automatically dispatches an event named `propertyChange` when the property changes to trigger the data binding. If the property value remains the same on a write operation, Flex does not dispatch the event or update the property.

When you define a property by using getter and setter methods so that the property is usable as the source for data binding, you include the `[Bindable]` metadata tag before the getter method, and optionally include the name of the event dispatched by the setter method when the property changes, as the following example shows:

```
package myComponents
{
    // createcomps_as/myComponents/TextAreaFontControlBinding.as
    import spark.components.TextArea;
    import flash.events.KeyboardEvent;
    import flash.events.Event;

    public class TextAreaFontControlBinding extends TextArea
    {
        public function TextAreaFontControlBinding()
        {
            super();
            addEventListener("keyDown", myKeyDown);
            addEventListener("creationComplete", myCreationComplete);
        }
        private var currentFontSize:Number;
        public var minFontSize:Number = 5;
        // Define private variable for maxFontSize.
        public var _maxFontSize:Number = 15;

        // Define public getter method, mark the property
        // as usable for the source of data binding,
        // and specify the name of the binding event.
        [Bindable("maxFontSizeChanged")]
        public function get maxFontSize():Number {
            return _maxFontSize;
        }
        // Define public setter method.
        public function set maxFontSize(value:Number):void {
            if (value <= 30) {
                _maxFontSize = value;
            } else _maxFontSize = 30;
            // Dispatch the event to trigger data binding.
            dispatchEvent(new Event("maxFontSizeChanged"));
        }

        private function myCreationComplete(eventObj:Event):void {
            // Get current font size
             currentFontSize = getStyle('fontSize');
        }
        // keyDown event handler.
        private function myKeyDown(eventObj:KeyboardEvent):void {
            // Was Ctrl key pressed?
            if (eventObj.ctrlKey)
            {
                switch (eventObj.keyCode) {
                    // Was Ctrl+Alt+I pressed?
                    case 73 :
                        if (currentFontSize < maxFontSize) {
                            currentFontSize = currentFontSize + 1;
                            setStyle('fontSize', currentFontSize);
                        }
                        break;
                    // Was Ctrl+Alt+M pressed?
                    case 77 :
                        if (currentFontSize > minFontSize) {
                            currentFontSize = currentFontSize - 1;
                            setStyle('fontSize', currentFontSize);
                        }
                        break;
                    default :
                        break;
                }
            }
        }

    }
}
```

In this example, the setter updates the value of the property, and then dispatches an event to trigger an update of any data binding destination. The name of the event is not restricted. You can use this component in an application, as the following example shows:

```
<?xml version="1.0"?>
<!-- createcomps_as/MainTextAreaFontControlBindingSource.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myComponents.*">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <MyComp:TextAreaFontControlBinding id="myTA"
        maxFontSize="{Number(myTI.text)}"/>
    <s:Label text="Enter max font size."/>
    <s:TextInput id="myTI" text="15"/>

    <s:Label text="Current max font size."/>
    <s:TextArea text="{String(myTA.maxFontSize)}"/>
</s:Application>
```

Defining a method override

You can override a method of a base class in your ActionScript component. To override the method, you add a method with the same signature to your class, and prefix it with the `override` keyword. The following example overrides the `HGroup.addElement()` method to open an Alert box when a new item is added to it:

```
package myComponents
{
    // createcomps_as/myComponents/HGroupWithAlert.as
    import mx.controls.Alert;
    import spark.components.HGroup;
    import mx.core.IVisualElement;
    public class HGroupWithAlert extends HGroup
    {
        // Define the constructor.
        public function HGroupWithAlert() {
            super();
        }
      // Define the override.
      override public function addElement(child:IVisualElement):IVisualElement {

            // Call super.addChild().
            super.addElement(child);

            // Open the Alert box.
            Alert.show("Item added successfully");
            return child;
        }
    }
}
```

Notice that the method implementation calls the `super.addElement()` method. The call to `super.addElement()` causes Flex to invoke the superclass's `addElement()` method to perform the operation. Your new functionality to open the Alert box occurs after the `super.addElement()` method.

You might have to use `super()` to call the base class method before your code, after your code, or not at all. The location is determined by your requirements. To add functionality to the method, you call `super()` before your code. To replace the base class method, you do not call `super()` at all.

The following example uses this component in an application:

```
<?xml version="1.0"?>
<!-- createcomps_as/MainHBoxWithAlert.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myComponents.*">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import spark.components.Button;
            public function addButton():void {
                var myButton:Button = new Button();
                myButton.label = "New Button";
                myHGroup.addElement(myButton);
            }
        ]]>
    </fx:Script>
    <MyComp:HGroupWithAlert id="myHGroup"/>
    <s:Button label="Add Button"
        click="addButton();"/>
</s:Application>
```

Initializing inherited properties with tag attributes in MXML

In an MXML component, you can initialize the value of any inherited public, writable property by defining a child tag of the MXML component with an `id` property that matches the name of the inherited property. For example, you define a custom Panel component based on the Flex Panel container, named MyPanel.as, as the following example shows:

```
package myComponents
{
    // createcomps_as/myComponents/MyPanel.as
    import spark.components.Panel;
    import spark.components.TextInput;
    public class MyPanel extends Panel {
        // Define public variables for two child components.
        public var myInput:TextInput;
        public var myOutput:TextInput;
        public function MyPanel() {
            super();
        }
        // Copy the text from one child component to another.
        public function xfer():void {
            myOutput.text = myInput.text;
        }
    }
}
```

In this example, the MyPanel component defines two variables corresponding to TextInput controls. You then create a custom MXML component, named MyPanelComponent.mxml, based on MyPanel.as, as the following example shows:

```
<?xml version="1.0"?>
<!-- createcomps_as/myComponents/MyPanelComponent.mxml -->
<MyComps:MyPanel xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComps="myComponents.*">
    <MyComps:layout>
        <s:VerticalLayout/>
    </MyComps:layout>
      <s:TextInput id="myInput"/>
      <s:TextInput id="myOutput"/>
</MyComps:MyPanel>
```

Notice that the value of the `id` property for the two TextInput controls matches the variable names of the properties defined in the MyPanel component. Therefore, Flex initializes the inherited properties with the TextInput controls that you defined in MXML. This technique for initializing properties can be referred to as *code behind*.

You can use your custom component in the following Flex application:

```
<?xml version="1.0"?>
<!-- createcomps_as/MainCodeBehindExample.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComps="myComponents.*">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
   <MyComps:MyPanelComponent id="myP"/>
   <s:Button label="Copy" click="myP.xfer();"/>
</s:Application>
```

If the value of the `id` property of a TextInput control does not match an inherited property name, Flex creates a property of the component, where the `id` property defines the name of the new property.

To support initialization from MXML, an inherited property must have the following characteristics:

- The inherited property must be public.

  If you try to initialize a nonpublic inherited property, the Flex compiler issues an error.

- The inherited property must be writable.

  If you try to initialize a constant, or a property defined by a getter method without a corresponding setter method, the Flex compiler issues an error.

- The data type of the value that you specify to the inherited property must by compatible with the data type of the property.

  If you try to initialize a property with a value of an incompatible data type, the Flex compiler issues an error.

Defining events in ActionScript components

Flex components dispatch their own events and listen to other events. An object that wants to know about another object's events registers as a listener with that object. When an event occurs, the object dispatches the event to all registered listeners.

The core class of the Flex architecture, mx.core.UIComponent, defines core events, such as updateComplete, `resize`, `move`, `creationComplete`, and others that are fundamental to all components. Subclasses of these classes inherit and dispatch these events.

Custom components that extend existing Flex classes inherit all the events of the superclass. If you extend the Button class to create the MyButton class, you can use the events inherited from the Button class, such as `mouseOver` or `creationComplete`, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- createcomps_as/MainMyButtonAS.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myComponents.*">

    <fx:Script>
        <![CDATA[

            import flash.events.Event;

            private function handleClick(eventObj:Event):void {
                // Define event listener.
            }

            private function handleCreationComplete(eventObj:Event):void {
                // Define event listener.
            }

        ]]>
    </fx:Script>

    <MyComp:MyButton
        click="handleClick(event);"
        creationComplete="handleCreationComplete(event);"/>
</s:Application>
```

Your custom components can also define new events based on the requirements of your components. For example, the section “Using data binding with custom properties” on page 2440 showed how to define a custom event so that properties of your component can work with the Flex data binding mechanism.

Handling predefined events within the custom component

The previous example showed a custom component, MyButton, dispatching two events. In that example, you defined the event listeners in the main application file.

Your custom component can also define event listeners within the component itself to handle the events internally. For example, “Defining public properties as variables” on page 2436 defined event listeners for the `keyDown` and `creationComplete` events within the body of the component. This allows the component to handle those events internally.

***Note:** Even though you define event listeners for the events in the component itself, your application can also register listeners for those events. The event listeners defined within the component execute before any listeners defined in the application.*

The example used the `creationComplete` event to access the default `fontSize` property of the component. You could not access this property in the constructor itself because Flex does not define it until after the component is created. For more information on the initialization order of a component, see "Create advanced MX visual components in ActionScript" on page 2475.

Dispatching custom events

Your ActionScript component can define custom events and use the predefined events. You use custom events to support data binding, to respond to user interactions, or to trigger actions by your component. For an example that uses events to support data binding, see "Using data binding with custom properties" on page 2440.

For each custom event dispatched by your component, you must do the following:

1. Create an Event object describing the event.
2. (Optional) Use the `[Event]` metadata tag to make the event public so that other components can listen for it.
3. Dispatch the event by using the dispatchEvent() method.

To add information to the event object, you define a subclass of the flash.events.Event class to represent the event object. For more information on creating custom event classes, see "Custom events" on page 2369.

You might define some custom events that are used internally by your component, and are not intended to be recognized by the other components. For example, the following component defines a custom event, dispatches it, and handles it all within the component:

```
package myComponents
{
    // createcomps_as/myComponents/ModalTextEvent.as
    import spark.components.TextArea;
    import flash.events.Event;
    [Event(name="enableChanged", type="flash.events.Event")]
    public class ModalTextEvent extends TextArea {
        public function ModalTextEvent() {
            super();

            // Register event listener.
            addEventListener("enableChanged", enableChangedListener);
        }
        public function enableInput(value:Boolean):void {
            // Method body.

            // Dispatch event.
            dispatchEvent(new Event("enableChanged"));
        }
        private function enableChangedListener(eventObj:Event):void {
            // Handle event.
        }
    }
}
```

In this example, the public method `enableInput()` lets the user enable or disable input to the control. When you call the `enableInput()` method, the component uses the `dispatchEvent()` method to dispatch the `enableChanged` event. The `dispatchEvent()` method has the following signature:

```
dispatchEvent(eventObj)
```

The *eventObj* argument is the event object that describes the event.

If you want an MXML component to be able to register a listener for the event, you must make the event known to the Flex compiler by using the [Event] metadata tag. For each public event that your custom component dispatches, you add an [Event] metadata keyword before the class definition that defines that event, as the following example shows:

```
[Event(name="enableChanged", type="flash.events.Event")]
public class ModalTextEvent extends TextArea {
    ...
}
```

If you do not identify an event in the class file with the [Event] metadata tag, the compiler generates an error when an MXML component attempts to register a listener for that event. Any component can register an event listener for the event in ActionScript using the addEventListener() method, even if you omit the [Event] metadata tag.

You can then handle the event in MXML, as the following example shows:

```
<?xml version="1.0"?>
<!-- as/ASMainModalTextEvent.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComps="myComponents.*">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import flash.events.Event;
            private function handleEnableChanged(event:Event):void {
                myTA.text="Got Event";
            }
        ]]>
    </fx:Script>
    <MyComps:ModalTextEvent id="myMT"
        enableChanged="handleEnableChanged(event);"/>

    <s:Button click="myMT.enableInput(true);"/>
    <s:TextArea id="myTA"/>
</s:Application>
```

Applying styles to custom components

Style properties define the look of a component, from the size of the fonts used to the color of the background. Your custom ActionScript components inherit all of the styles of the base class, so you can set them in the same way as for that base class.

To change style properties in custom components, use the setStyle() method in the component's constructor. This applies the same style to all instances of the component, but users of the component can override the settings of the setStyle() method in MXML tags. Any style properties that are not set in the component's class file are inherited from the component's superclass.

The following ActionScript class file sets the color and fontWeight styles of the BlueButton control:

```
package myComponents
{
    // createcomps_as/myComponents/BlueButton.as
    import spark.components.Button;
    public class BlueButton extends Button
    {

        public function BlueButton() {
            super();
            // Set the label text to blue.
            setStyle("color", 0x0000FF);
            // Set the borderColor to blue.
            setStyle("fontWeight", "bold");
        }
    }
}
```

The following MXML file uses the BlueButton control with the default `color` and `fontWeight` styles set in your component's class file:

```
<?xml version="1.0"?>
<!-- createcomps_as/ASMainBlueButton.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComps="myComponents.*">
    <MyComps:BlueButton label="Submit"/>

</s:Application>
```

Setting the styles in a constructor does not prevent users of the component from changing the style. For example, the user could still set their own value for the `color` style, as the following example shows:

```
<?xml version="1.0"?>
<!-- as/MainBlueButtonRed.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComps="myComponents.*">
    <MyComps:BlueButton label="Submit" color="0xFF0000"/>

</s:Application>
```

In addition to setting the `color` property, you can set the font face, font size, and other style properties. For more information on the available style properties, see the parent control's class information.

You can also define new style properties for your components. For more information, see "Custom style properties" on page 2501.

Applying styles from a defaults.css file

If you package your component in a SWC file, you can define a global style sheet, named defaults.css, in the SWC file. The defaults.css file defines the default style settings for all of the components defined in the SWC file.

For more information, see "Applying styles from a defaults.css file" on page 2409.

Create advanced Spark visual components in ActionScript

You can create advanced visual components for use in applications built in Adobe® Flex®. Advanced visual components override methods of the UIComponent or SkinnableComponent base classes.

About creating advanced Spark components

Simple visual components are subclasses of existing Flex components that modify the appearance of the component by using skins or styles, or add new functionality to the component. For example, you add a new event type to a Button control, or modify the default styles or skins of a DataGrid control. For more information, see "Create simple visual components in ActionScript" on page 2433.

In advanced components, you typically perform the following actions:

- Modify the basic functionality or logic of an existing component.
- Create a composite component that encapsulates two or more components within it.
- Create a skinnable component by creating a subclass of the SkinnableComponent class.

  A skinnable component uses two files: one for the component definition and one for the skin definition. Create a Spark skinnable component as a subclass of the SkinnableComponent class.
- Create a nonskinnable component by creating a subclass of the UIComponent or other nonskinnable Spark class.

  A nonskinnable component is defined by a single file. Create a nonskinnable component as a subclass of the UIComponent class. You can also create one from a Spark class that does not have the SkinnableComponent class in its class hierarchy, such a Group or DataGroup.

This topic contains several examples of Spark ActionScript components. For more examples, examine the source code for the Spark components in your Flex installation directory. The spark.components and spark.components.supportClasses packages contain many of the Spark components mentioned in this topic.

Spark skinnable components and skin classes

When creating an skinnable Spark component in ActionScript, you create two classes: the component class and the skin class.

The component class defines the core behavior of the component. This behavior includes defining the events dispatched by the component, the data that the component represents, the skin parts implemented by the skin class, and the view states that the skin class supports.

The skin class manages the visual appearance of the component and creates visual subcomponents. The skin class defines the default layout of the component, its default size, the supported view states, graphics, and data representation.

About overriding protected UIComponent methods for Spark components

All Flex visual components are subclasses of the UIComponent class. Therefore, visual components inherit the methods, properties, events, styles, and effects defined by the UIComponent class.

To create an advanced visual component, you must implement a class constructor. Also, you optionally override one or more of the following protected methods of the UIComponent class:

UIComponent method	Description
`commitProperties()`	Commits any changes to component properties, either to make the changes occur at the same time or to ensure that properties are set in a specific order. For more information, see "Implementing the commitProperties() method for Spark components" on page 2458.
`createChildren()`	Creates any child components of the component. For example, the Halo ComboBox control contains a Halo TextInput control and a Halo Button control as child components. Typically, you do not implement this method in a Spark component because any child components are defined in the skin class. This topic does not describe how to implement the `createChildren()` method. For more information, see the example for creating a Halo component in "Implementing the createChildren() method for MX components" on page 2482.
`measure()`	Sets the default size and default minimum size of the component. You typically do not have to implement this method for Spark components. The default size of a Spark component is defined by the skin class, and by the children of the skin class. You also set the minimum and maximum sizes of the component in the root tag of the skin class. This topic does not describe how to implement the `measure()` method. For more information, see the example for creating a MX components in "Implementing the measure() method for MX components" on page 2485.
`updateDisplayList()`	Sizes and positions the children of the component on the screen based on all previous property and style settings, and draws any skins or graphic elements used by the component. The parent container for the component determines the size of the component itself. Typically, you do not have to implement this method for Spark components. A few Spark components, such as spark.components.supportClasses.SkinnableComponent, do implement it. The SkinnableComponent class implements it to pass sizing information to the component's skin class. This topic does not describe how to implement the `updateDisplayList()` method. For more information, see the example for creating a Halo component in "Implementing the updateDisplayList() method for MX components" on page 2489.

Component users do not call these methods directly; Flex calls them as part of the initialization process of creating a component, or when other method calls occur. For more information, see "About the component instantiation life cycle for MX components" on page 2477.

About overriding SkinnableComponent methods for Spark components

All Spark skinnable components are subclasses of the SkinnableComponent class. Therefore, skinnable components inherit the methods, properties, events, styles, and effects defined by the SkinnableComponent class.

To create an skinnable Spark component, you optionally override one or more of the following methods of the SkinnableComponent class:

SkinnableComponent method	Description

`attachSkin()`
`detachSkin()`
	Called automatically by the `commitProperties()` method when a skin is added, `attachSkin()`, or a skin is removed, `detachSkin()`. You can optionally implement these methods to add a specific behavior to a skin.
	Typically you do not implement these methods.

`partAdded()`
`partRemoved()`
	Called automatically when a skin part is added or removed. You typically override `partAdded()` to attach event handlers to the skin part, configure the skin part, or perform other actions when a skin part is added. Implement the `partRemoved()` method to remove the even handlers added in `partAdded()`.
	For more information, see "Implementing the partAdded() and partRemoved() methods for skinnable components for Spark components" on page 2462.

`getCurrentSkinState()`	Called automatically by the `commitProperties()` method to set the view state of the skin class. For more information, see "Implementing the getCurrentSkinState() method for skinnable components for Spark components" on page 2463.

Component users do not call these methods directly; Flex calls them as part of the initialization process of creating a component, or when other method calls occur. For more information, see "About the component instantiation life cycle for MX components" on page 2477.

About the invalidation methods for Spark components

During the lifetime of a component, your application might modify the component by changing its size or position, modifying a property that controls its display, or modifying a style or skin property of the component. For example, you might change the font size of the text displayed in a component. As part of changing the font size, the component's size might also change, which requires Flex to update the layout of the application. The layout operation might require Flex to invoke the `commitProperties()`, `measure()`, `getCurrentSkinState()`, and the `updateDisplayList()` methods of your component.

Your application can programmatically change the font size of a component much faster than Flex can update the layout of an application. Therefore, you only want to update the layout after you are sure that you've determined the final value of the font size.

In another scenario, when you set multiple properties of a component, such as the `label` and `icon` properties of a Button control, you want the `commitProperties()`, `measure()`, `getCurrentSkinState()`, and `updateDisplayList()` methods to execute only once, after all properties are set. You do not want these methods to execute when you set the `label` property, and then execute again when you set the `icon` property.

Also, several components might change their font size at the same time. Rather than updating the application layout after each component changes its font size, you want Flex to coordinate the layout operation to eliminate any redundant processing.

Flex uses an invalidation mechanism to synchronize modifications to components. Flex implements the invalidation mechanism as a set of methods that you call to signal that something about the component has changed and requires Flex to call the component's `commitProperties()`, `measure()`, `getCurrentSkinState()`, or `updateDisplayList()` methods.

The following table describes the invalidation methods:

Invalidation method	**Description**
`invalidateDisplayList()`	Marks a component so that its `updateDisplayList()` method gets called during the next screen update.
`invalidateProperties()`	Marks a component so that its `commitProperties()` method gets called during the next screen update.
`invalidateSize()`	Marks a component so that its `measure()` method gets called during the next screen update.
`invalidateSkinState()`	Marks a component so that its `commitProperties()` method gets called on the next screen update to change the view state of the skin class. The `commitProperties()` method calls the `getCurrentSkinState()` method.

When a component calls an invalidation method, it signals to Flex that the component must be updated. When multiple components call invalidation methods, Flex coordinates updates so that they all occur together during the next screen update.

Typically, component users do not call the invalidation methods directly. Instead, they are called by the component's setter methods, or by any other methods of a component class as necessary. For more information and examples, see "Implementing the commitProperties() method for MX components" on page 2483.

About the Spark component instantiation life cycle

The component instantiation life cycle describes the sequence of steps that occur when you create a component object from a component class. As part of that life cycle, Flex automatically calls component methods, dispatches events, and makes the component visible.

The following example creates a Button control in ActionScript and adds it to a Group container:

```
// Create a Group container.
var groupContainer:Group = new Group();
// Configure the Group container.
groupContainer.x = 10;
groupContainer.y = 10;

// Create a Button control.
var b:Button = new Button()
// Configure the button control.
b.label = "Submit";
...
// Add the Button control to the Box container.
groupContainer.addElement(b);
```

The following steps show what occurs when you execute the code to create the Button control, and add the control to the container:

1 You call the component's constructor, as the following code shows:

```
// Create a Button control.
var b:Button = new Button()
```

2 You configure the component by setting its properties, as the following code shows:

```
// Configure the button control.
b.label = "Submit";
```

Component setter methods might call the `invalidateProperties()`, `invalidateSize()`, `invalidateSkinState()`, or `invalidateDisplayList()` methods.

3 You call the `addElement()` method to add the component to its parent, as the following code shows:

```
// Add the Button control to the Box container.
gropContainer.addElement(b);
```

Flex then performs the following actions:

4 Sets the `parent` property for the component to reference its parent container.

5 Computes the style settings for the component.

6 Dispatches the `preinitialize` event on the component.

7 Calls the component's `createChildren()` method. For skinnable components, this causes a call to `attachSkin()`, which calls `partAdded()`, for all static parts defined in the skin file.

8 Calls the `invalidateProperties()`, `invalidateSize()`, `invalidateSkinSate()`, and `invalidateDisplayList()` methods to trigger calls to the `commitProperties()`, `measure()`, `getCurrentSkinState()`, or `updateDisplayList()` methods during the next `render` event.

The only exception to this rule is that Flex does not call the `measure()` method when the user sets the height and width of the component.

9 Dispatches the `initialize` event on the component. At this time, all of the component's children are initialized, but the component has not been sized or processed for layout. You can use this event to perform additional processing of the component before it is laid out.

Because the `initialize` event is dispatched early in the component's startup sequence, make sure that none of your processing causes the component to invalidate itself. You typically perform any final processing during the `creationComplete` event.

10 Dispatches the `elementAdd` event on the parent container.

11 Dispatches the `initialize` event on the parent container.

12 During the next `render` event, Flex performs the following actions:

a Calls the component's `commitProperties()` method. For skinnable components, the `commitProperties()` method calls the `getCurrentSkinState()` methods.

b Calls the component's `measure()` method.

c Calls the component's `updateDisplayList()` method.

13 Flex dispatches additional `render` events if the `commitProperties()`, `measure()`, or `updateDisplayList()` methods call the `invalidateProperties()`, `invalidateSize()`, `invalidateSkinSate()`, or `invalidateDisplayList()` methods.

14 After the last `render` event occurs, Flex performs the following actions:

a Makes the component visible by setting the `visible` property to `true`.

b Dispatches the `creationComplete` event on the component. The component is sized and processed for layout. This event is only dispatched once when the component is created.

c Dispatches the `updateComplete` event on the component. Flex dispatches additional `updateComplete` events whenever the layout, position, size, or other visual characteristic of the component changes and the component is updated for display.

Most of the work for configuring a component occurs when you add the component to a container by using the `addElement()` method. That is because until you add the component to a container, Flex cannot determine its size, set inheriting style properties, or draw it on the screen.

You can also define your application in MXML, as the following example shows:

```
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:Group>
        <s:Button label="Submit"/>
    </s:Group>
</s:Application>
```

The sequence of steps that Flex executes when creating a component in MXML are equivalent to the steps described for ActionScript.

You can remove a component from a container by using the `removeElement()` method. If there are no references to the component, it is eventually deleted from memory by the garbage collection mechanism of Adobe® Flash® Player or Adobe® AIR™.

About the steps for creating a Spark component

When you implement a component, you override component methods, define new properties, dispatch new events, or perform any other customizations required by your application.

To implement your component, follow these general steps:

1 Create the skin class for the component. You typically create the skin class in MXML. For more information on skins, see "Spark Skinning" on page 1602.

2 Create the component's ActionScript class file.

   a For a skinnable component, extend one of the base classes, such as SkinnableComponent, or a subclass of class SkinnableComponent. For a nonskinnable component, extend UIComponent or a Spark class that does not have SkinnableComponent in it class hierarchy.

   b Implement the constructor.

   c Implement the UIComponent.createChildren() method. You rarely have to implement this method for Spark components.

   d Implement the UIComponent.commitProperties() method.

   e Implement the UIComponent.measure() method. You rarely have to implement this method for Spark components.

   f Implement the UIComponent.updateDisplayList() method. You rarely have to implement this method for Spark components.

   g For a skinnable component, implement the SkinnableComponent.partAdded() and SkinnableComponent.partRemoved() methods.

   h For a skinnable component, implement the SkinnableComponent.getCurrentSkinState() method.

   i Add properties, methods, styles, events, and metadata.

3 Deploy the component as an ActionScript file or as a SWC file.

For more information about MXML tag properties and embedding graphic and skin files, see "Create simple visual components in ActionScript" on page 2433.

You do not have to override all component methods to define a new component. You only override the methods required to implement the functionality of your component. If you create a subclass of an existing component, such as Button, you implement only the methods necessary for you to add any new functionality to the component.

About interfaces

Flex uses interfaces to divide the basic functionality of components into discrete elements so that they can be implemented piece by piece. For example, to make your component focusable, it must implement the IFocusManagerComponent interface; to let it participate in the layout process, it must implement ILayoutClient interface.

To simplify the use of interfaces, the UIComponent class implements all of the interfaces defined in the following table, except for the IFocusManagerComponent interface. However, many subclasses of UIComponent implement the IFocusManagerComponent interface.

Therefore, if you create a subclass of the UIComponent class or subclass of UIComponent, such as SkinnableComponent, you do not have to implement these interfaces. But, if you create a component that is not a subclass of UIComponent, and you want to use that component in Flex, you might have to implement one or more of these interfaces.

The following table lists the main interfaces implemented by Flex components:

Interface	Use
IAdvancedStyleClient	Indicates that the component supports the advanced style subsystem.
IAutomationObject	Indicates that a component is an object within the automation object hierarchy.
IChildList	Indicates the number of children in a container.
IConstraintClient	Indicates that the component support layout constraints.
IDeferredInstantiationUIComponent	Indicates that a component or object can effect deferred instantiation.
IFlexDisplayObject	Specifies the interface for skin elements.
IFlexModule	indicates that the component can be used with module factories
IFocusManagerComponent	Indicates that a component or object is focusable, which means that the components can receive focus from the FocusManager. The UIComponent class does not implement IFocusable because some components are not intended to receive focus.
IInvalidating	Indicates that a component or object can use the invalidation mechanism to perform delayed, rather than immediate, property commitment, measurement, and drawing or layout.
ILayoutManagerClient	Indicates that a component or object can participate in the LayoutManager's commit, measure, and update sequence.
IPropertyChangeNotifier	Indicates that a component supports a specialized form of event propagation.
IStateClient	Indicates that the component supports view states.
IToolTipManagerClient	Indicates that a component has a `toolTip` property, and therefore is monitored by the ToolTipManager.
IUIComponent	Defines the basic set of APIs that you must implement in order to be a child of layout containers and lists.
IValidatorListener	Indicates that a component can listen for validation events, and therefore show a validation state, such as a red border and error tooltips.
IVisualElement	Indicates that the component can be laid out and displayed in a Spark application.

Implementing a Spark component

When you create a custom component in ActionScript, you have to override the methods of UIComponent and, if the component is skinnable, of SkinnableComponent.

Basic component structure

The following example shows the basic structure of a skinnable Spark component:

```
package myComponents
{
    public class MyComponent extends SkinnableComponent
    {
        ....
    }
}
```

You must define your ActionScript custom components within a package. The package reflects the directory location of your component within the directory structure of your application.

The class definition of your component must be prefixed by the `public` keyword. A file that contains a class definition can have one, and only one, public class definition, although it can have additional internal class definitions. Place any internal class definitions at the bottom of your source file below the closing curly brace of the package definition.

Implementing the constructor

Your ActionScript class should define a public constructor method for a class that is a subclass of the UIComponent class, or a subclass of any child of the UIComponent class. The constructor has the following characteristics:

- No return type
- Declared public
- No arguments
- Calls the `super()` method to invoke the superclass' constructor

Each class can contain only one constructor method; ActionScript does not support overloaded constructor methods. For more information, see "Defining the constructor" on page 2366.

Use the constructor to set the initial values of class properties. For example, you can set default values for properties and styles, or initialize data structures, such as Arrays. You can also set the `skinClass` style to the name of your skin class.

Do not create child display objects in the constructor; you should use it only for setting initial properties of the component. If your component creates child components, create them in the skin class.

Implementing the commitProperties() method for Spark components

You use the commitProperties() method to coordinate modifications to component properties. Most often, you use it with properties that affect how a component appears on the screen.

Flex schedules a call to the `commitProperties()` method when a call to the `invalidateProperties()` method occurs. The `commitProperties()` method executes during the next `render` event after a call to the `invalidateProperties()` method. When you use the `addElement()` method to add a component to a container, Flex automatically calls the `invalidateProperties()` method.

The typical pattern for defining component properties is to define the properties by using getter and setter methods, as the following example shows:

```
// Define a private variable for the alignText property.
private var _alignText:String = "right";

// Define a flag to indicate when the _alignText property changes.
private var bAlignTextChanged:Boolean = false;

// Define getter and setter methods for the property.
public function get alignText():String {
        return _alignText;
}

public function set alignText(t:String):void {
    _alignText = t;
    bAlignTextChanged = true;

    // Trigger the commitProperties(), measure() method.
    invalidateProperties();
    invalidateSize();
}

// Implement the commitProperties() method.
override protected function commitProperties():void {
    super.commitProperties();

    // Check whether the flag indicates a change to the alignText property.
    if (bAlignTextChanged) {
        // Reset flag.
        bAlignTextChanged = false;

        // Handle alignment change
        ...

        // If necessary, call invalidateDisplayList() to update the display.
        invalidateDisplayList();
    }
}
```

As you can see in this example, the setter method modifies the property, calls the `invalidateProperties()` method, and then returns. The setter itself does not perform any calculations based on the new property value. This design lets the setter method return quickly, and leaves any processing of the new value to the `commitProperties()` method.

The `commitProperties()` method in the previous example process the changes to the property, then calls the `invalidateDisplay()` method to cause the component to update its display. The call to the `invalidateDisplay()` method is only necessary if the component has to update its display based on the property change.

The main advantages of using the `commitProperties()` method are the following:

- To coordinate the modifications of multiple properties so that the modifications occur synchronously.

  For example, you might define multiple properties that control the text displayed by the component, such as the alignment of the text within the component. A change to either the text or the alignment property requires Flex to update the appearance of the component. However, if you modify both the text and the alignment, you want Flex to perform any calculations for sizing or positioning the component once, when the screen updates.

  Therefore, you use the `commitProperties()` method to calculate any values based on the relationship of multiple component properties. By coordinating the property changes in the `commitProperties()` method, you can reduce unnecessary processing overhead.

- To coordinate the sequence that you set properties.

  Some properties may have to be set in a particular sequence. In the `commitProperties()` method, determine which properties are being modified, and, if necessary, set them in the proper order.

- To coordinate multiple modifications to the same property.

  You do not necessarily want to perform a complex calculation every time a user updates a component property. For example, users modify the `icon` property of the Button control to change the image displayed in the button. Calculating the label position based on the presence or size of an icon can be a computationally expensive operation that you want to perform only when necessary.

  To avoid this behavior, you use the `commitProperties()` method to perform the calculations. Flex calls the `commitProperties()` method when it updates the display. That means you perform the calculations once when Flex updates the screen, regardless of the number of times the property changed between screen updates.

The following example shows how you can handle two related properties in the `commitProperties()` method:

```
// Define a private variable for the text property.
private var _text:String = "ModalText";
private var bTextChanged:Boolean = false;

// Define the getter method.
public function get text():String {
        return _text;
}

//Define the setter method to call invalidateProperties()
// when the property changes.
public function set text(t:String):void {
    _text = t;
    bTextChanged = true;
    invalidateProperties();
}

// Define a private variable for the alignText property.
private var _alignText:String = "right";
private var bAlignTextChanged:Boolean = false;

public function get alignText():String {
        return _alignText;
}

public function set alignText(t:String):void {
    _alignText = t;
    bAlignTextChanged = true;
    invalidateProperties();
    invalidateSize();
}

// Implement the commitProperties() method.
override protected function commitProperties():void {
    super.commitProperties();

    // Check whether the flags indicate a change to both properties.
    if (bTextChanged && bAlignTextChanged) {
        // Reset flags.
        bTextChanged = false;
        bAlignTextChanged = false;

        // If necessary, update the dispaly.
        invalidateDisplayList();
    }

    // Check whether the flag indicates a change to the text property.
    if (bTextChanged) {
        // Reset flag.
        bTextChanged = false;

        // If necessary, update the dispaly.
        invalidateDisplayList();
    }

    // Check whether the flag indicates a change to the alignText property.
    if (bAlignTextChanged) {
        // Reset flag.
        bAlignTextChanged = false;

        // If necessary, update the dispaly.
        invalidateDisplayList();
    }
}
```

Implementing the updateDisplayList() method for Spark components

The updateDisplayList() method sizes and positions parts of the component based on all previous property and style settings. The parent container for the component determines the size of the component itself. You rarely have to implement this method for Spark components.

A component does not appear on the screen until its `updateDisplayList()` method gets called. Flex schedules a call to the `updateDisplayList()` method when a call to the `invalidateDisplayList()` method occurs. The `updateDisplayList()` method executes during the next `render` event after a call to the `invalidateDisplayList()` method. When you use the `addElement()` method to add a component to a container, Flex automatically calls the `invalidateDisplayList()` method.

In general, all visual aspects of a Spark component are controlled by the skin class. But, there are times when the component must participate in the visual display. The only time a Spark component implements the `updateDisplayList()` method is when the component has view-specific knowledge that it must control. For example, the slider thumb of the Spark HSlider and VSlider controls is positioned by the `updateDisplayList()` method.

Make sure to perform as much visual display as possible in the skin. For example, the `updateDisplayList()` method of the HSlider component only sets the x position of the slider thumb. The skin class sets the y position.

The main uses of the `updateDisplayList()` method are the following:

- To set the size and position of the elements of the component for display.

  Many components are made up of one or more child components, or have properties that control the display of information in the component.

  To size components in the `updateDisplayList()` method, you use the `setActualSize()` method, not the sizing properties, such as `width` and `height`. To position a component, use the `move()` method, not the `x` and `y` properties.

- To draw any visual elements necessary for the component.

Components support many types of visual elements such as graphics, styles, and borders. Within the `updateDisplayList()` method, you can add these visual elements, use the Flash drawing APIs, and perform additional control over the visual display of your component.

The `updateDisplayList()` method has the following signature:

```
protected function updateDisplayList(unscaledWidth:Number,
    unscaledHeight:Number):void
```

The properties have the following values:

unscaledWidth Specifies the width of the component, in pixels, in the component's coordinates, regardless of the value of the `scaleX` property of the component. This is the width of the component as determined by its parent container.

unscaledHeight Specifies the height of the component, in pixels, in the component's coordinates, regardless of the value of the `scaleY` property of the component. This is the height of the component as determined by its parent container.

Scaling occurs in Flash Player or AIR, after `updateDisplayList()` executes. For example, a component with an `unscaledHeight` value of 100, and with a `scaleY` property of 2.0, appears 200 pixels high in Flash Player or AIR.

Implementing the partAdded() and partRemoved() methods for skinnable components for Spark components

Some skinnable components are composed of one or more subcomponents. For example, a NumericStepper component contains a subcomponent for an up button, a down button, and a text area.

The component class is responsible for controlling the behavior of the subcomponents. The skin class is responsible for defining the subcomponents, including the appearance of the component, its subcomponents, and any other visual aspects of the component.

Flex clearly defines the relationship between the component class and the skin class. The component class must do the following:

- Identify the skin parts that it expects with the `[SkinPart]` metadata tag. The skin parts are implemented in the skin file. For more information on using the `[SkinPart]` metadata tag, see "SkinPart metadata tag" on page 2389.
- Identify the view states that the component supports with the `[SkinStates]` metadata tag. For more information on the `[SkinState]` metadata tag, see "SkinState metadata tag" on page 2390.
- Use CSS styles to associate the skin class with the component.

The skin class must do the following:

- Specify the component name with the `[HostComponent]` metadata tag. While the `[HostComponent]` metadata tag is not required, it is strongly recommended. For more information on the `[HostComponent]` metadata tag, see "HostComponent metadata tag" on page 2385.
- Declare the view states, and define their appearance.
- Define the appearance of the skin parts. The skin parts must use the same name as the corresponding skin-part property in the component.

Flex calls the `partAdded()` and `partRemoved()` methods automatically when a skin is created or destroyed. You typically override the `partAdded()` method to attach event handlers to a skin part, configure a skin part, or perform other actions when a skin part is added. You implement the `partRemoved()` method to remove the even handlers added in `partAdded()`.

In the component class, define skin parts as properties. In the following example, the component defines two required skin parts:

```
// Define the skin parts.
[SkinPart(required="true")]
public var modeButton:Button;

[SkinPart(required="true")]
public var textInput:RichEditableText;
```

The first skin part defines a Button control, and the second defines a RichEditableText control. While the skin parts are defined as properties of the component, component users do not directly modify them. The skin class defines their implementation and appearance. For more information on defining skin parts, see "Skin parts" on page 1615.

In your implementation of the `partAdded()` method, you first use `super` to invoke the `partAdded()` method of the base class. Then, determine the skin part that was added, and configure it. Use the property name of the skin part to reference it. In this example, you set properties on the skin part and add event listeners to it:

```
override protected function partAdded(partName:String, instance:Object):void {
    super.partAdded(partName, instance);

    if (instance == textInput) {
        textInput.editable = false;
        textInput.text= _text;
        textInput.addEventListener("change", modeButton_clickHandler);
    }

    if (instance == modeButton) {
        modeButton.label = "Toggle Editing Mode";
        modeButton.addEventListener("click", modeButton_changeHandler);
    }
}
```

In your implementation of the `partRemoved()` method, use `super` to invoke the `partRemoved()` method of the base class. You can then remove the event listeners added by the `partAdded()` method:

```
override protected function partRemoved(partName:String, instance:Object):void {
    super.partRemoved(partName, instance);

    if (instance == textInput) {
        textInput.removeEventListener("change", modeButton_clickHandler);
    }

    if (instance == modeButton) {
        modeButton.removeEventListener("click", modeButton_changeHandler);
    }
}
```

Implementing the getCurrentSkinState() method for skinnable components for Spark components

A component must identify the view states that its skin supports. Use the `[SkinState]` metadata tag to define the view states in the component class. This tag has the following syntax:

```
[SkinState("stateName")]
```

Specify the metadata before the class definition. For more information on the `[SkinState]` metadata tag, see "SkinState metadata tag" on page 2390.

The following example defines two view states for the component named ModalTextStates:

```
[SkinState("normal")]
[SkinState("textLeft")]
public class ModalTextStates extends SkinnableComponent
{
    ...
```

The component's skin class then define these view states, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<s:SparkSkin xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    minWidth="100" minHeight="25">

    <s:states>
        <s:State name="normal" />
        <s:State name="textLeft"/>
    </s:states>
    ...
```

In your component, implement the `getCurrentSkinState()` method to set the view state of the skin class. Flex calls the `getCurrentSkinState()` method automatically from the `commitProperties()` method.

The `getCurrentSkinState()` method takes no arguments, and returns a String identifying the view state of the skin. You can use information in the class to determine the new view state. In the following example, you examine the `_textPlacement` property of the component to determine the view state of the skin:

```
override protected function getCurrentSkinState():String {
    var returnState:String = "normal";

    // Use information in the class to determine the new view state of the skin class.
    if (_textPlacement == "left") {
        returnState = "textLeft";
    }
    return returnState;
}
```

Adding version numbers

When releasing components, you can define a version number. This lets developers know whether they should upgrade, and helps with technical support issues. When you set a component's version number, use the static variable `version`, as the following example shows:

```
static var version:String = "1.0.0.42";
```

***Note:** Flex does not use or interpret the value of the* `version` *property.*

If you create many components as part of a component package, you can include the version number in an external file. That way, you update the version number in only one place. For example, the following code imports the contents of an external file that stores the version number in one place:

```
include "../myPackage/ComponentVersion.as"
```

The contents of the ComponentVersion.as file are identical to the previous variable declaration, as the following example shows:

```
static var version:String = "1.0.0.42";
```

Best practices when designing a component

Use the following practices when you design a component:

- Keep the file size as small as possible.
- Make your component as reusable as possible by generalizing functionality.
- Assume an initial state. Because style properties are on the object, you can set initial settings for styles and properties so your initialization code does not have to set them when the object is constructed, unless the user overrides the default state.

Example: Creating a skinnable Spark component

Composite components are components that contain multiple subcomponents. They might be graphical assets or a combination of graphical assets and component classes. For example, you can create a component that includes as subcomponents a button, rich text field, and a border graphic. Or, you can create a component that includes a text field and a validator.

When you create composite components, you define the subcomponents inside the component's skin class. You must plan the layout of the subcomponents that you are including, and set properties such as default values in the skin class.

Properties of the individual subcomponents are not directly accessible in MXML. For example, if you create a component that extends the SkinnableComponent class and uses a Button and a RichEditableText component as subcomponents, you cannot set the Button control's `label` property in MXML.

Instead, you can define a myLabel property on the custom component that is exposed in MXML. When the user sets the myLabel property, your custom component can set that property on the Button.

Creating the ModalText component

This example component, called ModalText and defined in the file ModalText.as, combines a Button control and a RichEditableText component. You use the Button control to enable or disable text input in the RichEditableText component.

This control has the following attributes:

- By default, you cannot edit the RichEditableText component.
- Click the Button control to toggle editing of the RichEditableText component.
- Use the `ModalText.text` property to programmatically write content to the RichEditableText component.
- Editing the text in the RichEditableText component dispatches the `change` event.
- Use the `text` property as the source for a data binding expression.

The following is an example MXML file that uses the ModalText control:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- asAdvancedSpark/SparkMainModalText.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myComponents.*">

    <MyComp:ModalText/>

</s:Application>
```

Component users cannot directly access the properties of the Button and RichEditableText subcomponents. However, they can use descendant selectors to set the styles on the subcomponents, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- asAdvancedSpark/SparkMainModalTextStyled.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myComponents.*">

    <fx:Style>
        @namespace MyComp "myComponents.*";
        @namespace s "library://ns.adobe.com/flex/spark";
        MyComp|ModalText s|Button {
            chromeColor: #663366;
            color: #9999CC;
        }
    </fx:Style>

    <MyComp:ModalText/>

</s:Application>
```

In this example, you use descendent selectors to set the set the `chromeColor` and `color` styles of the Button subcomponent. For more information, see “Using Cascading Style Sheets” on page 1504.

Defining event listeners for composite components

Subcomponents can dispatch events. The main component can either handle the events internally, or propagate the event so that a component user can handle them.

Custom components implement the `partAdded()` method to create children of the component, as the following example shows:

```
override protected function partAdded(partName:String, instance:Object):void {
    super.partAdded(partName, instance);
    if (instance == textInput) {
        textInput.editable = false;
        textInput.text= _text;
        textInput.addEventListener("change", textInput_changeHandler);
    }
    if (instance == modeButton) {
        modeButton.label = "Toggle Editing Mode";
        modeButton.addEventListener("click", modeButton_changeHandler);
    }
}
```

The `partAdded()` method contains a call to the `addEventListener()` method to register an event listener for the `change` event generated by the RichEditableText subcomponent, and for the `click` event for the Button subcomponent. These event listeners are defined within the ModalText class, as the following example shows:

```
// Handle events for a change to RichEditableText.text property.
private function textInput_changeHandler(eventObj:Event):void {
        dispatchEvent(new Event("change"));
}

// Handle the click event for the Button subcomponent.
private function modeButton_changeHandler(eventObj:Event):void {
        text_mc.editable = !text_mc.editable;
}
```

You can handle an event dispatched by a child of a composite component in the component. In this example, the event listener for the Button subcomponent's `click` event is defined in the class definition to toggle the `editable` property of the RichEditableText subcomponent.

However, if a child component dispatches an event, and you want that opportunity to handle the event outside of the component, you must add logic to your custom component to propagate the event. Notice that the event listener for the `change` event for the RichEditableText subcomponent propagates the event. This lets you handle the event in your application, as the following example shows:

```
<?xml version="1.0"?>
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:MyComp="myComponents.*">

    <fx:Script>
        <![CDATA[

            import flash.events.Event;

            function handleText(eventObj:Event)
            {
                ...
            }
        ]]>
    </fx:Script>

    <MyComp:ModalText change="handleText(event);"/>
</s:Application>
```

Creating the skin class for the ModalText component

The ModalText component defines a Button subcomponent and a Rich TextArea subcomponent. Each of these subcomponents is defined in the ModalText.as file as a required skin part.

A component uses CSS styles to specify the skin class that implements the skin parts. The ModalText component uses the `setStyle()` method to set the style. However, calling the `setStyle()` method in the component definition does not make it easy to reskin the component. You can also use an external style sheet or other mechanism to set the style that defines the skin class.

The skin class performs the following:

- Uses the `[HostComponent]` metadata tag to specify ModalText as the host component of the skin.
- Defines a single view state named normal.
- Uses the Rect class to draw a border around the RichTextArea subcomponent.
- Uses a Scroller component to add scroll bars to the RichTextArea subcomponent.

The skin class is defined in MXML, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- asAdvancedSpark\myComponents\ModalTextSkin.mxml -->
<s:SparkSkin xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    minWidth="100" minHeight="25">
    <!-- Define ModalText as the host component of the skin. -->
    <fx:Metadata>
        <![CDATA[
            [HostComponent("myComponents.ModalText")]
        ]]>
    </fx:Metadata>
    <!-- Define the normal view state. -->
    <s:states>
        <s:State name="normal"/>
    </s:states>
    <!-- Define the border around the RichEditableText subcomponent. -->
    <s:Rect x="{myScroller.x}"
        width="{myScroller.width}"
        height="{myScroller.height}">
        <s:stroke>
            <s:SolidColorStroke color="0x686868" weight="1"/>
        </s:stroke>
    </s:Rect>
    <!--- Defines the appearance of the Button subcomponent. -->
    <s:Button id="modeButton"
        width="150"
        x="0"
        minHeight="25"/>

    <!--- Defines the appearance of the RichEditableText subcomponent. -->
    <s:Scroller id="myScroller"
        width="200"
        x="156">
        <s:RichEditableText id="textInput"
            minHeight="25"
            heightInLines="4"
            widthInChars="20"
            paddingLeft="4" paddingTop="4"
            paddingRight="4" paddingBottom="4"/>
    </s:Scroller>
</s:SparkSkin>
```

Creating the ModalText component

The following code implements the class definition for the ModalText component. The ModalText component is a composite component that contains a Button and a RichEditableText subcomponent:

```
package myComponents
{
    import flash.events.Event;
    import spark.components.Button;
    import spark.components.RichEditableText;
    import spark.components.supportClasses.SkinnableComponent;
    // ModalText dispatches a change event when the text of the
    // RichEditableText subcomponent changes.
    [Event(name="change", type="flash.events.Event")]

    /** a) Extend SkinnableComponent. */
    public class ModalText extends SkinnableComponent
    {
        /** b) Implement the constructor. */
        public function ModalText() {
            super();

            // Set the skinClass style to the name of the skin class.
            setStyle("skinClass", ModalTextSkin);
        }

        /** c) Define the skin parts for the Button
        *     and RichEditableText subcomponents. **/
        [SkinPart(required="true")]
        public var modeButton:Button;

        [SkinPart(required="true")]
        public var textInput:RichEditableText;

        /** d) Implement the commitProperties() method to handle the
        *     change to the ModalText.text property.
        *     Changes to the ModalText.text property are copied to
        *     the  RichEditableText subcomponent. */
        override protected function commitProperties():void {
            super.commitProperties();

            if (bTextChanged) {
                bTextChanged = false;
                textInput.text = _text;
            }
        }

        /** e) Implement the partAdded() method to
        *     initialize the Button and RichEditableText subcomponents. */
        override protected function partAdded(partName:String, instance:Object):void {
            super.partAdded(partName, instance);

            if (instance == textInput) {
                textInput.editable = false;
                textInput.text= _text;
                textInput.addEventListener("change", textInput_changeHandler);
            }
            if (instance == modeButton) {
                modeButton.label = "Toggle Editing Mode";
                modeButton.addEventListener("click", modeButton_clickHandler);
            }
        }
        /** f) Implement the partRemoved() method to remove the
        *     event listeners added by partAdded(). */
        override protected function partRemoved(partName:String, instance:Object):void {
            super.partRemoved(partName, instance);

            if (instance == textInput) {
                textInput.removeEventListener("change", textInput_changeHandler);
            }
            if (instance == modeButton) {
                textInput.removeEventListener("click", modeButton_clickHandler);
            }
        }
        /** g) Add methods, properties, and metadata.
        *     The general pattern for properties is to specify a
        *     private holder variable. */

        // Implement the ModalText.text property.
        private var _text:String = "ModalText";
        private var bTextChanged:Boolean = false;

        // Create a getter/setter pair for the text property.
        [Bindable]
        public function set text(t:String):void {
            _text = t;
            bTextChanged = true;
            invalidateProperties();
        }

        public function get text():String {
                return textInput.text;
        }

        // Dispatch a change event when the RichEditableText.text
        // property changes.
        private function textInput_changeHandler(eventObj:Event):void {
                dispatchEvent(new Event("change"));
        }

        // Handle the Button click event to toggle the
        // editting mode of the RichEditableText subcomponent.
        private function modeButton_clickHandler(eventObj:Event):void {
                textInput.editable = !textInput.editable;
        }
    }
}
```

Creating the ModalTextStates component

The following code example implements the class definition for the ModalTextStates component. The ModalTextStates component modifies the ModalText components shown in the previous section to add view states to the skin class. This control has all of the attributes of the ModalText class, and adds the following attributes:

- Uses the `textPlacement` property of the component to make the RichEditableText subcomponent appear on the right side or the left side of the component.
- Editing the `textPlacement` property of the control dispatches the `placementChanged` event.

- Uses the `textPlacement` property as the source for a data binding expression.
- Setting the `textPlacement` property so that the RichTextArea component appears on the right configures the skin class to use normal view state. Setting it to appear on the left uses the textLeft view state.
- Disabling editing of the RichTextArea component sets the view state of the skin class to normalDisabled or textLeftDisabled.

The following example uses the ModalTextStates component in an application:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- asAdvancedSpark/SparkMainModalTextStates.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myComponents.*">
     <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
      <![CDATA[
        import flash.events.Event;

        private function placementChangedListener(event:Event):void {
          myEvent.text="placementChanged event occurred - textPlacement = "
              + myMT.textPlacement as String;
        }
      ]]>
    </fx:Script>
    <MyComp:ModalTextStates id="myMT"
        textPlacement="left"
        placementChanged="placementChangedListener(event);"/>
    <s:TextArea id="myEvent" width="50%" height="25"/>
    <s:Label text="Change Placement"/>
    <s:Button label="Set Text Placement Right"
        click="myMT.textPlacement='right';" />
    <s:Button label="Set Text Placement Left"
        click="myMT.textPlacement='left';"/>
</s:Application>
```

This applications sets the initial placement of the RichEditableText subcomponent to left. Use the buttons to switch the placement between right and left. When the placement changes, the event handler for the placementChanged event displays the current placement.

Creating the skin class for the ModalTextStates component

The skin class for the ModalTextStates component, ModalTextStatesSkin.mxml, defines the following view states to control the display of the component:

- normal The RichEditableText subcomponent is on the right, and editing is enabled.
- disabled The RichEditableText subcomponent is on the right, and editing is disabled.
- textLeft The RichEditableText subcomponent is on the left, and editing is enabled.
- textLeftDisabled The RichEditableText subcomponent is on the left, and editing is disabled.

Shown below is the skin definition:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- asAdvancedSpark\myComponents\ModalTextStatesSkin.mxml -->
<s:SparkSkin xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    minWidth="100" minHeight="25">
    <!-- Define ModalTextState as the host component of the skin. -->
    <fx:Metadata>
        <![CDATA[
            [HostComponent("myComponents.ModalTextStates")]
        ]]>
    </fx:Metadata>
    <!-- Define the view states. -->
    <s:states>
        <s:State name="normal" />
        <s:State name="normalDisabled" stateGroups="disabledGroup"/>
        <s:State name="textLeft"/>
        <s:State name="textLeftDisabled" stateGroups="disabledGroup"/>
    </s:states>
    <!-- Define the border around the RichEditableText control. -->
    <s:Rect x="{myScroller.x}"
        width="{myScroller.width}"
        height="{myScroller.height}">
        <s:stroke>
            <s:SolidColorStroke color="0x686868" weight="1"/>
        </s:stroke>
    </s:Rect>
    <!--- Defines the appearance of the Button subcomponent. -->
    <s:Button id="modeButton"
        width="150"
        x="0"
        x.textLeft="206"
        x.textLeftDisabled="206"
        minHeight="25" height="100%"/>

    <!--- Defines the appearance of the RichEditableText subcomponent. -->
    <s:Scroller id="myScroller"
        width="200"
        x="156"
        x.textLeft="0"
        x.textLeftDisabled="0">
        <s:RichEditableText id="textInput"
            alpha="1.0" alpha.disabledGroup="0.5"
            minHeight="25"
            heightInLines="4"
            widthInChars="20"
            paddingLeft="4" paddingTop="4"
            paddingRight="4" paddingBottom="4"/>
    </s:Scroller>
</s:SparkSkin>
```

Creating the ModalTextStates component

Shown below is the code for the ModalTextStates component. The ModalTextStates class modifies the ModalText class in the following ways:

- Adds the implementation of the `ModalTextStates()` method to set the view state of the skin.

- Adds the implementation of the `textPlacement` property to set the placement of the RichEditableText subcomponent.

```
package myComponents
{
    import flash.events.Event;
    import spark.components.Button;
    import spark.components.RichEditableText;
    import spark.components.supportClasses.SkinnableComponent;
    // ModalText dispatches a change event when the text of the
    // RichEditableText subcomponent changes,
    // and a placementChanged event
    // when you change the textPlacement property of ModalText.
    [Event(name="change", type="flash.events.Event")]
    [Event(name="placementChanged", type="flash.events.Event")]
    // Define the skin states implemented by the skin class.
    [SkinState("normal")]
    [SkinState("normalDisabled")]
    [SkinState("textLeft")]
    [SkinState("textLeftDisabled")]

    /** a) Extend SkinnableComponent. */
    public class ModalTextStates extends SkinnableComponent
    {
        /** b) Implement the constructor. */
        public function ModalTextStates() {
            super();

            // Set the skin class.
            setStyle("skinClass", ModalTextStatesSkin);
        }

        /** C) Define the skin parts. */
        [SkinPart(required="true")]
        public var modeButton:Button;

        [SkinPart(required="true")]
        public var textInput:RichEditableText;

        /** d) Implement the commitProperties() method. */
        override protected function commitProperties():void {
            super.commitProperties();

            if (bTextChanged) {
                bTextChanged = false;
                textInput.text = _text;
            }
        }

        /** e) Implement the partAdded() method. */
        override protected function partAdded(partName:String, instance:Object):void {
            super.partAdded(partName, instance);

            if (instance == textInput) {
                textInput.editable = false;
                textInput.text= _text;
                textInput.addEventListener("change", textInput_changeHandler);
            }
            if (instance == modeButton) {
                modeButton.label = "Toggle Editing Mode";
                modeButton.addEventListener("click", modeButton_changeHandler);
            }
        }

        /** f) Implement the partRemoved() method. */
        override protected function partRemoved(partName:String, instance:Object):void {
            super.partRemoved(partName, instance);

            if (instance == textInput) {
                textInput.removeEventListener("change", textInput_changeHandler);
            }
            if (instance == modeButton) {
                textInput.removeEventListener("click", modeButton_changeHandler);
            }
        }
        /** g) Implement the getCurrentSkinState() method.
        *     The view state is determined by the _textPlacement property
        *     and the editable property of the RichEditableText subcomponent.*/
        override protected function getCurrentSkinState():String {
            var returnState:String = "normal";

            if (textInput.editable == true)
            {
                if (_textPlacement == "right") {
                    returnState = "normal";
                }
                else if (_textPlacement == "left") {
                    returnState = "textLeft";
                }
            }
            if (textInput.editable == false)
            {
                if (_textPlacement == "right") {
                    returnState = "normalDisabled";
                }
                else if (_textPlacement == "left") {
                    returnState = "textLeftDisabled";
                }
            }
            return returnState;
        }
        /** h) Add methods, properties, and metadata.
        *     The general pattern for properties is to specify a private
        *     holder variable. */

        // Define the text property.
        private var _text:String = "ModalText";
        private var bTextChanged:Boolean = false;

        // Then, create a getter/setter pair for the text property.
        [Bindable]
        public function set text(t:String):void {
            _text = t;
            bTextChanged = true;
```

```
            invalidateProperties();
        }

        public function get text():String {
            return textInput.text;
        }
        // Define the textPlacement property.
        private var _textPlacement:String = "right";

        // Create a getter/setter pair for the textPlacement property.
        // Dispatch the placementChanged event when it changes.
        [Bindable]
        public function set textPlacement(p:String):void {
            _textPlacement = p;
            invalidateSkinState();
            dispatchEvent(new Event("placementChanged"));
        }

        public function get textPlacement():String {
            return _textPlacement;
        }

        // Dispatch a change event when the RichEditableText.text
        // property changes.
        private function textInput_changeHandler(eventObj:Event):void {
            dispatchEvent(new Event("change"));
        }

        // Handle the Button click event to toggle the
        // editting mode of the RichEditableText subcomponent.
        private function modeButton_changeHandler(eventObj:Event):void {
            textInput.editable = !textInput.editable;
            invalidateSkinState();
        }
    }
}
```

Create advanced MX visual components in ActionScript

You can create advanced visual components for use in applications built with Adobe® Flex® .

About creating advanced MX components

Simple visual components are subclasses of existing Flex components that modify the appearance of the component by using skins or styles, or add new functionality to the component. For example, you add a new event type to a Button control, or modify the default styles or skins of a DataGrid control. For more information, see “Create simple visual components in ActionScript” on page 2433.

In advanced components, you typically perform the following actions:

- Modify the visual appearance or visual characteristics of an existing component.
- Create a composite component that encapsulates two or more components within it.
- Create a component by creating a subclass of the UIComponent class.

You usually create a component as a subclass of an existing class. For example, to create a component that is based on the Button control, you create a subclass of the mx.controls.Button class. To make your own component, you create a subclass of the mx.core.UIComponent class.

About overriding protected UIComponent methods for MX components

All Flex visual components are subclasses of the UIComponent class. Therefore, visual components inherit the methods, properties, events, styles, and effects defined by the UIComponent class.

To create an advanced visual component, you must implement a class constructor. Also, you optionally override one or more of the following protected methods of the UIComponent class:

UIComponent method	Description
`commitProperties()`	Commits any changes to component properties, either to make the changes occur at the same time or to ensure that properties are set in a specific order. For more information, see "Implementing the commitProperties() method for MX components" on page 2483.
`createChildren()`	Creates any child components of the component. For example, the ComboBox control contains a TextInput control and a Button control as child components. For more information, see "Implementing the createChildren() method for MX components" on page 2482.
`layoutChrome()`	Defines the border area around the container for subclasses of the Container class. For more information, see "Implementing the layoutChrome() method for MX components" on page 2488.
`measure()`	Sets the default size and default minimum size of the component. For more information, see "Implementing the measure() method for MX components" on page 2485.
`updateDisplayList()`	Sizes and positions the children of the component on the screen based on all previous property and style settings, and draws any skins or graphic elements used by the component. The parent container for the component determines the size of the component itself. For more information, see "Implementing the updateDisplayList() method for MX components" on page 2489.

Component users do not call these methods directly; Flex calls them as part of the initialization process of creating a component, or when other method calls occur. For more information, see "About the component instantiation life cycle for MX components" on page 2477.

About the invalidation methods for MX components

During the lifetime of a component, your application might modify the component by changing its size or position, modifying a property that controls its display, or modifying a style or skin property of the component. For example, you might change the font size of the text displayed in a component. As part of changing the font size, the component's size might also change, which requires Flex to update the layout of the application. The layout operation might require Flex to invoke the `commitProperties()`, `measure()`, `layoutChrome()`, and the `updateDisplayList()` methods of your component.

Your application can programmatically change the font size of a component much faster than Flex can update the layout of an application. Therefore, you should only want to update the layout after you are sure that you've determined the final value of the font size.

In another scenario, when you set multiple properties of a component, such as the `label` and `icon` properties of a Button control, you want the `commitProperties()`, `measure()`, and `updateDisplayList()` methods to execute only once, after all properties are set. You do not want these methods to execute when you set the `label` property, and then execute again when you set the `icon` property.

Also, several components might change their font size at the same time. Rather than updating the application layout after each component changes its font size, you want Flex to coordinate the layout operation to eliminate any redundant processing.

Flex uses an invalidation mechanism to synchronize modifications to components. Flex implements the invalidation mechanism as a set of methods that you call to signal that something about the component has changed and requires Flex to call the component's `commitProperties()`, `measure()`, `layoutChrome()`, or `updateDisplayList()` methods.

The following table describes the invalidation methods:

Invalidation method	**Description**
`invalidateProperties()`	Marks a component so that its `commitProperties()` method gets called during the next screen update.
`invalidateSize()`	Marks a component so that its `measure()` method gets called during the next screen update.
`invalidateDisplayList()`	Marks a component so that its `layoutChrome()` and `updateDisplayList()` methods get called during the next screen update.

When a component calls an invalidation method, it signals to Flex that the component must be updated. When multiple components call invalidation methods, Flex coordinates updates so that they all occur together during the next screen update.

Typically, component users do not call the invalidation methods directly. Instead, they are called by the component's setter methods, or by any other methods of a component class as necessary. For more information and examples, see "Implementing the commitProperties() method for MX components" on page 2483.

About the component instantiation life cycle for MX components

The component instantiation life cycle describes the sequence of steps that occur when you create a component object from a component class. As part of that life cycle, Flex automatically calls component methods, dispatches events, and makes the component visible.

The following example creates a Button control in ActionScript and adds it to a container:

```
// Create a Box container.
var boxContainer:Box = new Box();
// Configure the Box container.

// Create a Button control.
var b:Button = new Button()
// Configure the button control.
b.label = "Submit";
...
// Add the Button control to the Box container.
boxContainer.addChild(b);
```

The following steps show what occurs when you execute the code to create the Button control, and add the control to the Box container:

1 You call the component's constructor, as the following code shows:

```
// Create a Button control.
var b:Button = new Button()
```

2 You configure the component by setting its properties, as the following code shows:

```
// Configure the button control.
b.label = "Submit";
```

Component setter methods might call the `invalidateProperties()`, `invalidateSize()`, or `invalidateDisplayList()` methods.

3 You call the `addChild()` method to add the component to its parent, as the following code shows:

```
// Add the Button control to the Box container.
boxContainer.addChild(b);
```

Flex then performs the following actions:

4 Sets the `parent` property for the component to reference its parent container.

5 Computes the style settings for the component.

6 Dispatches the `preinitialize` event on the component.

7 Calls the component's `createChildren()` method.

8 Calls the `invalidateProperties()`, `invalidateSize()`, and `invalidateDisplayList()` methods to trigger later calls to the `commitProperties()`, `measure()`, or `updateDisplayList()` methods during the next `render` event.

The only exception to this rule is that Flex does not call the `measure()` method when the user sets the height and width of the component.

9 Dispatches the `initialize` event on the component. At this time, all of the component's children are initialized, but the component has not been sized or processed for layout. You can use this event to perform additional processing of the component before it is laid out.

10 Dispatches the `childAdd` event on the parent container.

11 Dispatches the `initialize` event on the parent container.

12 During the next `render` event, Flex performs the following actions:

a Calls the component's `commitProperties()` method.

b Calls the component's `measure()` method.

c Calls the component's `layoutChrome()` method.

d Calls the component's `updateDisplayList()` method.

e If steps 13 and 14 are not required, which is the most common scenario, dispatches the `updateComplete` event on the component.

13 Flex dispatches additional `render` events if the `commitProperties()`, `measure()`, or `updateDisplayList()` methods call the `invalidateProperties()`, `invalidateSize()`, or `invalidateDisplayList()` methods.

14 After the last `render` event occurs, Flex performs the following actions:

a Makes the component visible by setting the `visible` property to `true`.

b Dispatches the `creationComplete` event on the component. The component is sized and processed for layout. This event is only dispatched once when the component is created.

c Dispatches the `updateComplete` event on the component. Flex dispatches additional `updateComplete` events whenever the layout, position, size, or other visual characteristic of the component changes and the component is updated for display.

Most of the work for configuring a component occurs when you add the component to a container by using the `addChild()` method. That is because until you add the component to a container, Flex cannot determine its size, set inheriting style properties, or draw it on the screen.

You can also define your application in MXML, as the following example shows:

```
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <mx:Box>
        <mx:Button label="Submit"/>
    </mx:Box>
</s:Application>
```

The sequence of steps that Flex executes when creating a component in MXML are equivalent to the steps described for ActionScript.

You can remove a component from a container by using the `removeChild()` method. If there are no references to the component, it is eventually deleted from memory by the garbage collection mechanism of Adobe® Flash® Player or Adobe® AIR™.

About the steps for creating a component for MX components

When you implement a component, you override component methods, define new properties, dispatch new events, or perform any other customizations required by your application.

To implement your component, follow these general steps:

1 If necessary, create any skins for the component.

2 Create an ActionScript class file.

  a Extend one of the base classes, such as UIComponent or another component class.

  b Specify properties that the user can set by using an MXML tag property.

  c Embed any graphic and skin files.

  d Implement the constructor.

  e Implement the UIComponent.createChildren() method.

  f Implement the UIComponent.commitProperties() method.

  g Implement the UIComponent.measure() method.

  h Implement the UIComponent.layoutChrome() method.

  i Implement the UIComponent.updateDisplayList() method.

  j Add properties, methods, styles, events, and metadata.

3 Deploy the component as an ActionScript file or as a SWC file.

For more information about MXML tag properties and embedding graphic and skin files, see “Create simple visual components in ActionScript” on page 2433.

You do not have to override all component methods to define a new component. You only override the methods required to implement the functionality of your component. If you create a subclass of an existing component, such as Button control or VBox container, you must implement the methods necessary for you to add any new functionality to the component.

For example, you can implement a custom Button control that uses a new mechanism for defining its default size. In that case, you only need to override the `measure()` method. For an example, see "Implementing the measure() method for MX components" on page 2485.

Or you might implement a new subclass of the VBox container. Your new subclass uses all of the existing sizing logic of the VBox class, but changes the layout logic of the class to lay out the container children from the bottom of the container to the top, rather than from the top down. In this case, you only need to override the `updateDisplayList()` method. For an example, see "Implementing the updateDisplayList() method for MX components" on page 2489.

About interfaces

Flex uses interfaces to divide the basic functionality of components into discrete elements so that they can be implemented piece by piece. For example, to make your component focusable, it must implement the IFocusable interface; to let it participate in the layout process, it must implement ILayoutClient interface.

To simplify the use of interfaces, the UIComponent class implements all of the interfaces defined in the following table, except for the IFocusManagerComponent and IToolTipManagerClient interfaces. However, many subclasses of UIComponent implement the IFocusManagerComponent and IToolTipManagerClient interfaces.

Therefore, if you create a subclass of the class or subclass of UIComponent, you do not have to implement these interfaces. But, if you create a component that is not a subclass of UIComponent, and you want to use that component in Flex, you might have to implement one or more of these interfaces.

***Note:** For Flex, Adobe recommends that all of your components extend the UIComponent class or a class that extends UIComponent.*

The following table lists the main interfaces implemented by Flex components:

Interface	Use
IAdvancedStyleClient	Indicates that the component supports the advanced style subsystem.
IAutomationObject	Indicates that a component is an object within the automation object hierarchy.
IChildList	Indicates the number of children in a container.
IConstraintClient	Indicates that the component support layout constraints.
IDeferredInstantiationUIComponent	Indicates that a component or object can effect deferred instantiation.
IFlexDisplayObject	Specifies the interface for skin elements.
IFlexModule	indicates that the component can be used with module factories
IInvalidating	Indicates that a component or object can use the invalidation mechanism to perform delayed, rather than immediate, property commitment, measurement, and drawing or layout.
ILayoutManagerClient	Indicates that a component or object can participate in the LayoutManager's commit, measure, and update sequence.
IPropertyChangeNotifier	Indicates that a component supports a specialized form of event propagation.
IRepeaterClient	Indicates that a component or object can be used with the Repeater class.
IStateClient	Indicates that the component supports view states.

Interface	Use
IToolTipManagerClient	Indicates that a component has a `toolTip` property, and therefore is monitored by the ToolTipManager.
IUIComponent	Defines the basic set of APIs that you must implement in order to be a child of layout containers and lists.
IValidatorListener	Indicates that a component can listen for validation events, and therefore show a validation state, such as a red border and error tooltips.
IVisualElement	Indicates that the component can be laid out and displayed in a Spark application.

Implementing the component

When you create a custom component in ActionScript, you have to override the methods of the UIComponent class. You implement the basic component structure, the constructor, and the `createChildren()`, `commitProperties()`, `measure()`, `layoutChrome()`, and `updateDisplayList()` methods.

Basic component structure

The following example shows the basic structure of a Flex component:

```
package myComponents
{
    public class MyComponent extends UIComponent
    {
        ....
    }
}
```

You must define your ActionScript custom components within a package. The package reflects the directory location of your component within the directory structure of your application.

The class definition of your component must be prefixed by the `public` keyword. A file that contains a class definition can have one, and only one, public class definition, although it can have additional internal class definitions. Place any internal class definitions at the bottom of your source file below the closing curly brace of the package definition.

Implementing the constructor

Your ActionScript class should define a public constructor method for a class that is a subclass of the UIComponent class, or a subclass of any child of the UIComponent class. The constructor has the following characteristics:

- No return type
- Should be declared public
- No arguments
- Calls the `super()` method to invoke the superclass' constructor

Each class can contain only one constructor method; ActionScript does not support overloaded constructor methods. For more information, see "Defining the constructor" on page 2366.

Use the constructor to set the initial values of class properties. For example, you can set default values for properties and styles, or initialize data structures, such as Arrays.

Do not create child display objects in the constructor; you should use it only for setting initial properties of the component. If your component creates child components, create them in the `createChildren()` method.

Implementing the createChildren() method for MX components

A component that creates other components or visual objects within it is called a *composite component*. For example, the Flex ComboBox control contains a TextInput control to define the text area of the ComboBox, and a Button control to define the ComboBox arrow. Components implement the `createChildren()` method to create child objects (such as other components) in the component.

You do not call the createChildren() method directly; Flex calls it when the call to the `addChild()` method occurs to add the component to its parent. Notice that the `createChildren()` method has no invalidation method, which means that you do not have to call it a second time after the component is added to its parent.

For example, you might define a new component that consists of a Button control and a TextArea control, where the Button control enables and disables user input to the TextArea control. The following example creates the TextArea and Button controls:

```
// Declare two variables for the component children.
private var text_mc:TextArea;
private var mode_mc:Button;

override protected function createChildren():void {

    // Call the createChildren() method of the superclass.
    super.createChildren();

    // Test for the existence of the children before creating them.
    // This is optional, but do this so a subclass can create a different
    // child.
    if (!text_mc) {
        text_mc = new TextArea();
        text_mc.explicitWidth = 80;
        text_mc.editable = false;
        text_mc.addEventListener("change", handleChangeEvent);
        // Add the child component to the custom component.
        addChild(text_mc);
    }

    // Test for the existence of the children before creating them.
    if (!mode_mc) {
        mode_mc = new Button();
        mode_mc.label = "Toggle Editing";
        mode_mc.addEventListener("click", handleClickEvent);
        // Add the child component to the custom component.
        addChild(mode_mc);
    }
}
```

Notice in this example that the `createChildren()` method calls the `addChild()` method to add the child component. You must call the `addChild()` method for each child object.

After you create a child component, you can use properties of the child component to define its characteristics. In this example, you create the Button and TextArea controls, initialize them, and register event listeners for them. You could also apply skins to the child components. For a complete example, see "Example: Creating a composite MX component" on page 2493.

Implementing the commitProperties() method for MX components

You use the commitProperties() method to coordinate modifications to component properties. Most often, you use it with properties that affect how a component appears on the screen.

Flex schedules a call to the `commitProperties()` method when a call to the `invalidateProperties()` method occurs. The `commitProperties()` method executes during the next `render` event after a call to the `invalidateProperties()` method. When you use the `addChild()` method to add a component to a container, Flex automatically calls the `invalidateProperties()` method.

Calls to the `commitProperties()` method occur before calls to the `measure()` method. This lets you set property values that the `measure()` method might use.

The typical pattern for defining component properties is to define the properties by using getter and setter methods, as the following example shows:

```
// Define a private variable for the alignText property.
private var _alignText:String = "right";

// Define a flag to indicate when the _alignText property changes.
private var bAlignTextChanged:Boolean = false;

// Define getter and setter methods for the property.
public function get alignText():String {
        return _alignText;
}

public function set alignText(t:String):void {
    _alignText = t;
    bAlignTextChanged = true;

    // Trigger the commitProperties(), measure(), and updateDisplayList()
    // methods as necessary.
    // In this case, you do not need to remeasure the component.
    invalidateProperties();
    invalidateDisplayList();
}

// Implement the commitProperties() method.
override protected function commitProperties():void {
    super.commitProperties();

    // Check whether the flag indicates a change to the alignText property.
    if (bAlignTextChanged) {
        // Reset flag.
        bAlignTextChanged = false;

        // Handle alignment change
    }
}
```

As you can see in this example, the setter method modifies the property, calls the `invalidateProperties()` and `invalidateDisplayList()` methods, and then returns. The setter itself does not perform any calculations based on the new property value. This design lets the setter method return quickly, and leaves any processing of the new value to the `commitProperties()` method.

Changing the alignment of text in a control does not necessarily change the control’s size. However, if it does, include a call to the `invalidateSize()` method to trigger the `measure()` method.

The main advantages of using the `commitProperties()` method are the following:

- To coordinate the modifications of multiple properties so that the modifications occur synchronously.

  For example, you might define multiple properties that control the text displayed by the component, such as the alignment of the text within the component. A change to either the text or the alignment property requires Flex to update the appearance of the component. However, if you modify both the text and the alignment, you want Flex to perform any calculations for sizing or positioning the component once, when the screen updates.

  Therefore, you use the `commitProperties()` method to calculate any values based on the relationship of multiple component properties. By coordinating the property changes in the `commitProperties()` method, you can reduce unnecessary processing overhead.

- To coordinate multiple modifications to the same property.

  You do not necessarily want to perform a complex calculation every time a user updates a component property. For example, users modify the `icon` property of the Button control to change the image displayed in the button. Calculating the label position based on the presence or size of an icon can be a computationally expensive operation that you want to perform only when necessary.

  To avoid this behavior, you use the `commitProperties()` method to perform the calculations. Flex calls the `commitProperties()` method when it updates the display. That means you perform the calculations once when Flex updates the screen, regardless of the number of times the property changed between screen updates.

The following example shows how you can handle two related properties in the `commitProperties()` method:

```
// Define a private variable for the text property.
private var _text:String = "ModalText";
private var bTextChanged:Boolean = false;

// Define the getter method.
public function get text():String {
        return _text;
}

//Define the setter method to call invalidateProperties()
// when the property changes.
public function set text(t:String):void {
    _text = t;
    bTextChanged = true;
    invalidateProperties();
    // Changing the text causes the control to recalculate its default size.
    invalidateSize();
    invalidateDisplayList();
}

// Define a private variable for the alignText property.
private var _alignText:String = "right";
private var bAlignTextChanged:Boolean = false;

public function get alignText():String {
        return _alignText;
}

public function set alignText(t:String):void {
    _alignText = t;
    bAlignTextChanged = true;
    invalidateProperties();
    invalidateDisplayList();
}

// Implement the commitProperties() method.
override protected function commitProperties():void {
    super.commitProperties();

    // Check whether the flags indicate a change to both properties.
    if (bTextChanged && bAlignTextChanged) {
        // Reset flags.
        bTextChanged = false;
        bAlignTextChanged = false;

        // Handle case where both properties changed.
    }

    // Check whether the flag indicates a change to the text property.
    if (bTextChanged) {
        // Reset flag.
        bTextChanged = false;

        // Handle text change.
    }

    // Check whether the flag indicates a change to the alignText property.
    if (bAlignTextChanged) {
        // Reset flag.
        bAlignTextChanged = false;

        // Handle alignment change.
    }
}
```

Implementing the measure() method for MX components

The measure() method sets the default component size, in pixels, and optionally sets the component's default minimum size.

Flex schedules a call to the `measure()` method when a call to the `invalidateSize()` method occurs. The `measure()` method executes during the next `render` event after a call to the `invalidateSize()` method. When you use the `addChild()` method to add a component to a container, Flex automatically calls the `invalidateSize()` method.

When you set a specific height and width of a component, Flex does not call the `measure()` method, even if you explicitly call the `invalidateSize()` method. That is, Flex calls the `measure()` method only if the `explicitWidth` property or the `explicitHeight` property of the component is `NaN`.

In the following example, because you explicitly set the size of the Button control, Flex does not call the `Button.measure()` method:

```
<mx:Button height="10" width="10"/>
```

In a subclass of an existing component, you might implement the `measure()` method only if you are performing an action that requires modification to the default sizing rules defined in the superclass. Therefore, to set a new default size, or perform calculations at run time to determine component sizing rules, implement the `measure()` method.

You set the following properties in the `measure()` method to specify the default size:

Properties	Description
`measuredHeightmea suredWidth`	Specifies the default height and width of the component, in pixels. These properties are set to 0 until the `measure()` method executes. Although you can leave them set to 0, it makes the component invisible by default.
`measuredMinHeight measuredMinWidth`	Specifies the default minimum height and minimum width of the component, in pixels. Flex cannot set the size of a component smaller than its specified minimum size.

The `measure()` method only sets the default size of the component. In the `updateDisplayList()` method, the parent container of the component passes to it its actual size, which may be different than the default size.

Component users can also override the default size settings in an application by using the component in the following ways:

- Setting the `explicitHeight` and `exlicitWidth` properties
- Setting the `width` and `height` properties
- Setting the `percentHeight` and `percentWidth` properties

For example, you can define a Button control with a default size of 100 pixels wide and 50 pixels tall, and a default minimum size of 50 pixels by 25 pixels, as the following example shows:

```
package myComponents
{
    // asAdvanced/myComponents/BlueButton.as
    import mx.controls.Button;
    public class BlueButton extends Button {

        public function BlueButton() {
            super();
        }
        override protected function measure():void {
            super.measure();

            measuredWidth=100;
            measuredMinWidth=50;
            measuredHeight=50;
            measuredMinHeight=25;
        }
    }
}
```

The following application uses this button in an application:

```
<?xml version="1.0"?>
<!-- asAdvanced/ASAdvancedMainBlueButton.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:MyComp="myComponents.*" >
    <mx:VBox>
        <MyComp:BlueButton/>
        <mx:Button/>
    </mx:VBox>
</s:Application>
```

In the absence of any other sizing constraints on the button, the VBox container uses the default size and default minimum size of the button to calculate its size at run time. For information on the rules for sizing a component, see "Introduction to containers" on page 326.

You can override the default size settings in an application, as the following example shows:

```
<?xml version="1.0"?>
<!-- asAdvanced/MainBlueButtonResize.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:MyComp="myComponents.*" >
    <mx:VBox>
        <MyComp:BlueButton width="50%"/>
        <mx:Button/>
    </mx:VBox>
</s:Application>
```

In this example, you specify that the width of the button is 50% of the width of the VBox container. When 50% of the width of the container is smaller than the minimum width of the button, the button uses its minimum width.

Calculating default sizes

The example in "Implementing the measure() method for MX components" on page 2485 uses static values for the default size and default minimum size of a component. Some Flex components use static sizes. For example, the TextArea control has a default size of 100 pixels wide by 44 pixels high, regardless of the text it contains. If the text is larger than the TextArea control, the control displays scroll bars.

Often, you set the default size based on characteristics of the component or information passed to the component. For example, the Button control's measure() method examines its label text, margin settings, and font characteristics to determine the control's default size.

In the following example, you override the `measure()` method of the TextArea control so that it examines the text passed to the control, and calculates the default size of the TextArea control to display the entire text string in a single line:

```
package myComponents
{
    // asAdvanced/myComponents/MyTextArea.as
    import mx.controls.TextArea;
    import flash.text.TextLineMetrics;
    public class MyTextArea extends TextArea
    {
        public function MyTextArea() {
            super();
        }

        // The default size is the size of the text plus a 10 pixel margin.
        override protected function measure():void {
            super.measure();
            // Calculate the default size of the control based on the
            // contents of the TextArea.text property.
            var lineMetrics:TextLineMetrics = measureText(text);
            // Add a 10 pixel border area around the text.
            measuredWidth = measuredMinWidth = lineMetrics.width + 10;
            measuredHeight = measuredMinHeight = lineMetrics.height + 10;
        }
    }
}
```

For text strings that are longer than the display area of your application, you can add logic to increase the height of the TextArea control to display the text on multiple lines. The following application uses this component:

```
<?xml version="1.0"?>
<!-- asAdvanced/MainMyTextArea.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:MyComp="myComponents.*"
    width="1000">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <MyComp:MyTextArea id="myTA" text="This is a long text strring that would normally cause
a TextArea control to display scroll bars. But, the custom MyTextArea control calcualtes its
default size based on the text size."/>

    <mx:TextArea id="flexTA" text="This is a long text strring that would normally cause a
TextArea control to display scroll bars. But, the custom MyTextArea control calcualtes its
default size based on the text size."/>
</s:Application>
```

Implementing the layoutChrome() method for MX components

The Container class, and some subclasses of the Container class, use the layoutChrome() method to define the border area around the container.

Flex schedules a call to the `layoutChrome()` method when a call to the `invalidateDisplayList()` method occurs. The `layoutChrome()` method executes during the next `render` event after a call to the `invalidateDisplayList()` method. When you use the `addChild()` method to add a component to a container, Flex automatically calls the `invalidateDisplayList()` method.

Typically, you use the RectangularBorder class to define the border area of a container. For example, you can create the RectangularBorder object, and add it as a child of the component in your override of the `createChildren()` method.

When you create a subclass of the Container class, you can use the `createChildren()` method to create the content children of the container; the content children are the child components that appear within the container. You then use `updateDisplayList()` to position the content children.

You typically use the `layoutChrome()` method to define and position the border area of the container, and any additional elements that you want to appear in the border area. For example, the Panel container uses the `layoutChrome()` method to define the title area of the panel container, including the title text and close button.

The primary reason for dividing the handling of the content area of a container from its border area is to handle the situation when the `Container.autoLayout` property is set to `false`. When the `autoLayout` property is set to `true`, measurement and layout of the container and of its children are done whenever the position or size of a container child changes. The default value is `true`.

When the `autoLayout` property is set to `false`, measurement and layout are done only once, when children are added to or removed from the container. However, Flex executes the `layoutChrome()` method in both cases. Therefore, the container can still update its border area even when the `autoLayout` property is set to `false`.

Implementing the updateDisplayList() method for MX components

The updateDisplayList() method sizes and positions the children of your component based on all previous property and style settings, and draws any skins or graphic elements that the component uses. The parent container for the component determines the size of the component itself.

A component does not appear on the screen until its `updateDisplayList()` method gets called. Flex schedules a call to the `updateDisplayList()` method when a call to the `invalidateDisplayList()` method occurs. The `updateDisplayList()` method executes during the next `render` event after a call to the `invalidateDisplayList()` method. When you use the `addChild()` method to add a component to a container, Flex automatically calls the `invalidateDisplayList()` method.

The main uses of the `updateDisplayList()` method are the following:

- To set the size and position of the elements of the component for display.

  Many components are made up of one or more child components, or have properties that control the display of information in the component. For example, the Button control lets you specify an optional icon, and use the `labelPlacement` property to specify where the button text appears relative to the icon.

  The `Button.updateDisplayList()` method uses the settings of the `icon` and `labelPlacement` properties to control the display of the button.

  For containers that have child controls, the `updateDisplayList()` method controls how those child components are positioned. For example, the `updateDisplayList()` method on the HBox container positions its children from left to right in a single row; the `updateDisplayList()` method for a VBox container positions its children from top to bottom in a single column.

  To size components in the `updateDisplayList()` method, you use the `setActualSize()` method, not the sizing properties, such as `width` and `height`. To position a component, use the `move()` method, not the `x` and `y` properties.

- To draw any visual elements necessary for the component.

  Components support many types of visual elements such as skins, styles, and borders. Within the `updateDisplayList()` method, you can add these visual elements, use the Flash drawing APIs, and perform additional control over the visual display of your component.

The `updateDisplayList()` method has the following signature:

```
protected function updateDisplayList(unscaledWidth:Number,
    unscaledHeight:Number):void
```

The properties have the following values:

unscaledWidth Specifies the width of the component, in pixels, in the component’s coordinates, regardless of the value of the scaleX property of the component. This is the width of the component as determined by its parent container.

unscaledHeight Specifies the height of the component, in pixels, in the component’s coordinates, regardless of the value of the `scaleY` property of the component. This is the height of the component as determined by its parent container.

Scaling occurs in Flash Player or AIR, after `updateDisplayList()` executes. For example, a component with an `unscaledHeight` value of 100, and with a `scaleY` property of 2.0, appears 200 pixels high in Flash Player or AIR.

Overriding the layout mechanism of the VBox container

The VBox container lays out its children from the top of the container to the bottom, in the order in which the children are added to the container. The following example overrides the updateDisplayList() method, which causes the VBox container to layout its children from the bottom of the container to the top:

```
package myComponents
{
    // asAdvanced/myComponents/BottomUpVBox.as
    import mx.containers.VBox;
    import mx.core.EdgeMetrics;
    import mx.core.UIComponent;
    public class BottomUpVBox extends VBox
    {

        public function BottomUpVBox() {
            super();
        }

        override protected function updateDisplayList(unscaledWidth:Number,
            unscaledHeight:Number):void {
            super.updateDisplayList(unscaledWidth, unscaledHeight);

            // Get information about the container border area.
            // The usable area of the container for its children is the
            // container size, minus any border areas.
            var vm:EdgeMetrics = viewMetricsAndPadding;
            // Get the setting for the vertical gap between children.
            var gap:Number = getStyle("verticalGap");

            // Determine the y coordinate of the bottom of the usable area
            // of the VBox.
            var yOfComp:Number = unscaledHeight-vm.bottom;

            // Temp variable for a container child.
            var obj:UIComponent;

            for (var i:int = 0; i < numChildren; i++)
            {
                // Get the first container child.
                obj = UIComponent(getChildAt(i));

                // Determine the y coordinate of the child.
                yOfComp = yOfComp - obj.height;

                // Set the x and y coordinate of the child.
                // Note that you do not change the x coordinate.
                obj.move(obj.x, yOfComp);

                // Save the y coordinate of the child,
                // plus the vertical gap between children.
                // This is used to calculate the coordinate
                // of the next child.
                yOfComp = yOfComp - gap;
            }
        }
    }
}
```

In this example, you use the `UIComponent.move()` method to set the position of each child in the container. You can also use the `UIComponent.x` and `UIComponent.y` properties to set these coordinates. The difference is that the `move()` method changes the location of the component and then dispatches a `move` event when you call the method immediately; setting the `x` and `y` properties changes the location of the component and dispatches the event on the next screen update.

The following application uses this component:

```
<?xml version="1.0"?>
<!-- asAdvanced/MainBottomVBox.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:MyComp="myComponents.*" >
  <MyComp:BottomUpVBox>
    <mx:Label text="Label 1"/>
    <mx:Button label="Button 1"/>
    <mx:Label text="Label 2"/>
    <mx:Button label="Button 2"/>

    <mx:Label text="Label 3"/>
    <mx:Button label="Button 3"/>
    <mx:Label text="Label 4"/>
    <mx:Button label="Button 4"/>
  </MyComp:BottomUpVBox>
</s:Application>
```

Drawing graphics in your component

Every Flex component is a subclass of the Flash Sprite class, and therefore inherits the `Sprite.graphics` property. The `Sprite.graphics` property specifies a Graphics object that you can use to add vector drawings to your component.

For example, in the `updateDisplayList()` method, you can use methods of the Graphics class to draw borders, rules, and other graphical elements:

```
override protected function updateDisplayList(unscaledWidth:Number, unscaledHeight:Number):void {

    super.updateDisplayList(unscaledWidth, unscaledHeight);

    // Draw a simple border around the child components.
    graphics.lineStyle(1, 0x000000, 1.0);
    graphics.drawRect(0, 0, unscaledWidth, unscaledHeight);
}
```

Making components accessible

A growing requirement for web content is that it should be accessible to people who have disabilities. Visually impaired people can use the visual content in Flash applications by using screen reader software, which provides an audio description of the material on the screen.

When you create a component, you can include ActionScript that enables the component and a screen reader for audio communication. When developers use your component to build an application in Flash, they use the Accessibility panel to configure each component instance.

Flash includes the following accessibility features:

- Custom focus navigation
- Custom keyboard shortcuts
- Screen-based documents and the screen authoring environment
- An Accessibility class

To enable accessibility in your component, add the following line to your component's class file:

```
mx.accessibility.ComponentName.enableAccessibility();
```

For example, the following line enables accessibility for the MyButton component:

```
mx.accessibility.MyButton.enableAccessibility();
```

For additional information about accessibility, see "Accessible applications" on page 2122.

Adding version numbers

When releasing components, you can define a version number. This lets developers know whether they should upgrade, and helps with technical support issues. When you set a component's version number, use the static variable `version`, as the following example shows:

```
static var version:String = "1.0.0.42";
```

***Note:** Flex does not use or interpret the value of the `version` property.*

If you create many components as part of a component package, you can include the version number in an external file. That way, you update the version number in only one place. For example, the following code imports the contents of an external file that stores the version number in one place:

```
include "../myPackage/ComponentVersion.as"
```

The contents of the ComponentVersion.as file are identical to the previous variable declaration, as the following example shows:

```
static var version:String = "1.0.0.42";
```

Best practices when designing a component

Use the following practices when you design a component:

- Keep the file size as small as possible.
- Make your component as reusable as possible by generalizing functionality.
- Use the Border class rather than graphical elements to draw borders around objects.
- Assume an initial state. Because style properties are on the object, you can set initial settings for styles and properties so your initialization code does not have to set them when the object is constructed, unless the user overrides the default state.

Example: Creating a composite MX component

Composite components are components that contain multiple components. They might be graphical assets or a combination of graphical assets and component classes. For example, you can create a component that includes a button and a text field, or a component that includes a button, a text field, and a validator.

When you create composite components, you should instantiate the controls inside the component's class file. Assuming that some of these controls have graphical assets, you must plan the layout of the controls that you are including, and set properties such as default values in your class file. You must also ensure that you import all the necessary classes that the composite component uses.

Because the class extends one of the base classes, such as UIComponent, and not a controls class like Button, you must instantiate each of the controls as children of the custom component and arrange them on the screen.

Properties of the individual controls are not accessible from the MXML author's environment unless you design your class to allow this. For example, if you create a component that extends the UIComponent class and uses a Button and a TextArea component, you cannot set the Button control's label text in the MXML tag because you do not directly extend the Button class.

Creating the component

This example component, called ModalText and defined in the file ModalText.as, combines a Button control and a TextArea control. You use the Button control to enable or disable text input in the TextArea control.

Defining event listeners for composite components

Custom components implement the `createChildren()` method to create children of the component, as the following example shows:

```
override protected function createChildren():void {
    super.createChildren();

    // Create and initialize the TextArea control.
    if (!text_mc) {
        text_mc = new TextArea();
        ...
        text_mc.addEventListener("change", handleChangeEvent);
        addChild(text_mc);
    }

    // Create and initialize the Button control.
    if (!mode_mc) {
        mode_mc = new Button();
        ...
        mode_mc.addEventListener("click", handleClickEvent);
        addChild(mode_mc);
    }
}
```

The `createChildren()` method also contains a call to the `addEventListener()` method to register an event listener for the `change` event generated by the TextArea control, and for the `click` event for the Button control. These event listeners are defined within the ModalText class, as the following example shows:

```
// Handle events that are dispatched by the children.
private function handleChangeEvent(eventObj:Event):void {
        dispatchEvent(new Event("change"));
}

// Handle events that are dispatched by the children.
private function handleClickEvent(eventObj:Event):void {
        text_mc.editable = !text_mc.editable;
}
```

You can handle an event dispatched by a child of a composite component in the component. In this example, the event listener for the Button control's `click` event is defined in the class definition to toggle the `editable` property of the TextArea control.

However, if a child component dispatches an event, and you want that opportunity to handle the event outside of the component, you must add logic to your custom component to propagate the event. Notice that the event listener for the `change` event for the TextArea control propagates the event. This lets you handle the event in your application, as the following example shows:

```
<?xml version="1.0"?>
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:MyComp="myComponents.*">

    <fx:Script>
        <![CDATA[

            import flash.events.Event;

            function handleText(eventObj:Event)
            {
                ...
            }
        ]]>
    </fx:Script>

    <MyComp:ModalText change="handleText(event);"/>
</s:Application>
```

Creating the ModalText component

The following code example implements the class definition for the ModalText component. The ModalText component is a composite component that contains a Button control and a TextArea control. This control has the following attributes:

- You cannot edit the TextArea control by default.
- You click the Button control to toggle editing of the TextArea control.
- You use the `textPlacement` property of the control to make the TextArea appear on the right side or the left side of the control.
- Editing the `textPlacement` property of the control dispatches the `placementChanged` event.
- You use the `text` property to programmatically write content to the TextArea control.
- Editing the `text` property of the control dispatches the `textChanged` event.
- Editing the text in the TextArea control dispatches the `change` event.
- You can use both the `textPlacement` property or the `text` property as the source for a data binding expression.
- You can optionally use skins for the up, down, and over states of the Button control.

The following is an example MXML file that uses the ModalText control and sets the `textPlacement` property to `left`:

```
<?xml version="1.0"?>
<!-- asAdvanced/ASAdvancedMainModalText.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:MyComp="myComponents.*" >
    <MyComp:ModalText textPlacement="left" height="40"/>
</s:Application>
```

You can handle the `placementChanged` event to determine when the `ModalText.textPlacement` property is modified, as the following example shows:

```
<?xml version="1.0"?>
<!-- asAdvanced/ASAdvancedMainModalTextEvent.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:MyComp="myComponents.*" >
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
      <![CDATA[
        import flash.events.Event;

        private function placementChangedListener(event:Event):void {
          myEvent.text="placementChanged event occurred - textPlacement = "
              + myMT.textPlacement as String;
        }
      ]]>
    </fx:Script>
    <MyComp:ModalText id="myMT"
        textPlacement="left"
        height="40"
        placementChanged="placementChangedListener(event);"/>
    <mx:TextArea id="myEvent" width="50%"/>
    <mx:Label text="Change Placement" />
    <mx:Button label="Set Text Placement Right"
        click="myMT.textPlacement='right';" />
    <mx:Button label="Set Text Placement Left"
        click="myMT.textPlacement='left';" />
</s:Application>
```

The following example shows the ModalText.as file that defines this control:

```
package myComponents
{
    // asAdvanced/myComponents/ModalText.as
    // Import all necessary classes.
    import mx.core.UIComponent;
    import mx.controls.Button;
    import mx.controls.TextArea;
    import flash.events.Event;
    import flash.text.TextLineMetrics;
    // ModalText dispatches a change event when the text of the child
    // TextArea control changes, a textChanged event when you set the text
    // property of ModalText, and a placementChanged event
    // when you change the textPlacement property of ModalText.
    [Event(name="change", type="flash.events.Event")]
    [Event(name="textChanged", type="flash.events.Event")]
    [Event(name="placementChanged", type="flash.events.Event")]

    /*** a) Extend UIComponent. ***/
    public class ModalText extends UIComponent {
        /*** b) Implement the class constructor. ***/
        public function ModalText() {
            super();
        }
        /*** c) Define variables for the two child components. ***/
```

```
// Declare two variables for the component children.
private var text_mc:TextArea;
private var mode_mc:Button;

/*** d) Embed new skins used by the Button component. ***/
// You can create a SWF file that contains symbols  with the names
// ModalUpSkin, ModalOverSkin, and ModalDownSkin.
// If you do not have skins, comment out these lines.
[Embed(source="Modal2.swf", symbol="blueCircle")]
public var modeUpSkinName:Class;

[Embed(source="Modal2.swf", symbol="blueCircle")]
public var modeOverSkinName:Class;
[Embed(source="Modal2.swf", symbol="greenSquare")]
public var modeDownSkinName:Class;
/*** e) Implement the createChildren() method. ***/
// Test for the existence of the children before creating them.
// This is optional, but we do this so a subclass can create a
// different child instead.
override protected function createChildren():void {
    super.createChildren();
    // Create and initialize the TextArea control.
    if (!text_mc)
    {
        text_mc = new TextArea();
        text_mc.explicitWidth = 80;
        text_mc.editable = false;
        text_mc.text= _text;
        text_mc.addEventListener("change", handleChangeEvent);
        addChild(text_mc);
    }
    // Create and initialize the Button control.
    if (!mode_mc)
    {   mode_mc = new Button();
        mode_mc.label = "Toggle Editing Mode";
        // If you do not have skins available,
        // comment out these lines.
        mode_mc.setStyle('overSkin', modeOverSkinName);
        mode_mc.setStyle('upSkin', modeUpSkinName);
        mode_mc.setStyle('downSkin', modeDownSkinName);
        mode_mc.addEventListener("click", handleClickEvent);
        addChild(mode_mc);
    }
}

/*** f) Implement the commitProperties() method. ***/
override protected function commitProperties():void {
    super.commitProperties();

    if (bTextChanged) {
        bTextChanged = false;
        text_mc.text = _text;
        invalidateDisplayList();
    }
}
/*** g) Implement the measure() method. ***/
// The default width is the size of the text plus the button.
// The height is dictated by the button.
override protected function measure():void {

    // Since the Button control uses skins, get the
    // measured size of the Button control.
    var buttonWidth:Number = mode_mc.getExplicitOrMeasuredWidth();
    var buttonHeight:Number = mode_mc.getExplicitOrMeasuredHeight();
    // The default and minimum width are the measuredWidth
    // of the TextArea control plus the measuredWidth
    // of the Button control.
    measuredWidth = measuredMinWidth =
        text_mc.measuredWidth + buttonWidth;

    // The default and minimum height are the larger of the
    // height of the TextArea control or the measuredHeight of the
    // Button control, plus a 10 pixel border around the text.
    measuredHeight = measuredMinHeight =
        Math.max(mode_mc.measuredHeight,buttonHeight) + 10;
}

/*** h) Implement the updateDisplayList() method. ***/
// Size the Button control to the size of its label text
// plus a 10 pixel border area.
// Size the TextArea to the remaining area of the component.
// Place the children depending on the setting of
// the textPlacement property.
override protected function updateDisplayList(unscaledWidth:Number,
        unscaledHeight:Number):void {
    super.updateDisplayList(unscaledWidth, unscaledHeight);
    // Subtract 1 pixel for the left and right border,
    // and use a 3 pixel margin on left and right.
    var usableWidth:Number = unscaledWidth - 8;
    // Subtract 1 pixel for the top and bottom border,
    // and use a 3 pixel margin on top and bottom.
    var usableHeight:Number = unscaledHeight - 8;

    // Calculate the size of the Button control based on its text.
    var lineMetrics:TextLineMetrics = measureText(mode_mc.label);
    // Add a 10 pixel border area around the text.
    var buttonWidth:Number = lineMetrics.width + 10;
    var buttonHeight:Number = lineMetrics.height + 10;
    mode_mc.setActualSize(buttonWidth, buttonHeight);

    // Calculate the size of the text
    // Allow for a 5 pixel gap between the Button
    // and the TextArea controls.
    var textWidth:Number = usableWidth - buttonWidth - 5;
    var textHeight:Number = usableHeight;
    text_mc.setActualSize(textWidth, textHeight);

    // Position the controls based on the textPlacement property.
    if (textPlacement == "left") {
        text_mc.move(4, 4);
        mode_mc.move(4 + textWidth + 5, 4);
    }
    else {
```

```
                mode_mc.move(4, 4);
                text_mc.move(4 + buttonWidth + 5, 4);
            }

            // Draw a simple border around the child components.
            graphics.lineStyle(1, 0x000000, 1.0);
            graphics.drawRect(0, 0, unscaledWidth, unscaledHeight);
        }

        /*** i) Add methods, properties, and metadata. ***/
        // The general pattern for properties is to specify a private
        // holder variable.
        private var _textPlacement:String = "left";

        // Create a getter/setter pair for the textPlacement property.
        public function set textPlacement(p:String):void {
            _textPlacement = p;
            invalidateDisplayList();
            dispatchEvent(new Event("placementChanged"));
        }

        // The textPlacement property supports data binding.
        [Bindable(event="placementChanged")]
        public function get textPlacement():String {
            return _textPlacement;
        }

        private var _text:String = "ModalText";
        private var bTextChanged:Boolean = false;

        // Create a getter/setter pair for the text property.
        public function set text(t:String):void {
            _text = t;
            bTextChanged = true;
            invalidateProperties();
            dispatchEvent(new Event("textChanged"));
        }

        [Bindable(event="textChanged")]
        public function get text():String {
                return text_mc.text;
        }

        // Handle events that are dispatched by the children.
        private function handleChangeEvent(eventObj:Event):void {
                dispatchEvent(new Event("change"));
        }
        // Handle events that are dispatched by the children.
        private function handleClickEvent(eventObj:Event):void {
                text_mc.editable = !text_mc.editable;
        }
    }
}
```

Troubleshooting

I get an error “don't know how to parse…” when I try to use the component from MXML.

This means that the compiler could not find the SWC file, or the contents of the SWC file did not list the component. Ensure that the SWC file is in a directory that Flex searches, and ensure that your `xmlns` property is pointing to the right place. Try moving the SWC file to the same directory as the MXML file and setting the namespace to "*" as the following example shows:

```
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns="*">
```

For more information, see “Flex compilers” on page 2164.

I get an error “xxx is not a valid attribute…” when I try to use the component from MXML.

Ensure that the attribute is spelled correctly. Also ensure that it is not private.

I don't get any errors, but nothing appears.

Verify that the component was instantiated. One way to do this is to put a Button control and a TextArea control in the MXML application and set the `text` property to the ID for the component when the button is clicked. For example:

```
<!-- This verifies whether a component was instantiated. -->
<zz:mycomponent id="foo"/>
<mx:TextArea id="output"/>
<mx:Button label="Print Output" click="output.text = foo.id;"/>
```

The component is instantiated properly but does not appear (1).

In some cases, helper classes are not ready by the time your component requires them. Flex adds classes to the application in the order that they must be initialized (base classes, and then child classes). However, if you have a static method that gets called as part of the initialization of a class, and that static method has class dependencies, Flex does not know to place that dependent class before the other class, because it does not know when that method is going to be called.

One possible remedy is to add a static variable dependency to the class definition. Flex knows that all static variable dependencies must be ready before the class is initialized, so it orders the class loading correctly.

The following example adds a static variable to tell the linker that class A must be initialized before class B:

```
public class A {

    static function foo():Number {
        return 5;
    }
}

public class B {
    static function bar():Number {
        return mx.example.A.foo();
    }

    static var z = B.bar();
    // Dependency
    static var ADependency:mx.example.A = mx.example.A;
}
```

The component is instantiated properly but does not appear (2).

Verify that the `measuredWidth` and `measuredHeight` properties are nonzero. If they are zero or `NaN`, ensure that you implemented the `measure()` method correctly.

You can also verify that the `visible` property is set to `true`. If `visible is false`, ensure that your component called the `invalidateDisplayList()` method.

The component is instantiated properly but does not appear (3).

It is possible that there is another class or SWC file that overrides your custom class or the symbols used in your component. Ensure that there are no naming conflicts.

Custom style properties

Styles are useful for defining the look and feel of your applications, including letting users set component skins. You can use them to change the appearance of a single component, or apply them across all components, including custom components.

About styles

You can modify the appearance of Flex components through style properties. These properties can define the size of a font used in a Label control, or the background color used in the Tree control. In Flex, some styles are inherited from parent containers to their children, and across style types and classes. This means that you can define a style once, and then have that style apply to all controls of a single type or to a set of controls. Also, you can override individual properties for each control at a local, document, or global level, giving you great flexibility in controlling the appearance of your applications.

For more information, see "Styles and themes" on page 1492.

About inheritance in Cascading Style Sheets

When you implement a style property in an ActionScript component, that property is automatically inherited by any subclasses of your class, just as methods and properties are inherited. This type of inheritance is called object-oriented inheritance.

Some style properties also support Cascading Style Sheet (CSS) inheritance. CSS inheritance means that if you set the value of a style property on a parent container, a child of that container inherits the value of the property when your application runs. For example, if you define the `fontFamily` style as Times for a Panel container, all children of that container use Times for `fontFamily`, unless they override that property.

In general, color and text styles support CSS inheritance, regardless of whether they are set by using CSS or style properties. All other styles do not support CSS inheritance, unless otherwise noted.

If you set a style on a parent that does not support CSS inheritance, such as `textDecoration`, only the parent container uses that value, and not its children. There is an exception to the rules of CSS inheritance. If you use the global type selector in a CSS style definition, Flex applies those style properties to all controls, regardless of whether the properties are inheritable.

For more information about style inheritance, see "About style inheritance" on page 1526.

About setting styles

Flex provide several ways of setting component styles: using MXML tag attributes, calling the setStyle() method, and CSS.

Setting styles using MXML tag attributes

Component users can use MXML tag attributes to set a style property on a component. For example, the following code creates a TextArea control, and then sets the `backgroundColor` style of the component to blue (0x0000FF):

```
<mx:TextArea id="myTA" backgroundColor="0x0000FF"/>
```

Setting styles using the setStyle() method

Component users can use the `setStyle()` method to set a style property on a component. For example, the following code creates a TextArea control, and then sets the `fontWeight` style of the component to bold:

```
var myTA:TextArea=new TextArea();
myTA.setStyle('fontWeight', 'bold');
```

Setting styles using CSS

Component users can use the `<fx:Styles>` tag to set CSS styles in an MXML application, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- createcomps_styles/CCStyles.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myComponents.*" >

    <fx:Style>
        @namespace s "library://ns.adobe.com/flex/spark";
        s|TextArea {fontWeight: "bold"}
    </fx:Style>

    <s:TextArea/>

</s:Application>
```

You can also import an external CSS file, as the following example shows:

```
<fx:Style source="myStyle.css"/>
```

Overriding the styleChanged() method

When a user sets a style on a component, Flex calls the component's `styleChanged()` method, passing to it the name of the style being set. When you create a custom component, you can override the UIComponent.styleChanged() method to check the style name passed to it, and handle the change accordingly, as the following example shows:

```
var bBackgroundColor:Boolean=false;

override public function styleChanged(styleProp:String):void {

    super.styleChanged(styleProp);

    // Check to see if style changed.
    if (styleProp=="backgroundColor")
    {
        bBackgroundColor=true;
        invalidateDisplayList();
        return;
    }
}
```

The `styleChanged()` method first calls superclass' `styleChanged()` method to let the superclass handle the style change.

After the superclass gets a call to handle the style change, your component can detect that the user set the `backgroundColor` style, and handle it. By handling the style change after the superclass makes the change, you can override the way the superclass handles the style.

Notice that the method calls the invalidateDisplayList() method, which causes Flex to execute the component's `updateDisplayList()` method at the next screen update. Although you can detect style changes in the `styleChanged()` method, you still use the updateDisplayList() method to draw the component on the screen. For more information, see "Defining a style property" on page 2504.

Typically, you use a flag to indicate that a style changed. In the `updateDisplayList()` method, you check the flag and update the component based on the new style setting, as the following example shows:

```
override protected function updateDisplayList(unscaledWidth:Number, unscaledHeight:Number):void {

    super.updateDisplayList(unscaledWidth, unscaledHeight);

    // Check to see if style changed.
    if (bBackgroundColor==true)
    {
        // Redraw the component using the new style.
        ...
    }
}
```

By using flags to signal style updates to the `updateDisplayList()` method, the `updateDisplayList()` method has to perform only the updates based on the style changes; it may not have to redraw or recalculate the appearance of the entire component. For example, if you are changing only the border color of a component, it is more efficient to redraw only the border, rather than redrawing the entire component every time someone changes a style.

Example: Creating style properties

When you create a component, you might want to create a style property so that component users can configure it by using styles. For example, you create a component, named StyledRectangle, that uses a gradient fill pattern to define its color, as the following example shows:

This gradient is defined by two colors that you set by using a new style property called `fillColors`. The `fillColors` style takes an array of two colors that component users can set. The StyledRectangle.as class defines default colors for the `fillColors` style, but you can also set them, as the following example shows:

```
<?xml version="1.0"?>
<!-- skinstyle\MainRectWithFillStyles.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myComponents.*">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <!-- Set style by using a CSS type selector. -->
    <fx:Style>
        @namespace "myComponents.*";
        StyledRectangle {fillColors: #FF00FF, #00FFFF}
    </fx:Style>
    <!-- By default, use the style defined by the CSS type selector. -->
    <MyComp:StyledRectangle id="mySR1"/>
    <!-- By default, use the style defined by the CSS type selector. -->
    <MyComp:StyledRectangle id="mySR2"/>
    <!-- Change the default style by using the setStyle() method. -->
    <mx:Button label="Set gradient"
        click="mySR2.setStyle('fillColors', [0x000000, 0xFFFFFF]);"/>
    <!-- Set fillColors in MXML. -->
    <MyComp:StyledRectangle id="mySR3" fillColors="[0x00FF00, 0xFFFFFF]"/>
</s:Application>
```

In this example, the CSS type selector for the StyledRectangle component sets the initial values of the `fillColors` property to `#FF00FF` and `#00FFFF`. For the second StyledRectangle components, you use the `click` event of a Button control to change the `fillColor` style by using the `setStyle()` method. The third component sets the style property by using an MXML tag attribute.

Defining a style property

You define a style property for a component in the class definition.

1. Insert the `[Style]` metadata tag that defines the style before the class definition.

   You insert the `[Style]` metadata tag before the class definition to define the MXML tag attribute for a style property. If you omit the `[Style]` metadata tag, the MXML compiler issues a syntax error when you try to set the property as an MXML tag attribute.

   The `[Style]` metadata tag has the following syntax:

   ```
   [Style(name="style_name"[,property="value",...])]
   ```

   For more information, see "Metadata tags in custom components" on page 2376.

2. Override the styleChanged() method to detect changes to the property.

3. Override updateDisplayList() method to incorporate the style into the component display.

4. Define a static initializer to set the default value of the style property.

   For more information, see "Setting default style values" on page 2506.

The following code example defines the StyledRectangle component and the `fillColors` style. It also defines a second style property named `alphas` that you can use to set the alpha values of the fill:

```
package myComponents
{
    // skinstyle/myComponents/StyledRectangle.as
    import mx.core.UIComponent;
    import mx.styles.CSSStyleDeclaration;
    import mx.styles.StyleManager;
    import flash.display.GradientType;
    import mx.core.FlexGlobals;
    // Insert the [Style] metadata tag to define the name, type
    // and other information about the style property for the
    // MXML compiler.
    [Style(name="fillColors",type="Array",format="Color",inherit="no")]
    [Style(name="alphas",type="Array",format="Number",inherit="no")]
    public class StyledRectangle extends UIComponent
    {
        // Define a static variable.
        private static var classConstructed:Boolean = classConstruct();

        // Define a static method.
        private static function classConstruct():Boolean {
            if 
(!FlexGlobals.topLevelApplication.styleManager.getStyleDeclaration("myComponents.StyledRecta
ngle"))
            {
                // If there is no CSS definition for StyledRectangle,
                // then create one and set the default value.
                var myRectStyles:CSSStyleDeclaration = new CSSStyleDeclaration();
                myRectStyles.defaultFactory = function():void
                {
                    this.fillColors = [0xFF0000, 0x0000FF];
                    this.alphas = [0.5, 0.5];
                }

FlexGlobals.topLevelApplication.styleManager.setStyleDeclaration("myComponents.StyledRectang
le", myRectStyles, true);
            }
            return true;
        }

        // Constructor
        public function StyledRectangle() {
            super();
        }

        // Define a default size of 100 x 100 pixels.
        override protected function measure():void {
            super.measure();
            measuredWidth = measuredMinWidth = 100;
            measuredHeight = measuredMinHeight = 100;
        }
        // Define the flag to indicate that a style property changed.
        private var bStypePropChanged:Boolean = true;
        // Define the variable to hold the current gradient fill colors.
        private var fillColorsData:Array;
        // Define the variable to hold the current alpha values.
        private var alphasData:Array;
        // Define the variable for additional control on the fill.
        // You can create a style property for this as well.
        private var ratios:Array = [0x00, 0xFF];

        // Override the styleChanged() method to detect changes in your new style.
        override public function styleChanged(styleProp:String):void {
            super.styleChanged(styleProp);
            // Check to see if style changed.
            if (styleProp=="fillColors" || styleProp=="alphas")
            {
                bStypePropChanged=true;
                invalidateDisplayList();
                return;
            }
        }

        // Override updateDisplayList() to update the component
        // based on the style setting.
        override protected function updateDisplayList(unscaledWidth:Number,
                unscaledHeight:Number):void {
            super.updateDisplayList(unscaledWidth, unscaledHeight);
            // Check to see if style changed.
            if (bStypePropChanged==true)
            {
                // Redraw gradient fill only if style changed.
                fillColorsData=getStyle("fillColors");
                alphasData=getStyle("alphas");

                graphics.beginGradientFill(GradientType.LINEAR,
                    fillColorsData, alphasData, ratios);
                graphics.drawRect(0, 0, unscaledWidth, unscaledHeight);

                bStypePropChanged=false;
            }
        }
    }
}
```

Setting default style values

One of the issues that you have to decide when you create a style property for your component is how to set its default value. Setting a default value for a style property is not as simple as calling the setStyle`()` method in the component's constructor; you must take into consideration how Flex processes styles, and the order of precedence of styles.

When Flex compiles your application, Flex first examines any style definitions in the `<fx:Style>` tag, before it creates any components. Therefore, if you call `setStyle()` from within the component's constructor, which occurs after processing the `<fx:Style>` tag, you set the style property on each instance of the component; this overrides any conflicting CSS declarations in the `<fx:Style>` tag.

The easiest way to set a default value for a style property is to define a static initializer in your component. A static initializer is executed once, the first time Flex creates an instance of a component. In "Defining a style property" on page 2504, you defined a static initializer, by using the `classConstructed` variable and the `classConstruct()` method, as part of the StyledRectangle.as class.

The `classConstruct()` method is invoked the first time Flex creates a StyledRectangle component. This method determines whether a style definition for the StyledRectangle class already exists, defined by using the `<fx:Style>` tag. If no style is defined, the `classConstruct()` method creates one, and sets the default value for the style property.

Therefore, if you omit the `<fx:Style>` tag from your application, the style definition is created by the `classConstruct()` method, as the following example shows:

```
<?xml version="1.0"?>
<!-- skinstyle\MainRectNoStyles.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myComponents.*">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <MyComp:StyledRectangle/>

</s:Application>
```

If you include the `<fx:Style>` tag, the `<fx:Style>` tag creates the default style definition, as the following example shows:

```
<?xml version="1.0"?>
<!-- skinstyle\MainRectCSSStyles.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myComponents.*">

    <fx:Style>
        @namespace "myComponents.*";
        StyledRectangle {fillColors: #FF00FF, #00FFFF}
    </fx:Style>
    <MyComp:StyledRectangle/>

</s:Application>
```

Template components

One way to create reusable components is to define them as template components. A template component defines properties with a general data type that lets the component user specify an object of a concrete data type when using the component. By using a general data type to define component properties, you create highly reusable components that can work with many different types of objects.

About template components

A standard component defines a property with a concrete data type, such as Number or String. The component user must then pass a value that exactly matches the property's data type or else Adobe® Flex® issues a compiler error.

A *template component* is a component in which one or more of its properties is defined with a general data type. This property serves as a slot for values that can be of the exact data type of the property, or of a value of a subclass of the data type. For example, to accept any Flex visual component as a property value, you define the data type of the property as UIComponent. To accept only container components, you define the data type of the property as Container.

When you use the template component in an application, the component user sets the property value to be an object with a concrete data type. You can think of the property as a placeholder for information, where it is up to the component user, rather than the component developer, to define the actual data type of the property.

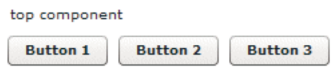
The following example shows an application that uses a template component called MyTemplateComponent:

```
<?xml version="1.0"?>
<!-- templating/MainTemplateButton.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myComponents.*"
    height="700" width="700">
    <s:Panel>
        <MyComp:MyTemplateComponent id="myTComp1">
            <MyComp:topRow>
                <s:Label text="top component"/>
            </MyComp:topRow>
            <MyComp:bottomRow>
                <s:Button label="Button 1"/>
                <s:Button label="Button 2"/>
                <s:Button label="Button 3"/>
            </MyComp:bottomRow>
        </MyComp:MyTemplateComponent>
    </s:Panel>
</s:Application>
```

The MyTemplateComponent takes two properties:

- The `topRow` property specifies the single Flex component that appears in the top row of the VGroup container.
- The `bottomRow` property specifies one or more Flex components that appear along the bottom row of the VGroup container.

The implementation of the MyTemplateComponent consists of a VGroup container that displays its children in two rows. The following image shows the output of this application:



The implementation of the `topRow` and `bottomRow` properties lets you specify any Flex component as a value, as the following example shows:

```
<?xml version="1.0"?>
<!-- templating/MainTemplateLink.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myComponents.*"
    height="700" width="700">
    <s:Panel>

        <MyComp:MyTemplateComponent id="myTComp2">
            <MyComp:topRow>
                <s:TextArea text="top component"/>
            </MyComp:topRow>
            <MyComp:bottomRow>
                <mx:LinkButton label="Link 1"/>
                <mx:LinkButton label="Link 2"/>
                <mx:LinkButton label="Link 3"/>
            </MyComp:bottomRow>
        </MyComp:MyTemplateComponent>
    </s:Panel>
</s:Application>
```

In this example, the top component is a TextArea control, and the bottom components are two LinkButton controls.

Implementing a template component

The section “About template components” on page 2507 shows an example of a template component named MyTemplateComponent. Flex provides you with two primary ways to create template components:

- Create properties with general data types, such as UIComponent or Container.
- Create properties with the type IDeferredInstance.

Using general data types in a template component

One way to implement the component MyTemplateComponent (see “About template components” on page 2507) is to define the properties `topRow` and `bottomRow` as type UIComponent. Users of the component can specify any object to these properties that is an instance of the UIComponent class, or an instance of a subclass of UIComponent.

The following code shows the implementation of MyTemplateComponent:

```
<?xml version="1.0"?>
<!-- templating/myComponents/MyTemplateComponent.mxml -->
<s:VGroup xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    initialize="init();">
    <fx:Script>
        <![CDATA[

            import spark.components.HGroup;
            import mx.core.UIComponent;

            // Define a property for the top component.
            public var topRow:UIComponent;
            // Define an Array of properties for a row of components.
            // Restrict the type of the Array elements
            // to mx.core.UIComponent.
            [ArrayElementType("mx.core.UIComponent")]
            public var bottomRow:Array;

            private function init():void {
                // Add the top component to the VGroup container.
                addElement(topRow);
                // Create an HGroup container. This container
                // is the parent container of the bottom row of components.
                var controlHGroup:HGroup = new HGroup();
                // Add the bottom row of components
                // to the HGroup container.
                for (var i:int = 0; i < bottomRow.length; i++)
                    controlHGroup.addElement(bottomRow[i]);
                // Add the HGroup container to the VGroup container.
                addElement(controlHGroup);
            }
        ]]>
    </fx:Script>
</s:VGroup>
```

For the `bottomRow` property, you define it as an Array and include the `[ArrayElementType]` metadata tag to specify to the compiler that the data type of the Array elements is also UIComponent. For more information on the `[ArrayElementType]` metadata tag, see “Metadata tags in custom components” on page 2376.

Using IDeferredInstance in a template component

Deferred creation is a feature of Flex where Flex containers create only the controls that initially appear to the user. Flex then creates the container’s other descendants if the user navigates to them. For more information, see “Improving startup performance” on page 2333.

You can create a template component that also takes advantage of deferred creation. Rather than having Flex create your component and its properties when the application loads, you can define a component that creates its properties only when a user navigates to the area of the application that uses the component. This is especially useful for large components that may have many child components. Flex view states make use of this feature.

The following example shows an alternative implementation for the MyTemplateComponent component shown in the section “About template components” on page 2507, named MyTemplateComponentDeferred.mxml, by defining the topRow and bottomRow properties to be of type IDeferredInstance:

```
<?xml version="1.0"?>
<!-- templating/myComponents/MyTemplateComponentDeferred.mxml -->
<s:VGroup xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    initialize="init();">
    <fx:Script>
        <![CDATA[

            import spark.components.HGroup;
            import mx.core.UIComponent;

            // Define a deferred property for the top component.
            public var topRow:IDeferredInstance;
            // Define an Array of deferred properties
            // for a row of components.
            [ArrayElementType("mx.core.IDeferredInstance")]
            public var bottomRow:Array;

            private function init():void {
                // Add the top component to the VGroup container.
                // Cast the IDeferredInstance object to UIComponent
                // so that you can add it to the parent container.
                addElement(UIComponent(topRow.getInstance()));
                // Create an HGroup container. This container
                // is the parent container of the bottom row of components.
                var controlHGroup:HGroup = new HGroup();

                // Add the bottom row of components
                // to the HGroup container.
                for (var i:int = 0; i < bottomRow.length; i++)
            controlHGroup.addElement(UIComponent(bottomRow[i].getInstance()));
                // Add the HBox container to the VGroup container.
                addElement(controlHGroup);
            }
        ]]>
    </fx:Script>
</s:VGroup>
```

The IDeferredInstance interface defines a single method, `getInstance()`. Flex calls the `getInstance()` method to initialize a property when it creates an instance of the component. A subsequent call to the `getInstance()` method returns a reference to the property value.

In MXML, when the compiler encounters a value declaration for a property of type IDeferredInstance, instead of generating code to construct and assign the value to the property, the compiler generates code to construct and assign an IDeferredInstance implementation object, which then produces the value at run time.

You can pass any data type to a property of type IDeferredInstance. In the example in the section “About template components” on page 2507, you pass a Label control to the `topRow` property, and three Button controls to the `bottomRow` property.

Notice in the example that the `addElement()` methods that take `topRow` and `bottomRow` as arguments cast them to UIComponent. This cast is necessary because the `addElement()` method can only add an object that implements the IUIComponent interface to a container, and the `DeferredInstance.getInstance()` method returns a value of type Object.

Defining properties using the IDeferredInstance interface

You can define component properties of type IDeferredInstance.

Defining a generic property

To define a generic property, one with no associated data type, you define its type as IDeferredInstance, as the following example shows:

```
// Define a deferred property for the top component.
public var topRow:IDeferredInstance;
```

The user of the component can then specify an object of any type to the property. It is your responsibility in the component implementation to verify that the value passed by the user is of the correct data type.

Restricting the data type of a property

You use the `[InstanceType]` metadata tag to specify the allowed data type of a property of type IDeferredInstance, as the following example shows:

```
// Define a deferred property for the top component.
[InstanceType("spark.components.Label")]
public var topRow:IDeferredInstance;
```

The Flex compiler validates that users only assign values of the specified type to the property. In this example, if the component user sets the `topRow` property to a value of a type other than spark.components.Label, the compiler issues an error message.

Defining an array of template properties

You can define an Array of template properties, as the following example shows:

```
// Define an Array of deferred properties for a row of components.
// Do not restrict the type of the component.
[ArrayElementType("mx.core.IDeferredInstance")]
public var bottomRow:Array;

// Define an Array of deferred properties for a row of components.
// Restrict the type of the component to mx.controls.Button.
[InstanceType("mx.controls.Button")]
[ArrayElementType("mx.core.IDeferredInstance")]
public var bottomRow:Array;
```

In the first example, you can assign a value of any data type to the `bottomRow` property. Each array element's `getInstance()` method is not called until the element is used.

In the second example, you can only assign values of type spark.components.Button to it. Each Array element is created when the application loads. The following template component shows an alternative implementation of the MyTemplateComponent that restricts the type of components to be of type mx.controls.Button:

```
<?xml version="1.0"?>
<!-- templating/myComponents/MyTemplateComponentDeferredSpecific.mxml -->
<s:VGroup xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    initialize="init();">

    <fx:Script>
        <![CDATA[

            import spark.components.HGroup;
            import mx.core.UIComponent;

            [InstanceType("spark.components.Label")]
            public var topRow:IDeferredInstance;
            // Define an Array of deferred properties
            // for a row of components.
            // Restrict the type of the component
            // to mx.controls.Button.
            [InstanceType("spark.components.Button")]
            [ArrayElementType("mx.core.IDeferredInstance")]
            public var bottomRow:Array;

            private function init():void {
                addElement(UIComponent(topRow.getInstance()));
                var controlHGroup:HGroup = new HGroup();
                for (var i:int = 0; i < bottomRow.length; i++)
            controlHGroup.addElement(UIComponent(bottomRow[i].getInstance()));
                addElement(controlHGroup);
            }
        ]]>
    </fx:Script>
</s:VGroup>
```

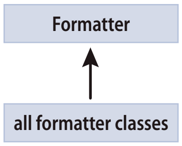
Custom formatters

Adobe® Flex® includes several predefined formatters that you can use in your applications to format data. You also might have to extend the functionality of these predefined formatters, or create formatters for your specific application needs.

For more information on using formatters, see “Formatting Data” on page 2004.

Creating a custom formatter

You create a custom formatter by creating a class that extends the mx.formatters.Formatter base class, or by creating a class that extends one of the standard formatter classes, which all extend mx.formatters.Formatter. The following example shows the class hierarchy for formatters:



Like standard formatter classes, your custom formatter class must contain a public `format()` method that takes a single argument and returns a String that contains the formatted data. Most of the processing of your custom formatter occurs within the `format()` method.

Your custom formatter also might let the user specify which pattern formats the data. Where applicable, the Flex formatters, such as the ZipCodeFormatter, use a `formatString` property to pass a format pattern. Some Flex formatters, such as the NumberFormatter and CurrencyFormatter classes, do not have `formatString` properties, because they use a set of properties to configure formatting.

Creating a simple formatter

This example defines a simple formatter class that converts any String to all uppercase or all lowercase letters depending on the value passed to the `formatString` property. By default, the formatter converts a String to all uppercase.

```
package myFormatters
{
    // formatters/myFormatter/SimpleFormatter.as
    import mx.formatters.Formatter
    import mx.formatters.SwitchSymbolFormatter
    public class SimpleFormatter extends Formatter
    {
        // Declare the variable to hold the pattern string.
        public var myFormatString:String = "upper";
        // Constructor
        public function SimpleFormatter() {
            // Call base class constructor.
            super();
        }
        // Override format().
        override public function format(value:Object):String {
            // 1. Validate value - must be a nonzero length string.
            if( value.length == 0)
                {   error="0 Length String";
                    return ""
                }
            // 2. If the value is valid, format the string.
            switch (myFormatString) {
                case "upper" :
                    var upperString:String = value.toUpperCase();
                    return upperString;
                    break;
                case "lower" :
                    var lowerString:String = value.toLowerCase();
                    return lowerString;
                    break;
                default :
                    error="Invalid Format String";
                    return ""
            }
        }
    }
}
```

You can use this formatter in an application, as the following example shows:

```
<?xml version="1.0" ?>
<!-- createcomps_formatters/FormatterSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myFormatters.*">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Declarations>
        <!-- Declare a formatter and specify formatting properties. -->
        <MyComp:SimpleFormatter id="upperFormat" myFormatString="upper" />
    </fx:Declarations>
    <!-- Trigger the formatter while populating a string with data. -->
    <mx:TextInput id="myTI" />

    <mx:TextArea text="Your uppercase string is {upperFormat.format(myTI.text)}" />
</s:Application>
```

The namespace declaration in the `<s:Application>` tag specifies to use the `MyComp` prefix when referencing the formatter, and the location of the formatter's ActionScript file. That file is in the myFormatters subdirectory of the application, or in the default classpath of the application. For more information on deploying your formatters, see "Component compilation" on page 2392.

Handling errors in formatters

For all formatter classes, except for the SwitchSymbolFormatter class, when an error occurs, the formatter returns an empty string and writes a string that describes the error condition to the formatter's `error` property. The `error` property is inherited from the Formatter superclass.

In your application, you can test for an empty string in the result returned by the formatter. If detected, you can check the `error` property to determine the cause of the error. For an example that handles a formatter error, see "Formatting Data" on page 2004. For more information on the SwitchSymbolFormatter class, see "Using the SwitchSymbolFormatter class" on page 2515.

Using the SwitchSymbolFormatter class

You can use the SwitchSymbolFormatter utility class when you create custom formatters. You use this class to replace placeholder characters in one string with numbers from a second string.

For example, you specify the following information to the SwitchSymbolFormatter class:

Format string The Social Security number is: ###-##-####"

Input string "123456789"

The SwitchSymbolFormatter class parses the format string and replaces each placeholder character with a number from the input string in the order in which the numbers are specified in the input string. The default placeholder character is the number sign (#). You can define a different placeholder character by passing it to the constructor when you create a SwitchSymbolFormatter object. For an example, see "Using a different placeholder character" on page 2516.

The SwitchSymbolFormatter class creates the following output string from the Format and Input strings:

```
"The Social Security number is: 123-45-6789"
```

You pass the format string and input string to the SwitchSymbolFormatter.formatValue() method to create the output string, as the following example shows:

```
<?xml version="1.0" ?>
<!-- createcomps_formatters/FormatterSwitchSymbol.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <fx:Script>
    <![CDATA[

      import mx.formatters.SwitchSymbolFormatter;
      // Event handler to validate and format input.
      private function formatVal():void {

        var switcher:SwitchSymbolFormatter=new SwitchSymbolFormatter('#');
        formattedSCNumber.text =
          switcher.formatValue("Formatted Social Securty number: ###-##-#### ", scNum.text);
      }
    ]]>
  </fx:Script>
    <mx:Label
        text="Enter a 9 digit Social Security number with no separator characters:"/>
    <mx:TextInput id="scNum"
        text=""
        maxChars="9" width="50%"/>
  <mx:Button label="Format"
      click="formatVal();"/>
  <mx:TextInput id="formattedSCNumber"
      editable="false" width="75%"/>
</s:Application>
```

You can mix alphanumeric characters and placeholder characters in this format string. The format string can contain any characters that are constant for all values of the numeric portion of the string. However, the input string for formatting must be numeric. The number of digits supplied in the source value must match the number of digits defined in the format string.

Using a different placeholder character

By default, the SwitchSymbolFormatter class uses a number sign (#) as the placeholder character to indicate a number substitution within its format string. However, sometimes you might want to include a number sign in your actual format string. Then, you must use a different symbol to indicate a number substitution slot within the format string. You can select any character for this alternative symbol as long as it doesn’t appear in the format string.

For example, to use the ampersand character (&) as the placeholder, you create an instance of the SwitchSymbolFormatter class, as the following example shows:

```
var dataFormatter = new SwitchSymbolFormatter("&");
```

Handling errors with the SwitchSymbolFormatter class

Unlike other formatters, the SwitchSymbolFormatter class does not write its error messages into an `error` property. Instead, it is your responsibility to test for error conditions and return an error message if appropriate.

The custom formatter component in the following example formats nine-digit Social Security numbers by using the SwitchSymbolFormatter class:

```
package myFormatters
{
    // formatters/myFormatter/CustomSSFormatter.as
    import mx.formatters.Formatter
    import mx.formatters.SwitchSymbolFormatter
    public class CustomSSFormatter extends Formatter
    {
        // Declare the variable to hold the pattern string.
        public var formatString : String = "###-##-####";
        // Constructor
        public function CustomSSFormatter() {
            // Call base class constructor.
            super();
        }
        // Override format().
        override public function format( value:Object ):String {
            // Validate input string value - must be a 9-digit number.
            // You must explicitly check if the value is a number.
            // The formatter does not do that for you.
            if( !value  || value.toString().length != 9)
                {   error="Invalid String Length";
                    return ""
                }
            // Validate format string.
            // It must contain 9 number placeholders.
            var numCharCnt:int = 0;
            for( var i:int = 0; i<formatString.length; i++ )
                {
                    if( formatString.charAt(i) == "#" )
                    {   numCharCnt++;
                    }
                }
            if( numCharCnt != 9 )
            {
                error="Invalid Format String";
                return ""
            }
            // If the formatString and value are valid, format the number.
            var dataFormatter:SwitchSymbolFormatter =
                new SwitchSymbolFormatter();
            return dataFormatter.formatValue( formatString, value );
        }
    }
}
```

The following example uses this custom formatter in an application:

```
<?xml version="1.0" encoding="UTF-8"?>
<!-- createcomps_formatters/FormatterSS.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myFormatters.*">
    <fx:Declarations>
        <!-- Declare a formatter and specify formatting properties. -->
        <MyComp:CustomSSFormatter id="SSFormat"
            formatString="SS: #-#-#-#-#-#-#-#-#"/>
    </fx:Declarations>
    <!-- Trigger the formatter while populating a string with data. -->
    <mx:TextInput text="Your SS number is {SSFormat.format('123456789')}"/>
</s:Application>
```

Extending a Formatter class

You can extend the Formatter class to create a custom formatter, or any formatter class. The example in this section extends the ZipCodeFormatter class by allowing an extra format pattern: "#####*####".

In this example, if the user omits a format string, or specifies the default value of "#####*####", the formatter returns the ZIP code using the format "#####*####". If the user specifies any other format string, such as a five-digit string in the form "#####", the custom formatter calls the `format()` method in the superclass ZipCodeFormatter class to format the data.

```
package myFormatters
{
    // formatters/myFormatter/ExtendedZipCodeFormatter.as
    import mx.formatters.Formatter
    import mx.formatters.ZipCodeFormatter
    import mx.formatters.SwitchSymbolFormatter
    public class ExtendedZipCodeFormatter extends ZipCodeFormatter {
        // Constructor
        public function ExtendedZipCodeFormatter() {
            // Call base class constructor.
            super();
            // Initialize formatString.
            formatString = "#####*####";
        }
        // Override format().
        override public function format(value:Object):String {
            // 1. If the formatString is our new pattern,
            // then validate and format it.
            if( formatString == "#####*####" ){
                if( String( value ).length == 5 )
                    value = String( value ).concat("0000");
                if( String( value ).length == 9 ){
                    var dataFormatter:SwitchSymbolFormatter =
                        new SwitchSymbolFormatter();
                    return dataFormatter.formatValue( formatString, value );
                }
                else {
                    error="Invalid String Length";
                    return ""
                    }
                }
            // If the formatString is anything other than '#####*####,
            // call super and validate and format as usual using
            // the base ZipCodeFormatter.
            return super.format(value);
        }
    }
}
```

Notice that the ExtendedZipCodeFormatter class did not have to define a `formatString` property because it is already defined in its base class, ZipCodeFormatter.

The following example uses this custom formatter in an application:

```
<?xml version="1.0" encoding="UTF-8"?>
<!-- createcomps_formatters/FormatterZC.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myFormatters.*">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Declarations>
        <!-- Declare a formatter and specify formatting properties. -->
        <MyComp:ExtendedZipCodeFormatter id="ZipCodeFormat"/>
    </fx:Declarations>
    <!-- Trigger the formatter while populating a string with data. -->
    <mx:TextInput width="220"
        text="Your zipcode number is {ZipCodeFormat.format('123456789')}"/>
</s:Application>
```

Custom validators

Data validators let you validate the data in an object. Adobe® Flex® supplies a number of standard validators that you can use in your application, but you can also define custom validators for your specific application needs.

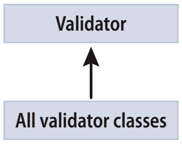
For information on the standard validators, see “Validating Data” on page 1964.

Validating data by using custom validators

The data that a user enters in a user interface might or might not be appropriate for the application. In Flex, you use a *validator* to ensure the values in the fields of an object meet certain criteria. For example, you can use a validator to ensure that a user enters a valid phone number value in a TextInput control.

Flex includes a set of validators for common types of user input data, such as ZIP codes, phone numbers, and credit cards. Although Flex supplies a number of commonly used validators, your application may require you to create custom validator classes. The mx.validators.Validator class is an ActionScript class that you can extend to add your own validation logic. Your classes can extend the functionality of an existing validator class, or you can implement new functionality in your custom validator class.

The following image shows the class hierarchy for validators:



About overriding the doValidation() method

Your custom validator class must contain an override of the protected Validator.doValidation() method that takes a single argument, `value`, of type Object, and returns an Array of ValidationResult objects. You return one ValidationResult object for each field that the validator examines and that fails the validation. For fields that pass the validation, you omit the ValidationResult object.

You do not have to create a ValidationResult object for fields that validate successfully. Flex creates those ValidationResult objects for you.

The base Validator class implements the logic to handle required fields by using the `required` property. When set to `true`, this property specifies that a missing or empty value in a user-interface control causes a validation error. To disable this verification, set this property to `false`.

In the `doValidation()` method of your validator class, you typically call the base class's `doValidation()` method to perform the verification for a required field. If the user did not enter a value, the base class issues a validation error stating that the field is required.

The remainder of the `doValidation()` method contains your custom validation logic.

About the ValidationResult class

The `doValidation()` method returns an Array of ValidationResult objects, one for each field that generates a validation error. The ValidationResult class defines several properties that let you record information about any validation failures, including the following:

errorCode A String that contains an error code. You can define your own error codes for your custom validators.

errorMessage A String that contains the error message. You can define your own error messages for your custom validators.

isError A Boolean value that indicates whether or not the result is an error. Set this property to `true`.

subField A String that specifies the name of the subfield associated with the ValidationResult object.

In your override of the `doValidation()` method, you can define an empty Array and populate it with ValidationResult objects as your validator encounters errors.

About the validate() method

You use the `Validator.validate()` method to programmatically invoke a validator from within a Flex application. However, you should never override this method in your custom validator classes. You need to override only the `doValidation()` method.

Example: Creating a simple validator

You can use the StringValidator class to validate that a string is longer than a minimum length and shorter than a maximum length, but you cannot use it to validate the contents of a string. This example creates a simple validator class that determines if a person is more than 18 years old based on their year of birth.

This validator extends the Validator base class, as the following example shows:

```
package myValidators
{
    import mx.validators.Validator;
    import mx.validators.ValidationResult;
    public class AgeValidator extends Validator {
        // Define Array for the return value of doValidation().
        private var results:Array;
        // Constructor.
        public function AgeValidator() {
            // Call base class constructor.
            super();
        }

        // Define the doValidation() method.
        override protected function doValidation(value:Object):Array {

            // Convert value to a Number.
            var inputValue:Number = Number(value);
            // Clear results Array.
            results = [];
            // Call base class doValidation().
            results = super.doValidation(value);
            // Return if there are errors.
            if (results.length > 0)
                return results;

            // Create a variable and initialize it to the current date.
            var currentYear:Date = new Date();

            // If input value is not a number, or contains no value,
            // issue a validation error.
            if (isNaN(inputValue) || !value )
            {
                results.push(new ValidationResult(true, null, "NaN",
                    "You must enter a year."));
                return results;
            }
            // If calculated age is less than 18, issue a validation error.
            if ((currentYear.getFullYear() - inputValue) < 18) {
                results.push(new ValidationResult(true, null, "tooYoung",
                    "You must be 18."));
                return results;
            }

            return results;
        }
    }
}
```

This example first defines a public constructor that calls `super()` to invoke the constructor of its base class. The base class can perform the check to ensure that data was entered into a required field, if you set the `required` property of the validator to `true`.

Notice that the second argument of the constructor for the ValidationResult class is `null`. You use this argument to specify a subfield, if any, of the object being validated that caused the error. When you are validating a single field, you can omit this argument. For an example that validates multiple fields, see “Example: Validating multiple fields” on page 2523.

You can use this validator in your Flex application, as the following example shows:

```
<?xml version="1.0" ?>
<!-- createcomps_validators/MainAgeValidator.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myValidators.*">
    <fx:Declarations>
        <MyComp:AgeValidator id="ageV"
            required="true"
            source="{birthYear}"
            property="text" />
    </fx:Declarations>

    <s:Form >
        <s:FormItem label="Enter birth year: ">
            <s:TextInput id="birthYear"/>
        </s:FormItem>
        <s:FormItem label="Enter birth year: ">
            <s:Button label="Submit"/>
        </s:FormItem>
    </s:Form>
</s:Application>
```

The `package` statement for your custom validator specifies that you should deploy it in a directory called `myValidators`. In the previous example, you place it in the subdirectory of the directory that contains your Flex application. Therefore, the namespace definition in your Flex application is `xmlns:MyComp="myValidators.*"`. For more information on deployment, see “Component compilation” on page 2392.

Example: Validating multiple fields

A validator can validate more than one field at a time. For example, you could create a custom validator called NameValidator to validate three input controls that represent a person’s first, middle, and last names.

To create a validator that examines multiple fields, you can either define properties on the validator that let you specify the multiple input fields, as does the Flex DateValidator class, or you can require that the single item passed to the validator includes all of the fields to be validated.

In the following example, you use a NameValidator that validates an item that contains three fields named `first`, `middle`, and `last`:

```
<?xml version="1.0" ?>
<!-- createcomps_validators/MainNameValidator.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myValidators.*">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Declarations>
        <fx:Model id="person">
            <name>
              <custName>
                 <first>{firstInput.text}</first>
                 <middle>{middleInput.text}</middle>
                 <last>{lastInput.text}</last>
              </custName>
            </name>
        </fx:Model>
        <MyComp:NameValidator id="nameVal"
            source="{person}" property="custName"
            listener="{firstInput}"/>
    </fx:Declarations>
    <mx:TextInput id="firstInput"/>
    <mx:TextInput id="middleInput"/>
    <mx:TextInput id="lastInput"/>
    <mx:Button label="Validate"
        click="nameVal.validate();"/>
</s:Application>
```

This validator examines three input fields. You specify `firstInput` as the validation listener. Therefore, when a validation error occurs, Flex shows a validation error message on the first TextInput control.

You can implement the NameValidator class, as the following example shows:

```
package myValidators
{
    import mx.validators.Validator;
    import mx.validators.ValidationResult;
    public class NameValidator extends Validator {
        // Define Array for the return value of doValidation().
        private var results:Array;
        public function NameValidator () {
            super();
        }
        override protected function doValidation(value:Object):Array {

            var fName:String = value.first;
            var mName:String = value.middle;
            var lName:String = value.last;

            // Clear results Array.
            results = [];
            // Call base class doValidation().
            results = super.doValidation(value);
            // Return if there are errors.
            if (results.length > 0)
```

```
                return results;
            // Check first name field.
            if (fName == "" || fName == null) {
                results.push(new ValidationResult(true,
                    "first", "noFirstName", "No First Name."));
                return results;
            }

            // Check middle name field.
            if (mName == "" || mName == null) {
                results.push(new ValidationResult(true,
                    "middle", "noMiddleName", "No Middle Name."));
                return results;
            }
            // Check last name field.
            if (lName == "" || lName == null) {
                results.push(new ValidationResult(true,
                    "last", "noLastName", "No Last Name."));
                return results;
            }

            return results;
        }
    }
}
```

In this example, because you are using a single validator to validate three subfields of the Object passed to the validator, you include the optional second argument to the constructor for the ValidationResult class to specify the subfield that caused the validation error. This inclusion permits Flex to identify the input component that caused the error, and to highlight that component in the application.

Custom effects

Adobe® Flex® supplies a number of standard effects that you can use in your application. However, you also can define custom effects for your specific application needs.

For information on the standard effects, see “Introduction to effects” on page 1784.

About creating a custom effect

Flex implements effects by using an architecture in which each effect is represented by two classes: a factory class and an instance class. Therefore, to implement a custom effect, you create two classes: the factory class and the instance class.

You create a factory class by creating a subclass of the mx.effects.Effect class, or by creating a subclass of one of the subclasses of the mx.effects.Effect class. You create an instance class by creating a subclass of the mx.effects.EffectInstance class, or a subclass of one of the subclasses of the mx.effects.EffectInstance class.

Defining factory and instance classes

To define a custom effect, you create two classes: the factory class and the instance class:

Factory class The factory class creates an object of the instance class to perform the effect on the target. You create a factory class instance in your application, and configure it with the necessary properties to control the effect, such as the zoom size or effect duration, as the following example shows:

```
<fx:Declarations>
    <!-- Define factory class. -->
    <s:Resize id="myResizeEffect" target="{myImage}"
        widthBy="10" heightBy="10"/>
</fx:Declarations>

<mx:Image id="myImage" source="@Embed(source='assets/logo.jpg')"/>
<s:Button label="Resize Me" click="myResizeEffect.end();myResizeEffect.play();"/>
```

By convention, the name of a factory class is the name of the effect, such as Zoom or Fade.

Instance class The instance class implements the effect logic. When you invoke an effect, the factory class creates an object of the instance class to perform the effect on the target. When the effect ends, Flex destroys the instance object. If the effect has multiple target components, the factory class creates multiple instance objects, one per target.

By convention, the name of an instance class is the name of the effect with the suffix *Instance*, such as ZoomInstance or FadeInstance.

About the effect base classes

You define effects by creating a subclass from the effects class hierarchy. Typically, you create a subclass from one of the following classes:

- mx.effects.Effect Create a subclass from this class for simple effects that do not require an effect to play over a period of time. For example, the Pause effect inserts a delay between two consecutive effects. You can also define a simple sound effect that plays an MP3 file.
- spark.effects.Animate Create a subclass from this class to define an effect that animates a set of properties between values over a period of time. For example, the Spark AnimateColor effect is a subclass of the Animate class that modifies a color property of its target over a specified duration.
- mx.effects.TweenEffect Create a subclass from this class to define an effect that plays over a period of time, such as an animation. For example, the MX Resize effect is a subclass of the TweenEffect class that modifies the size of its target over a specified duration.

About implementing your effects classes

You must override several methods and properties in your custom effect classes, and define any new properties and methods that are required to implement the effect. You can optionally override additional properties and methods based on the type of effect that you create.

The following table lists the methods and properties that you define in a factory class:

Factory method/property	**Description**
`constructor`	(Required) The class constructor. You typically call the `super()` method to invoke the superclass constructor to initialize the inherited items from the superclasses. Your constructor must take at least one optional argument, of type Object. This argument specifies the target component of the effect.
`Effect.initInstance()`	(Required) Copies properties of the factory class to the instance class. Flex calls this protected method from the `Effect.createInstance()` method; you do not have to call it yourself. In your override, you must call the `super.initInstance()` method.
`Effect.getAffectedProperties()`	(Required) Returns an Array of Strings, where each String is the name of a property of the target object that is changed by this effect. If the effect does not modify any properties, it should return an empty Array.
`Effect.instanceClass`	(Required) Contains an object of type Class that specifies the name of the instance class for this effect class. All subclasses of the Effect class must set this property, typically in the constructor.
`Effect.effectEndHandler()`	(Optional) Called when an effect instance finishes playing. If you override this method, ensure that you call the `super()` method.
`Effect.effectStartHandler()`	(Optional) Called when the effect instance starts playing. If you override this method, ensure that you call the `super()` method.
Additional methods and properties	(Optional) Define any additional methods and properties that the user requires to configure the effect.

The following table lists the methods and properties that you define in an instance class:

Instance method/property	**Description**
constructor	(Required) The class constructor. You typically call the `super()` method to invoke the superclass constructor to initialize the inherited items from the superclasses.
`EffectInstance.play()`	(Required) Invokes the effect. You must call `super.play()` from your override.
`EffectInstance.end()`	(Optional) Interrupts an effect that is currently playing, and jumps immediately to the end of the effect.
`EffectInstance.initEffect()`	(Optional) Called if the effect was triggered by the EffectManager. You rarely have to implement this method. For more information, see "Overriding the initEffect() method" on page 2542.
`TweenEffectInstance.onTweenUpdate()`	(Required) Use when you create a subclass from TweenEffectInstance. A callback method called at regular intervals to implement a tween effect. For more information, see "Example: Creating a tween effect" on page 2532.
`TweenEffectInstance.onTweenEnd()`	(Optional) Use when you create a subclass from TweenEffectInstance. A callback method called when the tween effect ends. You must call `super.onTweenEnd()` from your override. For more information, see "Example: Creating a tween effect" on page 2532.
Additional methods and properties	(Optional) Define any additional methods and properties. These typically correspond to the public properties and methods from the factory class, and any additional properties and methods that you require to implement the effect.

Example: Defining a simple effect

To define a simple custom effect, you create a factory class from the Effect base class, and the instance class from the mx.effects.EffectInstance class. The following example shows an effect class that uses a Sound object to play an embedded MP3 file when a user action occurs. This example is a simplified version of the SoundEffect class that ships with Flex.

```
package myEffects
{
   // createcomps_effects/myEffects/MySound.as
   import mx.effects.Effect;
   import mx.effects.EffectInstance;
   import mx.effects.IEffectInstance;
   public class MySound extends Effect
   {
       // Define constructor with optional argument.
       public function MySound(targetObj:Object = null) {
           // Call base class constructor.
           super(targetObj);

           // Set instanceClass to the name of the effect instance class.
           instanceClass= MySoundInstance;
       }

       // This effect modifies no properties, so your
       // override of getAffectedProperties() method
       // returns an empty array.
       override public function getAffectedProperties():Array {
           return [];
       }

       // Override initInstance() method.
       override protected function initInstance(inst:IEffectInstance):void {
           super.initInstance(inst);
       }
   }
}
```

The `package` statement in your class specifies that you should deploy it in a directory called myEffects. In this example, you place it in the subdirectory of the directory that contains your Flex application. Therefore, the namespace definition in your Flex application is `xmlns:MyComp="myEffects.*"`. For more information on deployment, see "Component compilation" on page 2392.

To define your instance class, you create a subclass from the mx.effects.EffectInstance class. In the class definition, you must define a constructor and `play()` methods, and you can optionally define an `end()` method to stop the effect.

```
package myEffects
{
    // createcomps_effects/myEffects/MySoundInstance.as
    import mx.effects.EffectInstance;
    import flash.media.SoundChannel;
    import flash.media.Sound;
    public class MySoundInstance extends EffectInstance
    {
        // Embed the MP3 file.
        [Embed(source="sample.mp3")]
        [Bindable]
        private var sndCls:Class;

        // Define local variables.
        private var snd:Sound = new sndCls() as Sound;
        private var sndChannel:SoundChannel;

        // Define constructor.
        public function MySoundInstance(targetObj:Object) {
            super(targetObj);
        }
        // Override play() method.
        // Notice that the MP3 file is embedded in the class.
        override public function play():void {
            super.play();
            sndChannel=snd.play();
        }

        // Override end() method class to stop the MP3.
        override public function end():void {
            sndChannel.stop();
            super.end();
        }
    }
}
```

To use your custom effect class in an MXML file, you insert a tag with the same name as the factory class in the MXML file. You reference the custom effect the same way that you reference a standard effect.

The following example shows an application that uses the MySound effect:

```
<?xml version="1.0"?>
<!-- createcomps_effects/MainSoundEffect.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myEffects.*">
    <fx:Declarations>
        <MyComp:MySound id="mySoundEffect" target="{myLabel}" />
    </fx:Declarations>
    <!-- Use the SoundEffect effect with a mouseOver trigger. -->
    <s:Label id="myLabel"
        text="play MP3"
        rollOver="mySoundEffect.end();mySoundEffect.play();"/>
</s:Application>
```

Example: Passing parameters to effects

To make your effects more robust, you often design them to let the user pass parameters to them. The example in this section modifies the sound effect from the previous section to take a parameter that specifies the MP3 file to play:

```
package myEffects
{
    // createcomps_effects/myEffects/MySoundParam.as
    import mx.effects.Effect;
    import mx.effects.EffectInstance;
    import mx.effects.IEffectInstance;
    public class MySoundParam extends Effect
    {

       // Define a variable for the MP3 URL
       // and give it a default value.
       public var soundMP3:String=
           "http://localhost:8100/flex/assets/default.mp3";

       // Define constructor with optional argument.
       public function MySoundParam(targetObj:Object = null) {
           // Call base class constructor.
           super(targetObj);
           // Set instanceClass to the name of the effect instance class.
          instanceClass= MySoundParamInstance;
       }
       // Override getAffectedProperties() method to return an empty array.
       override public function getAffectedProperties():Array {
           return [];
       }

       // Override initInstance() method.
       override protected function initInstance(inst:IEffectInstance):void {
           super.initInstance(inst);
           // initialize the corresponding parameter in the instance class.
           MySoundParamInstance(inst).soundMP3 = soundMP3;
       }
    }
}
```

In the MySoundParam class, you define a variable named `soundMP3` that enables the user of the effect to specify the URL of the MP3 file to play. You also modify your override of the `initInstance()` method to pass the value of the `soundMP3` variable to the instance class.

Notice that the getAffectedProperties() method still returns an empty Array. That is because `getAffectedProperties()` returns the list of properties of the effect target that are modified by the effect, not the properties of the effect itself.

In your instance class, you define a property named soundMP3, corresponding to the property with the same name in the factory class. Then, you use it to create the URLRequest object to play the sound, as the following example shows:

```
package myEffects
{
    // createcomps_effects/myEffects/MySoundParamInstance.as
    import mx.effects.EffectInstance;
    import flash.media.Sound;
    import flash.media.SoundChannel;
    import flash.net.URLRequest;
    public class MySoundParamInstance extends EffectInstance
    {
        // Define local variables.
        private var s:Sound;
        private var sndChannel:SoundChannel;
        private var u:URLRequest;
        // Define a variable for the MP3 URL.
        public var soundMP3:String;
        // Define constructor.
        public function MySoundParamInstance(targetObj:Object) {
            super(targetObj);
        }
        // Override play() method.
        override public function play():void     {
            // You must call super.play() from within your override.
            super.play();
            s = new Sound();
            // Use the new parameter to specify the URL.
            u = new URLRequest(soundMP3);
            s.load(u);
            sndChannel=s.play();
        }

        // Override end() method to stop the MP3.
        override public function end():void  {
            sndChannel.stop();
            super.end();
        }
    }
}
```

You can now pass the URL of an MP3 to the effect, as the following example shows:

```
<?xml version="1.0"?>
<!-- createcomps_effects/MainSoundParam.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComps="myEffects.*">
    <fx:Declarations>
        <MyComps:MySoundParam id="mySoundEffect"
            soundMP3="http://localhost:8100/flex/assets/sample.mp3"/>
    </fx:Declarations>
    <!-- Use the SoundEffect effect with a mouseOver trigger. -->
    <mx:Label id="myLabel"
        text="play MP3"
        rollOver="mySoundEffect.end();mySoundEffect.play();"/>
</s:Application>
```

About MX tween effects

Most MX effects are implemented by using the tweening mechanism, where a *tween* defines a transition performed on a target object over a period of time. That transition could be a change in size, such as the Zoom or Resize effects perform; a change in visibility, such as the Fade or Dissolve effects perform; or other types of transitions.

You use the following classes to implement a tween effect:

- mx.effects.Tween A class used to implement tween effects. A Tween object accepts a start value, an end value, and an optional easing function. When you define tween effect classes, you create an instance of the Tween class in your override of the `Effect.play()` method.

  The Tween object invokes the `mx.effects.TweenEffect.onTweenUpdate()` callback method on a regular interval, passing the callback method an interpolated value between the start and end values. Typically, the callback method updates some property of the target component, causing that component's property to animate over time. For example, the Move effect modifies the `x` and `y` properties of the target component for the duration of the effect to show an animated movement.

  When the effect ends, the Tween object invokes the `mx.effects.TweenEffect.onTweenEnd()` callback method. This method performs any final processing before the effect terminates. You must call `super.onTweenEnd()` from your override.

- mx.effects.TweenEffect The base factory class for all tween effects. This class encapsulates methods and properties that are common among all Tween-based effects.

- mx.effects.effectClasses.TweenEffectInstance The instance class for all tween effects.

  When you define effects based on the TweenEffect class, you must override the `TweenEffectInstance.onTweenUpdate`() method, and optionally override the `TweenEffectInstance.onTweenEnd`() method.

The following example creates a tween effect. However, Flex supplies the AnimateProperty class that you can use to create a tween effect for a single property of the target component. For more information, see "Introduction to effects" on page 1784.

Example: Creating a tween effect

In this example, you create a tween effect that rotates a component in a circle. This example implements a simplified version of the Rotate effect. The rotation is controlled by two parameters that are passed to the effect: `angleFrom` and `angleTo`:

```
package myEffects
{
   // createcomps_effects/myEffects/Rotation.as
   import mx.effects.TweenEffect;
   import mx.effects.EffectInstance;
   import mx.effects.IEffectInstance;
   public class Rotation extends TweenEffect
   {
       // Define parameters for the effect.
       public var angleFrom:Number = 0;
       public var angleTo:Number = 360;

       // Define constructor with optional argument.
       public function Rotation(targetObj:* = null) {
           super(targetObj);
           instanceClass= RotationInstance;
       }
       // Override getAffectedProperties() method to return "rotation".
       override public function getAffectedProperties():Array {
           return ["rotation"];
       }

       // Override initInstance() method.
       override protected function initInstance(inst:IEffectInstance):void {
           super.initInstance(inst);
           RotationInstance(inst).angleFrom = angleFrom;
           RotationInstance(inst).angleTo = angleTo;
       }
   }
}
```

In this example, the effect works by modifying the `rotation` property of the target component. Therefore, your override of the `getAffectedProperties()` method returns an array that contains a single element.

You derive your instance class from the TweenEffectInstance class, and override the `play()`, `onTweenUpdate()`, and `onTweenEnd()` methods, as the following example shows:

```
package myEffects
{
    // createcomps_effects/myEffects/RotationInstance.as
    import mx.effects.effectClasses.TweenEffectInstance;
    import mx.effects.Tween;
    public class RotationInstance extends TweenEffectInstance
    {
        // Define parameters for the effect.
        public var angleFrom:Number;
        public var angleTo:Number;

        public function RotationInstance(targetObj:*) {
            super(targetObj);
        }

        // Override play() method class.
        override public function play():void {
            // All classes must call super.play().
            super.play();
            // Create a Tween object. The tween begins playing immediately.
            var tween:Tween =
                createTween(this, angleFrom, angleTo, duration);
        }
        // Override onTweenUpdate() method.
        override public function onTweenUpdate(val:Object):void {
            target.rotation = val;
        }

        // Override onTweenEnd() method.
        override public function onTweenEnd(val:Object):void {
            // All classes that implement onTweenEnd()
            // must call    super.onTweenEnd().
            super.onTweenEnd(val);
        }
    }
}
```

In this example, the Tween object invokes the `onTweenUpdate()` callback method on a regular interval, passing it values between `angleFrom` and `angleTo`. At the end of the effect, the Tween object calls the `onTweenUpdate()` callback method with a value of `angleTo`. By invoking the `onTweenUpdate()` callback method at regular intervals throughout the duration of the effect, the target component displays a smooth animation as it rotates.

You use your new effect in an MXML application, as the following example shows:

```
<?xml version="1.0"?>
<!-- createcomps_effects/MainRotation.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myEffects.*"
    height="450">
    <fx:Declarations>
        <MyComp:Rotation id="Rotate90"
            angleFrom="0" angleTo="360"
            duration="1000"
            target="{myImage}"/>
    </fx:Declarations>

    <mx:Image id="myImage"
        x="250" y="200"
        source="@Embed(source='../assets/myRotationImage.jpg')"
        mouseDown="Rotate90.end();Rotate90.play();"/>
</s:Application>
```

In this example, you use the effect to rotate an image when the user clicks it.

Writing an effect for a transition

Transitions define how a change of view state appears on the screen. You define a transition by using a combination of the Flex effect classes. For more information on transitions, see "Transitions" on page 1870.

You can define your own custom effects for use in transitions. To do so, you have to account for the effect being used in a transition when you override the EffectInstance.play() method. The `EffectInstance.play()` method must be able to determine default values for effect properties when the effect is used in a transition.

Defining the default values for a transition effect

Like any effect, an effect in a transition has properties that you use to configure it. For example, most effects have properties that define starting and ending information for the target component, such as the `xFrom`, `yFrom`, `xTo`, and `yTo` properties of the Move effect.

Flex uses the following rules to determine the start and end values of effect properties when you use the effect in a transition:

1 If the effect defines the values of any properties, it uses the properties in the transition, as the following example shows:

```
<mx:Transition fromState="*" toState="*">
    <mx:Sequence id="t1" targets="{[p1,p2,p3]}">
        <mx:Blur duration="100"
            blurXFrom="0.0" blurXTo="10.0" blurYFrom="0.0" blurYTo="10.0"/>
     <mx:Parallel>
            <mx:Move duration="400"/>
            <mx:Resize duration="400"/>
        </mx:Parallel>
     <mx:Blur duration="100"
            blurXFrom="10.0" blurXTo="0.0" blurYFrom="10.0" blurYTo="0.0"/>
    </mx:Sequence>
</mx:Transition>
```

In this example, the two Blur filters define the properties of the effect.

2 If the effect does not define the start values of the effect, the effect determines the values from the EffectInstance.propertyChanges property passed to the effect instance. Flex sets the `propertyChanges` property by using information from the current settings of the component, as defined by the current view state. For more information on the `propertyChanges` property, see "How Flex initializes the propertyChanges property" on page 2536.

In the example in step 1, notice that the Move and Resize effects do not define start values. Therefore, Flex determines the start values from the current size and position of the effect targets in the current view state, and passes that information to each effect instance by using the `propertyChanges` property.

3 If the effect does not define the end values of the effect, the effect determines the values from the `Effectinstance.propertyChanges` property passed to the effect instance. Flex sets the `propertyChanges` property by using information about the component, as defined by the destination view state. For more information on the `propertyChanges` property, see "How Flex initializes the propertyChanges property" on page 2536.

In the example in rule 1, Flex determines the end values of the Move and Resize effects from the size and position of the effect targets in the destination view state. In some cases, the destination view state defines those values. If the destination view state does not define the values, Flex determines them from the setting of the base view state, and passes that information to each effect instance by using the `propertyChanges` property.

4 If there are no explicit values, and Flex cannot determine values from the current or destination view states, the effect uses its default property values.

Using the propertyChanges property

The EffectInstance.propertyChanges property contains a PropertyChanges object. A PropertyChanges object contains the properties described in the following table:

Property	Description
`target`	A target component of the effect. The `end` and `start` properties of the PropertyChanges class define how the target component is modified by the change to the view state.
`start`	An object that contains the starting properties of the `target` component, as defined by the current view state. For example, for a `target` component that is moved and resized by a change to the view state, the `start` property contains the starting position and size of the component, as the following example shows: `{x:00, y:00, width:100, height:100}`
`end`	An object that contains the ending properties of the `target` component, as defined by the destination view state. For example, for a `target` component that is moved and resized by a change to the view state, the `end` property contains the ending position and size of the component, as the following example shows: `{x:100, y:100, width:200, height:200}`

In the body of the `Effectinstance.play()` method, you can examine the information in the `propertyChanges` property to configure the effect.

How Flex initializes the propertyChanges property

Before you can use the EffectInstance.propertyChanges property in your effect instance, it has to be properly initialized. When you change the view state, Flex initializes `propertyChanges.start` and `propertyChanges.end` separately.

The following steps describe the actions that occur when you change view states. Notice that Flex initializes `propertyChanges.start` as part of step 4, and initializes `propertyChanges.end` as part of step 7.

1 You set the `currentState` property to the destination view state.

2. Flex dispatches the `currentStateChanging` event.
3. Flex examines the list of transitions to determine the one that matches the change of view state.
4. Flex calls the `Effect.captureStartValues()` method to initialize `propertyChanges.start` for all effect instances.

   You can also call `Effect.captureStartValues()` to initialize an effect instance used outside of a transition.
5. Flex applies the destination view state to the application.
6. Flex dispatches the `currentStateChange` event.
7. Flex plays the effects defined in the transition.

   As part of playing the effect, Flex invokes the factory class play() method and the `Effect.play()` method to initialize `propertyChanges.end` for effect instances.

Example: Creating a transition effect

The following example modifies the Rotation effect created in “Example: Creating a tween effect” on page 2532 to make the effect usable in a transition.

This example shows the RotationTrans.as class that defines the factory class for the effect. To create RotationTrans.as, the only modification you make to Rotation.as is to remove the default value definitions for the `angleFrom` and `angleTo` properties. The `RotationTransInstance.play()` method determines the default values.

```
package myEffects
{
   // createcomps_effects/myEffects/RotationTrans.as
   import mx.effects.TweenEffect;
   import mx.effects.EffectInstance;
   import mx.effects.IEffectInstance;
   public class RotationTrans extends TweenEffect
   {
       // Define parameters for the effect.
       // Do not specify any default values.
       // The default value of these properties is NaN.
       public var angleFrom:Number;
       public var angleTo:Number;

       // Define constructor with optional argument.
       public function RotationTrans(targetObj:Object = null) {
           super(targetObj);
           instanceClass= RotationTransInstance;
       }
       // Override getAffectedProperties() method to return "rotation".
       override public function getAffectedProperties():Array {
           return ["rotation"];
       }

       // Override initInstance() method.
       override protected function initInstance(inst:IEffectInstance):void {
           super.initInstance(inst);
           RotationTransInstance(inst).angleFrom = angleFrom;
           RotationTransInstance(inst).angleTo = angleTo;
       }
   }
}
```

In the RotationTransInstance.as class, you modify the `play()` method to calculate the default values for the `angleFrom` and `angleTo` properties. This method performs the following actions:

1 Determines whether the user set values for the `angleFrom` and `angleTo` properties.

2 If not, determines whether the `Effectinstance.propertyChanges` property was initialized with start and end values. If so, the method uses those values to configure the effect.

3 If not, sets the `angleFrom` and `angleTo` properties to the default values of 0 for the `angleFrom` property, and 360 for the `angleTo` property.

The following example shows the RotationTransInstance.as class:

```
package myEffects
{
    // createcomps_effects/myEffects/RotationTransInstance.as
    import mx.effects.effectClasses.TweenEffectInstance;
    import mx.effects.Tween;
    public class RotationTransInstance extends TweenEffectInstance
    {
        // Define parameters for the effect.
        public var angleFrom:Number;
        public var angleTo:Number;

        public function RotationTransInstance(targetObj:Object) {
            super(targetObj);
        }

        // Override play() method class.
        override public function play():void {
            // All classes must call super.play().
            super.play();

            // Check whether angleFrom is set.
            if (isNaN(angleFrom))
            {
              // If not, look in propertyChanges.start for a value.
              // Otherwise, set it to 0.
              angleFrom = (propertyChanges.start["rotation"] != undefined) ?
                    propertyChanges.start["rotation"] : 0;
            }

            // Check whether angleTo is set.
            if (isNaN(angleTo))
            {
                // If not, look in propertyChanges.end for a value.
                // Otherwise, set it to 360.
                angleTo = (propertyChanges.end["rotation"] != undefined) ?
```

```
                    propertyChanges.end["rotation"] : 360;
            }

            // Create a Tween object. The tween begins playing immediately.
            var tween:Tween =
                createTween(this, angleFrom, angleTo, duration);
        }
        // Override onTweenUpdate() method.
        override public function onTweenUpdate(val:Object):void {
            target.rotation = val;
        }

        // Override onTweenEnd() method.
        override public function onTweenEnd(val:Object):void {
            // All classes that implement onTweenEnd()
            // must call super.onTweenEnd().
            super.onTweenEnd(val);
        }
    }
}
```

The following application uses the RotationTrans effect:

```
<?xml version="1.0" encoding="UTF-8"?>
<!-- createcomps_effects/MainRotationTrans.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myEffects.*">

                width.One="100" height.One="100"
                width.Two="100" height.Two="100"
                click="currentState=''" >
            <mx:Label fontSize="24" text="Three"/>
        </mx:Panel>
    </mx:Canvas>
</s:Application>
```

Defining a custom effect trigger for MX effects

You can create a custom effect trigger to handle situations for which the standard Flex triggers do not meet your needs. An effect trigger is paired with a corresponding event that invokes the trigger. For example, a Button control has a `mouseDown` event and a `mouseDownEffect` trigger. The event initiates the corresponding effect trigger when a user clicks a component. You use the `mouseDown` event to specify the event listener that executes when the user selects the component. You use the `mouseDownEffect` trigger to associate an effect with the trigger.

Suppose that you want to apply an effect that sets the brightness level of a component when a user action occurs. The following example shows a custom Button control that uses a new property, `bright`, and dispatches two new events, `darken` and `brighten`, based on changes to the `bright` property. The control also defines two new effect triggers, `darkenEffect` and `brightenEffect`, which are paired with the `darken` event and the `brighten` event.

```
<?xml version="1.0"?>
<!-- createcomps_effects\myComponents\MyButton.mxml -->
<mx:Button xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx" >
    <fx:Metadata>
        <!-- Define the metadata for the events and effect triggers. -->
        [Event(name="darken", type="flash.events.Event")]
        [Event(name="brighten", type="flash.events.Event")]
        [Effect(name="darkenEffect", event="darken")]
        [Effect(name="brightenEffect", event="brighten")]
    </fx:Metadata>

    <fx:Script>
        <![CDATA[
            import flash.events.Event;
            // Define the private variable for the bright setting.
            private var _bright:Boolean = true;

            // Define the setter to dispatch the events
            // corresponding to the effect triggers.
            public function set bright(value:Boolean):void {
                _bright = value;

                if (_bright)
                    dispatchEvent(new Event("brighten"));
                else
                    dispatchEvent(new Event("darken"));
            }

            // Define the getter to return the current bright setting.
            public function get bright():Boolean {
                return _bright;
            }
        ]]>
    </fx:Script>
</mx:Button>
```

When you declare an event in the form `[Event(name="`*eventName*`", type="`*package.eventType*`")]`, you can also create a corresponding effect, in the form `[Effect(name="`*eventname*`Effect", event="`*eventname*`")]`. As in the previous example, in the `<fx:Metadata>` tag, you insert the metadata statements that define the two new events, `darken` and `brighten`, and the new effect triggers, `darkenEffect` and `brightenEffect`, to the Flex compiler.

For more information on using metadata, see "Metadata tags in custom components" on page 2376.

The application in the following example uses the MyButton control. The `darkenEffect` and `brightenEffect` properties are set to the FadeOut and FadeIn effects, respectively. The `click` event of a second Button control toggles the MyButton control's `bright` property and executes the corresponding effect (FadeOut or FadeIn).

```
<?xml version="1.0"?>
<!-- createcomps_effects/MainMyButton.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:MyComp="myComponents.*" >
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Declarations>
        <!-- Define two fade effects for darkening and brightening target. -->
        <mx:Fade id="FadeOut"
            duration="1000"
            alphaFrom="1.00" alphaTo=".20"/>
        <mx:Fade id="FadeIn"
            duration="1000"
            alphaFrom=".20" alphaTo="1.00"/>
    </fx:Declarations>
    <!-- Define custom button that defines the
        darkenEffect and brightenEffect. -->
    <MyComp:MyButton
        label="MyButton" id="btn"
        darkenEffect="{FadeOut}"
        brightenEffect="{FadeIn}"
        darken="debugW.text='got darken event';"
        brighten="debugW.text='got brighten event';"/>

    <!-- Define button that triggers darken event. -->
    <mx:Button
        label="set bright to false"
        click="btn.bright = false; myTA.text=String(btn.bright);"/>

    <!-- Define button that triggers brighten event. -->
    <mx:Button
        label="set bright to true"
        click="btn.bright = true; myTA.text=String(btn.bright);"/>

    <!-- TextArea displays the current value of bright. -->
    <mx:TextArea id="myTA" />

    <!-- TextArea displays event messages. -->
    <mx:TextArea id="debugW" />
    <!-- Define button to make sure effects working. -->
    <MyComp:MyButton id="btn2" label="test effects"
        mouseDownEffect="{FadeOut}"
        mouseUpEffect="{FadeIn}"/>
</s:Application>
```

Overriding the initEffect() method

The EffectInstance class defines the initEffect() method that you can override in your custom effect. This method has the following signature:

```
public initEffect(event:Event):void
```

where *event* is the Event object dispatched by the event that triggered the effect.

For example, a user might create an instance of an effect, but not provide all of the configuration information that is required to play the effect. Although you might be able to assign default values to all properties within the definition of the effect class, in some cases you might have to determine the default values at run time.

In this method, you can examine the event object and the effect target to calculate values at run time. For more information on how to create a custom event and an effect trigger, see “Defining a custom effect trigger for MX effects” on page 2540. As part of that example, you can add properties to the event object passed to the `dispatchEvent()` method. You can then access that event object, and its additional properties, from the `initEffect()` method.

By overriding the `initEffect()` method, you can also access the `target` property of the Event object to reference the target component of the effect. For example, if you must determine the current x and y coordinates of the component, or its current height and width, you can access them from your override of the `initEffect()` method.

Chapter 11: Deploying applications

Deploying applications

When you deploy an application written in Adobe® Flex®, you make the application accessible to your users. The process of deploying an application is dependent on your application, your application requirements, and your deployment environment. For example, the process of deploying an application on an internal website that is only accessible by company employees might be different from the process for deploying the same application on a public website accessible by anyone.

Use the overview of the deployment process and the general checklist as a guide when you deploy your application. This topic does not attempt to define the exact set of steps that you use for deploying all applications. Instead, it contains an overview of the deployment process, and a general checklist that you might use when you deploy your application.

About deploying an application

When you deploy an application, you move the application from your development environment to your deployment environment. After you deploy it, customers have full access to the application.

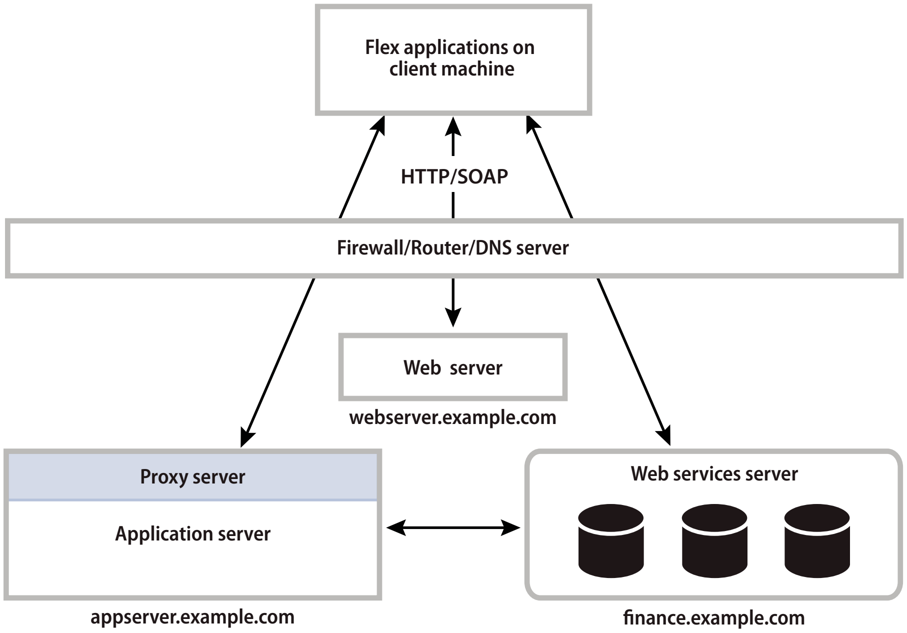
The deployment process that your organization uses might only require you to copy a application's SWF file from your development server to your deployment server. In many organizations however, the deployment process is more complicated, and involves people from groups outside the development organization. For example, you might have an IT department that maintains your corporate website. The IT department might be responsible for staging, testing, and then deploying your application.

Your application architecture might also require you to deploy more than just a single SWF file. For example, your application might access Runtime Shared Libraries (RSLs) or other assets at run time. You must make sure to copy all required files to your deployment environment.

Deployment might also require you to perform operations other than just copying application files to a deployment server. Your application might access data services on your server, or on another server. You must ensure that your data services are accessible by a deployed Flex application that executes on a client's computer.

Deployment options

The following example shows a typical deployment environment for an application:



Deploying an application for Flex SDK and Adobe® Flex® Builder® - might require you to perform some or all of the following actions:

- Copy the application SWF file to your deployment server. As the previous example shows, you copy the application to webserver.example.com.
- Copy any asset files, such as icons, media files, or other assets, to your deployment server.
- Copy any custom RSLs to your web server or application server. For more information, see "Deploying RSLs with Flex SDK" on page 2546.
- Copy the framework RSLs to your deployment server. For more information, see "Using the framework RSLs" on page 260.
- Copy any SWF files for your module to your deployment server in the same directory structure as you used for your development environment. "Deploying modules with Flex SDK" on page 2546.
- Copy any SWF files required to support Flex features, such as deep linking or runtime CSS. For more information, see "Deploying additional Flex files" on page 2546.
- Write a wrapper for the SWF file if you access it from an HTML, JSP, ASP, or another type of page.

  A deployed SWF file can encompass your entire web application, however it is often used as a part of the application. Therefore, users do not typically request the SWF file directly, but request a web page that references the SWF file. Flash Builder can generate the wrapper for you, or, you can write the wrapper. For more information, see "Creating a wrapper" on page 2552.
- Create a crossdomain.xml file on the server for data service, if you directly access any data services outside of the domain that serves the SWF file. For more information, see "Accessing data services from a deployed application" on page 2546

Deploying RSLs with Flex SDK

When your application uses custom RSLs, you must make sure to deploy the RSL on your deployment server, in the same domain, unless you are using cross-domain RSLs. You use the `runtime-shared-libraries` option of the Flex compiler to specify the directory location of the RSL at compile time. Ensure that you copy the RSL to the same directory that you specified with `runtime-shared-libraries`.

By default, the Flex compilers dynamically link your application against the framework RSLs. This means that classes in the SDK are externally loaded at run time from the framework RSLs. The default location of these RSLs is on the Adobe web site. If you clients do not have network connectivity, you must deploy the framework RSLs to a local location, or disable framework RSLs. To customize the location of framework RSLs, edit the flex-config.xml file or edit their location in the Flash Builder Flex Build Path dialog box. To disable framework RSLs, set the `static-link-runtime-shared-libraries` compiler option to `true`.

Flex also provides framework RSLs. These libraries are comprised of the Flex class libraries and can be used with any application built with Flex. The framework RSLs are precompiled libraries of framework classes and components. If your client does not have internet connectivity, be sure to deploy both the signed (*.SWZ) and unsigned (*.SWF) RSLs. Flash Player will first try to load the signed RSLs from the Adobe web site, so you should not have to deploy them in most cases.

For more information, see “Runtime Shared Libraries” on page 253.

Deploying modules with Flex SDK

Modules are SWF files that can be loaded and unloaded by an application. They cannot be run independently of an application, but any number of applications can share the modules. When your application uses a module, you must make sure to deploy the module’s SWF file on your deployment server in the same directory structure as you used for your development environment. For more information, see “Modular applications” on page 138.

Deploying additional Flex files

The implementation of some Flex features requires that you deploy additional files along with your application’s SWF file. For example, if you use deep linking functionality in your application, you must deploy the historyFrame.html, history.css, and history.js files. If you use the Express Install version detection feature, you also must deploy the playerProductInstall.swf file with your SWF file. You typically deploy these files in the same location that the default HTML wrapper looks for them. For example, the deep linking files are typically in a sub directory called /history.

For a complete list of additional Flex files that you might deploy with your application, see “Deployment checklist” on page 2548.

Accessing data services from a deployed application

In a typical Flex development environment, you build and test your application behind a corporate firewall, where security restrictions are much less strict than when a customer runs the application on their own computer. However, when you deploy the application, it runs on a customers computer outside your firewall. That simple change of location might cause the application to fail if you do not correctly configure your data services to allow external access.

Most run-time accesses to application resources fall into one of the following categories:

- Direct access to asset files on a web server, such as image files.
- Direct access to resources on your J2EE application server.
- Data services requests through a proxy. A proxy redirects that request to the server that handles the data service request.
- Direct access to a data service.

As part of deploying your application, ensure that all run-time data access requests work correctly from the application that is executing outside of your firewall.

Compiling for deployment

When you create a deployable SWF file, ensure that you compile the application correctly. Typically, you disable certain compiler features, such as the generation of debug output, and enable other options, such as the generation of accessible content.

This section contains an overview of some common compiler options that you might use when you create a deployable SWF file. For a complete list of compiler options, see "Flex compilers" on page 2164.

Creating a release build of your application in Flash Builder

When you create and run an application in Flash Builder, the Flex compiler includes debug information in that application so that you can set breakpoints and view variables and perform other debugging tasks. However, the SWF file that Flash Builder generates by default includes debugging information that makes it larger than the release build of the SWF file.

To create a release build of your application in Flash Builder, select Project > Export Release Build. This compiles a version of your application's SWF file that does not contain any debug information in it. This SWF file is smaller than the SWF files you compile normally. This also compiles any modules that are in the application's project without debug information.

In general, all compiled SWF files that are stored in the project's /bin-debug directory contain debug information. When you export the application, you choose a new output directory. The default is the /bin-release directory.

To compile a release build on the command line, set the `debug` compiler option to `false`. This prevents debug information from being included in the final SWF file.

Enabling accessibility

The Flex accessibility option lets you create applications that are accessible to users with disabilities. By default, accessibility is disabled. You enable the accessibility features of Flex components at compile time by using options to a Flash Builder project, setting the `accessible` option to `true` for the command-line compiler, or setting the `<accessible>` tag in the flex-config.xml file to `true`.

For more information on creating accessible applications, see "Accessible applications" on page 2122.

Preventing users from viewing your source code

Flex lets you publish your source code with your deployed application. You might want to enable this option during the development process, but disable it for deployment. Or, you might want to include your source code along with your deployed application.

In Flash Builder, the Export Release Build wizard lets you specify whether to publish your source code. You can also use the `viewSourceURL` property of the Application class to set the URL of your source code.

Disabling incremental compilation

You can use incremental compilation to decrease the time it takes to compile an application or component library with the Flex application compilers. When incremental compilation is enabled, the compiler inspects changes to the bytecode between revisions and only recompiles the section of bytecode that has changed.

For more information, see "Flex compilers" on page 2164.

Using a headless server

A *headless server* is one that is running UNIX or Linux and often does not have a monitor, keyboard, mouse, or even a graphics card. Headless servers are most commonly encountered in ISPs and ISVs, where available space is at a premium and servers are often mounted in racks. Enabling the headless mode reduces the graphics requirements of the underlying system and can allow for a more efficient use of memory.

If you deploy a Flex application on a headless server, you must set the `headless-server` option of the compiler to `true`. Setting this option to `true` is required to support fonts and SVG images in a nongraphical environment.

Deployment checklist

The deployment checklist contains some common system configuration issues that customers have found when deploying Flex applications for production. It also contains troubleshooting tips to diagnose common deployment problems.

Application assets

When deploying a Flex application, you must make sure you also deploy all the assets that the application uses at run time. These include files that are used by the wrapper to support features such as deep linking and Express Install, as well as files that are loaded by the application such as resource bundles or RSLs.

In the case of wrapper code, you will probably be cutting and pasting it from the HTML template included with the SDK into your JSP or ASP or PHP pages.

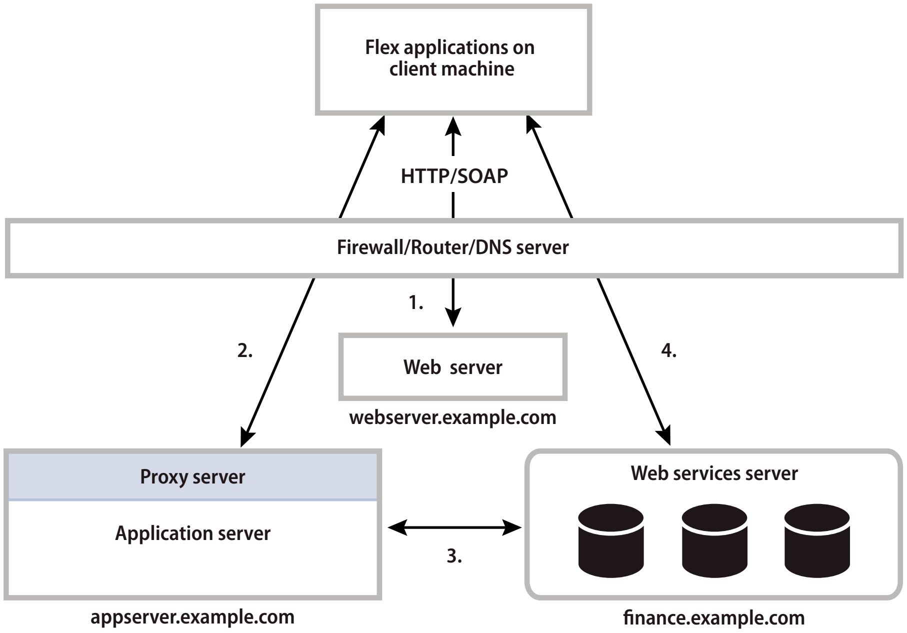
Check that the following assets are deployed with your application if you use those assets in your Flex applications:

Feature	Assets to Deploy
Wrapper files	If you use a wrapper, be sure to include it in the deployment process. The wrapper can be any file that returns HTML, such as PHP, ASP, JSP, or ColdFusion. Typically, this file uses the SWFObject 2 logic, or includes an `<object>` or `<embed>` tag to embed the Flex application. In addition, if you use dynamic pages to query databases or perform other server-side actions for your Flex application, be sure to deploy those as well. This is especially important if you use the data wizard in Flash Builder to generate these pages. For more information, see "Creating a wrapper" on page 2552.
Version detection	To support version detection or Express Install in your HTML wrapper, you must add the code based on the Flex wrapper template to your wrapper, as well as deploy the swfobject.js file. You must also deploy the playerProductInstall.swf file. For more information, see "Creating a wrapper" on page 2552.
Deep linking	To support deep linking, you must include the following files in your deployment: • history.js • history.css • historyFrame.html You must import the first two files into your HTML wrapper, and store all of these files in a /history subdirectory. For more information, see "Deep linking" on page 2022.

Feature	**Assets to Deploy**
Runtime shared libraries (RSLs)	For standard RSLs, deploy the RSL SWF files with your Flex application. You must be sure to deploy the SWF files to the same relative location that the compiler used. If you are deploying an a custom RSL, be sure to optimize the RSL's SWF file prior to deployment. For framework RSLs, if your client does not have internet connectivity, be sure to deploy both the signed (*.SWZ) and unsigned (*.SWF) RSLs. Flash Player will first try to load the signed RSLs from the Adobe web site, so you should not have to deploy them in most cases. For framework and cross-domain RSLs, be sure to deploy failover RSLs to the locations you specified when you compiled the application. For more information, see "Runtime Shared Libraries" on page 253.
Runtime stylesheets	If you use runtime stylesheets in your application, you must deploy the SWF files so that they can be loaded. You can load run-time stylesheet SWF files either locally or remotely. However, if you load them locally, the stylesheets must be in the same relative location that you specified in the application. For more information, see "Loading style sheets at run time" on page 1547.
Modules	If your application uses modules, you must deploy the module SWF files so that they can be loaded. Modules are SWF files that can be loaded and used by any number of applications. If multiple applications use your modules, then you should deploy them to a location that all applications can load them from rather than deploy them multiple times across different domains. For more information, see "Modular applications" on page 138.
Runtime localization	If your application uses run-time localization (if it, for example, lets the user switch from English to Japanese language at run time), then you might need to deploy resource module SWF files. These modules can contain one or more resources bundles for one or more locales. For more information, see "Localization" on page 2055.
Security files	If you use container-based security, then be sure to update your security constraints to include your Flex application. In addition, if you load assets from multiple domains, be sure to deploy any crossdomain.xml files that are required by your applications.
Miscellaneous runtime assets	Not all assets are embedded at compile time. For example, FLV and image files are usually loaded at run time to keep the SWF file as small as possible. Be sure to check that you deploy the following types of assets that are typically loaded at run time with your Flex application: • FLV files • SWF files • Sound files (such as MP3 files) • Images (such as GIF, JPG, and PNG files)
Data files	It is not uncommon for flat data files to be used as a data provider in Flex applications. Be sure to deploy any text files, which might appear in various formats such as XML, that are loaded at run time.
View source	If you use the view source functionality in Flash Builder, be sure to include the supporting files when you deploy your application. These files include the selected source code files, the source viewer's SWF file, HTML and CSS files for the source viewe, an XML file, and a ZIP file of the source code that users can download. You must maintain the directory structure that Flash Builder generates in the output directory. To enable view source and generate the ZIP file in Flash Builder, select Project > Export Release Build. Then select the Enable View Source option. For more information, see Publish source code.

Types of network access

Deployed applications typically make several types of requests to services within your firewall, as the following example shows:



Most of the deployment issues that customers report are related to network security and routing, and fall into one of the following scenarios:

1. Direct access to resources on a web server, such as image files. In the preceding example, the client directly accesses resources on webserver.example.com.
2. Direct access to resources on your application server. In the preceding example, the client directly accesses resources on appserver.example.com. Ensure that deployed applications can access the appropriate servers.
3. Web services requests through a proxy. A proxy redirects a request to the server that handles the web service. In the preceding example, the client accesses a resource on appserver.example.com, but that request is redirected to finance.example.com. Ensure that you configure the proxy server correctly so that deployed Flex applications can access your web services, or other data services, through the proxy.
4. Direct access of a web service. In the preceding example, the client directly accesses a service on finance.example.com. If a deployed Flex application directly accesses web services, or other data services, ensure that access is allowed.

Step 1. Create a list of server-side resources

Before you start testing your network configuration, make a list of the IP addresses and DNS names of all the servers that a Flex application might access. A Flex application might directly access these servers, for example by using a web service, or another server might access them as part of handling a redirected request.

Enter the information about your servers in the following table:

Name	DNS name	IP address

Enter information about the server hosting the web service proxy:

Name	DNS Name	IP Address

Enter information about your web services or any other services accessible from a deployed Flex application:

Name	Location (URL)

Step 2. Verify access from server to server within your firewall

In some cases, an external request to one server can be redirected to another server behind your firewall. A redirected request can occur for a request to a web service or to any file, depending on the system configuration. Where it is necessary, ensure that your servers can communicate with each other so that a redirected request can be properly handled.

To determine if one server, called Server A in this example, can communicate with another server, called Server B, create a temporary file called temp.htm on Server A in its web root directory. Then, log in to Server B and ensure that it can access temp.htm on Server A. Try to access the file by using Server A's DNS name and also its IP address.

Servers can have multiple NIC cards or multiple IP addresses. Ensure that each server can communicate with all of the IP addresses on your other servers.

Also, log in to the server that hosts your web service proxy to make sure that it can access all web services on all other servers. You can test the web service proxy by making an HTTP request to the WSDL file for each web service. In the previous example, log in to appserver.example.com and ensure that it can access the WSDL files on finance.example.com.

If any server cannot access the other servers in your system, an external request from a Flex application might also fail. For more information, contact your system administrator.

Step 3. Verify access to your servers from outside the firewall

Some servers might have to be accessed from outside the firewall to handle HTTP, SOAP, or AMF requests from clients. You can use the following methods to determine if a deployed Flex application can access your servers from outside the firewall:

1. On each server that can be accessed from outside the firewall, create a temporary file, such as temp.htm, on the server in its web root directory. From a computer outside the firewall, use a browser to make an HTTP request to the temporary file to ensure that an external computer can access it.

   For example, for a file named temp.htm, try accessing it by using the following URL:

   ```
   http://webserver.example.com/server1/temp.htm
   ```

2. From a computer outside the firewall, use a browser to make an HTTP request to the WSDL file for each web service that can be accessed from outside the firewall to ensure that the WSDL file can be accessed.

   For example, try accessing the WSDL file for a web service by using the following URL:

   ```
   http://finance.example.com/server1/myWS.wsdl
   ```

You should be able to access the temp.htm file or the WSDL file on all of your servers from outside the firewall. If these requests fail, contact your IT department to determine why the files cannot be accessed.

Step 4. Configure the proxy server

In “Step 3. Verify access to your servers from outside the firewall” on page 2552, you ensure that you can directly access your servers and server resources from outside the firewall.

After you configure your proxy server, ensure that the deployed Flex application can access web services and other server-side resources as necessary.

Step 5. Create a crossdomain policy file

Your system might be configured to allow a Flex application to directly access server-side resources on different domains or different computers without going through a proxy. These operations fail under the following conditions:

- When the Flex application’s SWF file references a URL, and that URL is outside the exact domain of the SWF file that makes the request
- When the Flex application’s SWF file references an HTTPS URL, and the SWF file that makes the request is not served over HTTPS

To make a data service or asset available to SWF files in different domains or on different computers, use a crossdomain policy file on the server that hosts the data service or asset. A *crossdomain policy file* is an XML file that provides a way for the server to indicate that its data services and assets are available to SWF files served from certain domains, or from all domains. Any SWF file that is served from a domain specified by the server’s policy file is permitted to access a data service or asset from that server. By default, place the crossdomain.xml at the root directory of the server that is serving the data.

For more information on using a cross-domain policy file, see “Using cross-domain policy files” on page 125.

Creating a wrapper

You typically embed an application built with Flex™ as a SWF file in an HTML page. The HTML page often includes script or external files that provide other functionality. Collectively, the HTML page and other external files are known as the *wrapper*.

About the wrapper

A simple wrapper is responsible for embedding the application's SWF file in a web page, such as an HTML, ASP, JSP, or Adobe ColdFusion page. In more complex wrappers, you can enable features such as deep linking and Express Install. The wrapper can also ensure that users both with and without JavaScript enabled in their browsers can access your applications built with Flex. You can also use the wrapper to pass `flashVars` variables into your applications and to use the ExternalInterface API. These topics are described in "Communicating with the wrapper" on page 226.

There are several ways to create a wrapper:

- Write a simple wrapper using the instructions in "Create a custom wrapper" on page 2559.
- Generate an HTML wrapper in Flash Builder. This wrapper includes features such as deep linking and Express Install support by default.
- Use the `html-wrapper` Flex Ant task. For more information, see "Using the html-wrapper task" on page 2350.

The mxmlc command-line compiler does not generate a wrapper. When using mxmlc, you generally write the wrapper manually or use the existing template as a guide. You can start out with a simple wrapper that just embeds your application's SWF file. You can then add features such as deep linking and Express Install support to your wrapper.

About the Flash Builder wrapper

Adobe® Flash® Builder™ generates a wrapper that embeds your application built with Flex. The Flash Builder wrapper includes support for Express Install and deep linking by default, although you can disable these features or configure them to your specifications.

To view the wrapper generated by Flash Builder, run the current project. Flash Builder generates an HTML page in the same location as the project's SWF file output. This directory also includes the wrapper's supporting files such as the swfobject.js and playerProductInstall.swf files.

You can configure the wrapper by using the Flex Compiler properties dialog box in Flash Builder. Configuration settings include:

- Enable or disable wrapper generation
- Set the minimum required version of Flash Player
- Use Express Install
- Enable deep linking support

For more information, see Flex compiler options.

About the HTML template

Flex SDK includes an HTML template and supporting files in the *flex_install_dir*/templates/swfobject directory. For Flash Builder, these files are located in the *install_dir*/sdks/4.6.0/templates/swfobject directory. The file name is index.template.html.

For clients with scripting enabled, the template uses SWFObject 2 to embed the SWF file built with Flex. For clients with scripting disabled, the template provides a `<noscript>` section that uses the `<object>` and `<embed>` tags to embed the SWF file.

For deployment, rename the template to index.html or whatever filename fits your web site's configuration. If you already have the HTML set up for your web site and are incorporating applications built with Flex into that site, then you can copy and paste the code from the template into your existing web site's files. The template HTML also works with dynamic scripting code such as PHP, ASP, or JSP.

The template uses tokens, such as `${height}` and `${title}`. Flash Builder replaces these tokens with the appropriate values when it compiles a project. If you are editing the wrapper manually and deploying an application built with the SDK, then you manually replace these tokens with the appropriate values.

In many cases, the tokens set the values of parameters that are passed to the `swfobject.embedSWF()` JavaScript method, or are used in the `<object>` and `<embed>` tags in the `<noscript>` block of the template.

The following table describes the template tokens:

Token	Description
`${application}`	Identifies the SWF file to the host environment (a web browser, typically) so that it can be referenced by using a scripting language. This token sets the value of the `attributes.id` and `attributes.name` properties in the SWFObject 2 logic.
`${bgcolor}`	Specifies the background color of the application. Use this property to override the background color setting specified in the application. This property does not affect the background color of the HTML page. Valid formats for `bgcolor` are any #RRGGBB, hexadecimal, or RGB value. This token sets the value of the `params.bgcolor` property in the SWFObject 2 logic.
`${expressInstallSwf}`	Enables Express Install for the embedded SWF file. To enable Express Install, set this property to "playerProductIntsall.swf". To disable Express Install, set this property to an empty string. If you enable Express Install, you must also deploy this SWF file with your application built with Flex. This token sets the value of the `xiSwfUrlStr` property in the SWFObject 2 logic. To toggle Express Install in Flex Builder, use the Use Express Install option on the Flex Compiler Properties dialog box.
`${height}`	Defines the height, in pixels, of the SWF file. Flash Player makes a best guess to determine the height of the application if none is provided. The browser scales an object or image to match the height and width specified by the author. You can set this value to a fixed number or a percentage value; for example, `'100'` or `'50%'`. Lengths expressed as percentages are based on the horizontal or vertical space currently available, not on the default size of the SWF file. You can also set the height of an application by setting the `height` property of the `<s:Application>` tag in an MXML file. This token sets the value of the `heightStr` property in the SWFObject 2 logic.
`${swf}`	Specifies the location of the SWF file. This token sets the value of the `swfUrlStr` property in the SWFObject 2 logic.
`${title}`	The title of the HTML page. This value appears in the browser's title bar when the user requests the HTML page. The default value supplied by Flash Builder is the name of the application.
`${useBrowserHistory}`	Enables deep linking for the embedded SWF file. To enable deep linking, set this property to "--". To disable deep linking, remove the token and the `<script>` tags that follow it. If you enable deep linking, youmust also deploy the files in the /templates/swfobject/history file with your application built with Flex. To toggle deep linking in Flex Builder, use the Enable Integration with Browser Navigation option on the Flex Compiler Properties dialog box.

Token	Description
`${version_major}`	The required major version number of Flash Player. For example, 10. This token is one part of the `swfVersionStr` property in the SWFObject 2 logic. It is used for Express Install. The value of this token is set in Flash Builder's Flex Compiler Properties dialog box.
`${version_minor}`	The required minor version number of Flash Player. For example, 0. This token is one part of the `swfVersionStr` property in the SWFObject 2 logic. It is used for Express Install. The value of this token is set in Flash Builder's Flex Compiler Properties dialog box.
`${version_revision}`	The required revision version number of Flash Player. For example, 162. This token is one part of the `swfVersionStr` property in the SWFObject 2 logic. It is used for Express Install. The value of this token is set in Flash Builder's Flex Compiler Properties dialog box.
`${width}`	Defines the width, in pixels, of the SWF file. Flash Player makes a best guess to determine the width of the application if none is provided. Browsers scale an object or image to match the height and width specified by the author. You can set this value to a fixed number or a percentage value. For example, `'100'` or `'50%'`. Lengths expressed as percentages are based on the horizontal or vertical space currently available, not on the natural size of the SWF file. You can also set the width of an application by setting the `width` property of the `<s:Application>` tag in an MXML file. This token sets the value of the `widthStr` property in the SWFObject 2 logic.

About SWFObject 2

SWFObject 2 is a standards-based library that embeds SWF files in HTML pages. It abstracts implementation details about Plugin detection, embedding, and other features so that you only need to call a single method to embed your SWF file. The default template included with Flex SDK and Flash Builder embeds the SWFObject 2 functionality with the following `<script>` tag:

```
<script type="text/javascript" src="swfobject.js"></script>
```

To embed a SWF file built with Flex, the HTML wrapper creates a number of properties and objects, and then passes them to the `swfobject.embedSWF()` method.

The `embedSWF()` method has the following signature:

```
embedSWF(
    swfUrlStr:String,
    replaceElemIdStr:String,
    heightStr:String,
    widthStr:String,
    swfVersionStr:String,
    xiSwfUrlStr:String,
    flashvars:Object,
    params:Object,
    attributes:Object
)
```

The following is an example of the `embedSWF()` method in an HTML wrapper:

```
swfobject.embedSWF("TestProject.swf", "flashContent","100%", "100%", "10.0.0",
"playerProductInstall.swf", flashvars, params, attributes);
```

You set the values of several of these arguments in the HTML wrapper's script prior to passing them to the `embedSWF()` method. The following table describes these arguments.

Argument	Description
`swfUrlStr`	Defines the location of the application built with Flex. In most cases, this is the name of the output SWF file. If you use Flash Builder to generate a wrapper, the default value is "*project_name*.swf".
`replaceElemIdStr`	The name of the alternative content that appears if Flash Player is not available. You define the alternative content in a `<div>` tag. For an example, view the source of HTML wrapper that is generated by Flash Builder.
`heightStr`	The height of the application built with Flex. If you use Flash Builder to generate a wrapper, this argument is the value of the {`height`} token.
`widthStr`	The width of the application built with Flex. If you use Flash Builder to generate a wrapper, this argument is the value of the {`width`} token.
`swfVersionStr`	The minimum version of Flash Player that is required to run the application built with Flex. The default value is "10.0.0". Set this property to "0" to disable version detection. If you use Flash Builder to generate a wrapper, this value is made up of the {`version_major`}, {`version_minor`}, and {`version_revision`} tokens.
`xiSwfUrlStr`	Enables Express Install. Set this argument to the location of the playerProductInstall.swf file. The default value is "playerProductInstall.swf". This SWF file is in the same directory as the HTML wrapper. If you deploy it to another location, change the value of the `xiSwfUrlStr` argument to the new path. To disable Express Install, set the value of this argument to an empty string. If you use Flash Builder to generate a wrapper, this argument is the value of the {`expressInstallSwf`} token.

Argument	Description

`flashvars`	Adds `flashVars` variables to your template. To do this, attach dynamic properties to the flashvars object in the HTML template.
	The following example adds `firstName` and `lastName` as dynamic properties to flashvars object:
	`var flashvars = {};`
	`flashvars.firstName = "Nick";`
	`flashvars.lastName = "Danger";`
	For more information about using `flashVars` variables in applications built with Flex, see “Passing request data with flashVars properties” on page 229.

`params`	Sets parameters for the SWF object. These properties typically define how it interacts with the HTML wrapper or appears in the browser.
	You can set the values of the following properties by using the `params` argument:
	• `menu`
	• `quality`
	• `scale`
	• `salign`
	• `wmode`
	• `bgcolor`
	• `base`
	• `flashvars`
	• `devicefont`
	• `allowscriptaccess`
	• `seamlesstabbing`
	• `allowfullscreen`
	• `allownetworking`
	For more information about these properties, see the property’s description in “About the object and embed tags” on page 2564.
	The following example adds several parameters to the `params` object in the HTML wrapper:
	`var params = {};`
	`params.quality = "high";`
	`params.bgcolor = "${bgcolor}";`
	`params.allowscriptaccess = "sameDomain";`

Argument	Description

`attributes`	Sets attributes for the SWF object.
	You can set the values of the following properties with the `attributes` argument:
	• `id`
	• `name`
	• `class`
	• `align`
	The `id` and `name` properties are required.
	For more information about these properties, see the property's description in "About the object and embed tags" on page 2564.
	The following example adds the `id`, `name`, and `align` properties to the attributes object.
	`var attributes = {};`
	`attributes.id = "${application}";`
	`attributes.name = "${application}";`
	`attributes.align = "middle";`

For more information on SWFObject 2, see http://code.google.com/p/swfobject/wiki/documentation.

Using deep linking in the wrapper

Deep linking lets users navigate the history of their interactions within the application by using the browser's Forward and Back buttons. Deep linking also lets users read and write to the browser's address bar.

To enable or disable deep linking in the Flash Builder wrapper:

1. Select Project > Properties.
2. Select Flex Compiler from the list on the left of the Project Properties dialog box.
3. Select the Enable Integration With Browser Navigation option to enable deep linking. Deselect this option to disable deep linking.
4. Click OK to save your changes.

When you deploy an application that uses deep linking, you must deploy the files in the /templates/swfobject/history directory with that application.

Using Express Install in the wrapper

The recommended method of ensuring that Flash Player can run the application on the client is to use Express Install. With Express Install, you can detect when users do not have the latest version of Flash Player, and you can initiate an update process that installs the latest version of the player. The updated Player can be installed from the Adobe website or from a local intranet site. When the installation is complete, users are directed back your website, where they can run your application.

Express Install runs a SWF file in the existing Flash Player to upgrade users to the latest version of the player. As a result, Express Install requires that Flash Player already be installed on the client, and that it be version 6.0.65 or later. The Express Install feature also relies on JavaScript detection logic in the browser to ensure that the player required to start the process exists. As a result, the browser must have JavaScript enabled for Express Install to work. If the player on the client is not new enough to support Express Install, you can display alternate content, redirect the user to the Flash Player download page, or initiate another type of Flash Player upgrade experience.

By default, Express Install is enabled in the wrapper generated by Flash Builder.

To enable or disable Express Install in Flash Builder:

1. Select Project > Properties.
2. Select Flex Compiler from the list on the left of the Project Properties dialog box.
3. Select the Use Express Install option to enable Express Install. Deselect the option to disable Express Install.
4. Click OK to save your changes.

When you deploy an application with a wrapper that supports Express Install, you must also deploy the playerProductInstall.swf file. This file is located in the /templates/swfobject directory.

Create a custom wrapper

You can write your own wrapper for your SWF files rather than use the wrapper generated by Flash Builder. Your own wrapper can be simple HTML, or it can be a JavaServer Page (JSP), a PHP page, an Active Server Page (ASP), or anything that can return HTML that is rendered in your client's browser. Typically, you integrate wrapper logic into your website's own HTML templates.

You can create a simple wrapper that uses SWFObject 2 but not other features such as deep linking and Express Install. You do this by creating an HTML file that imports the swfobject.js file. You then call the `swfobject.embedSWF()` method. The following is a simple wrapper that uses SWFObject 2:

```
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN"
"http://www.w3.org/TR/xhtml1/DTD/xhtml1-transitional.dtd">
<!-- saved from url=(0014)about:internet -->
<html xmlns="http://www.w3.org/1999/xhtml" lang="en" xml:lang="en">
    <head>
        <title>wrapper/SimpleSwfObjectWrapper.html</title>
        <script type="text/javascript" src="swfobject.js"></script>
        <script type="text/javascript">
            var swfVersionStr = "0";
            var xiSwfUrlStr = "";
            var flashvars = {};
            var params = {};
            params.quality = "high";
            params.bgcolor = "#ffffff";
            params.allowscriptaccess = "sameDomain";
            var attributes = {};
            attributes.id = "TestProject";
            attributes.name = "TestProject";
            attributes.align = "middle";
            swfobject.embedSWF(
                "TestProject.swf", "flashContent",
                "100%", "100%",
                swfVersionStr, xiSwfUrlStr,
                flashvars, params, attributes);
        </script>
    </head>
    <body>
        <div id="flashContent"/>
   </body>
</html>
```

This wrapper sets the `swfVersionStr` property to 0 and the `xiSwfUrlStr` property to an empty string. Doing this disables Express Install and deep linking functionality. These features improve the user experience and should be omitted only after careful consideration.

When you deploy this example wrapper, you must also deploy the swfobject.js file from the /templates/swfobject directory.

To write an even simpler wrapper, you can use just the `<object>` and `<embed>` tags rather than the SWFObject 2 JavaScript code.

A basic wrapper consists of the following files:

HTML page This is the file that the client browser requests directly. It typically defines two possible experiences (one for users with JavaScript enabled and one for users without JavaScript enabled). This page also references a separate JavaScript file in a `<script>` tag.

JavaScript file The JavaScript file referenced by the `<script>` tag in the HTML page defines the following:

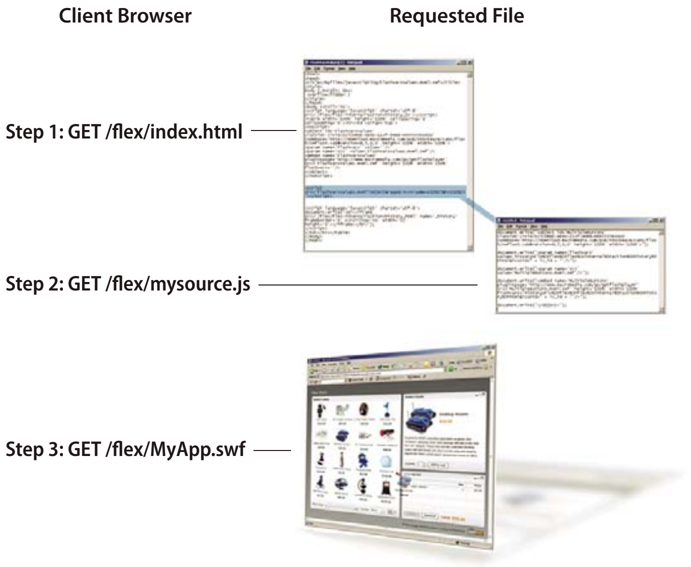
- `<object>` tag This tag embeds the SWF file for Internet Explorer.
- `<embed>` tag This tag embeds the SWF file for Netscape-based browsers.

In the default HTML template, the JavaScript file is named swfobject.js. This JavaScript file contains the SWFObject 2 logic. If you want to create your own basic wrapper, you can load a different JavaScript file that only has `<object>` and `<embed>` tags in it.

The client first requests the HTML page. If the user's browser has JavaScript enabled, the HTML page then loads the JavaScript file. The JavaScript file embeds the application's SWF file.

To make your application respond immediately without user interaction, use a `<script>` tag to load the JavaScript file that contains the embedding logic. Do not write the embed logic directly in the HTML file. Controls that are directly loaded by the embedding page require activation before they will run in Microsoft Internet Explorer 6 or later. If you load the controls directly in the HTML page, users will be required to activate those controls before they can use them by clicking on the control or giving it focus. This is undesirable because you want your application to run immediately when the page loads, not after the user interacts with the control.

The following example illustrates a typical series of requests that a JavaScript-enabled client browser makes when requesting a simple HTML wrapper:



Client Browser
Requested File
Step 1: GET /flex/index.html
Step 2: GET /flex/mysource.js
Step 3: GET /flex/MyApp.swf

The following example shows a simple HTML page and JavaScript file that embeds an application named MyApp:

```
<!-- index.html -->
<!-- saved from url=(0014)about:internet -->
<html>
    <body>
        <script src="mysource.js"></script>
    </body>
</html>

<!-- mysource.js -->
document.write("<object id='MyApp' classid='clsid:D27CDB6E-AE6D-11cf-96B8-444553540000'
height='100%' width='100%'>");
document.write("<param name='movie' value='MyApp.swf'/>");
document.write("<embed name='MyApp' src='MyApp.swf' height='100%' width='100%'/>");
document.write("</object>");
```

The first line in the index.html page is called the Mark of the Web (MOTW). Adding the MOTW to your wrapper is optional. However, if you do not add the MOTW to your wrapper, your application might not open in the expected security zone within Internet Explorer. The following example MOTW forces Internet Explorer to open the page in the Internet zone:

```
<!-- saved from url=(0014)about:internet -->
```

In general, add a MOTW when you are previewing pages locally before publishing them on a server. For more information about the MOTW, see http://msdn.microsoft.com/en-us/library/ms537628%28VS.85%29.aspx.

To support browsers that do not have scripting enabled, you can add a `<noscript>` block to your simple wrapper. The tags in this block of code usually mirror the output of the `document.write()` methods in the embedded JavaScript file. The following example adds the `<noscript>` block:

```
<!-- index.html -->
<!-- saved from url=(0014)about:internet -->
<html>
    <body>
        <script src="mysource.js"></script>
        <noscript>
            <object id='MyApp' classid='clsid:D27CDB6E-AE6D-11cf-96B8-444553540000'
                height='100%' width='100%'>
                <param name='src' value='MyApp.swf'/>
                <embed name='MultipleButtons' src='MyApp.swf' height='100%'
                    width='100%'/>
            </object>
        </noscript>
    </body>
</html>
```

This simple wrapper does not include any assurances that the client can run the application. If they do not have a minimum version of Flash Player, their attempt to run this application will fail and they might be prompted to upgrade. The upgrade experience is considerably better with Express Install. If the user's Player does not meet the minimum requirements, the new player is automatically installed for them. You add Express Install by editing your wrapper. For more information, see "Adding Express Install to a custom wrapper" on page 2563.

With a generic wrapper, a user who clicks the Back and Forward buttons in their browser navigates the HTML pages in the browser's history and not the history of their interactions within the application. Deep linking lets users navigate their interactions with the application by using the Back and Forward buttons in their browser. You can add deep linking by editing your wrapper and deploying additional files with it. For more information, see "Adding deep linking to a custom wrapper" on page 2563.

For more information about using the `<object>` and `<embed>` tags, see "About the object and embed tags" on page 2564.

About customizing a wrapper

Use the following guidelines when you create a custom wrapper.

- You can use the HTML template in the /templates/swfobject directory as a guide to adding new features to the wrapper. For information about the template, see "About the HTML template" on page 2553.
- You must embed the SWF file and not the MXML file of an application built with Flex. Set the value of the `src` property to *mxml_filename*`.swf`.

  The following example defines the `src` property of the `<object>` tag for an MXML application called MyApp.mxml:

  ```
  <param name='src' value='MyApp.swf'>
  ```

  The `<embed>` tag uses the `src` property to define the source of the SWF file:

  ```
  src='MyApp.mxml.swf'
  ```

- Do not include periods or other special characters in the `id` and `name` properties of the `<object>` and `<embed>` tags. These tags identify the SWF object on the page, and you use them when you use the ExternalInterface API. This API lets Flex communicate with the wrapper, and vice versa. For more information about using the ExternalInterface API, see "Communicating with the wrapper" on page 226.

- Do not put the contents of the JavaScript file directly in the HTML page. This causes Internet Explorer to prompt the user before enabling Flash Player. If the client has "Disable Script Debugging (Internet Explorer)" unchecked in Internet Explorer's advanced settings, the browser still prompts the user to load the ActiveX plug-in before running it.
- If you use both the `<object>` and the `<embed>` tags in your custom wrapper, use identical values for each attribute to ensure consistent playback across browsers. For more information about the `<object>` and the `<embed>` tags, see "About the object and embed tags" on page 2564.
- To add support for deep linking, follow the instructions in "Adding deep linking to a custom wrapper" on page 2563.
- To add support for Flash Player detection, follow the instructions in "Adding Express Install to a custom wrapper" on page 2563.
- When using Flash Builder, the default wrapper includes deep linking and Express Install support. You can disable one or both of these features by using the Compiler Properties dialog box. You can also use this dialog box to set the minimum required version of Flash Player.

Adding Express Install to a custom wrapper

Express Install uses the existing Flash Player to upgrade users to the latest version of the Player when it is required for viewing content. Express Install requires that the user has Flash Player 6.0.65 or later installed on a Mac or Windows operating system. Express Install also requires the user to have JavaScript enabled in the browser.

Support for Express Install is included in the wrapper that is generated by Flash Builder. You can enable or disable it in Flash Builder prior to generating the wrapper in Flash Builder's Flex Compiler Properties dialog box.

If you write your own custom wrapper and want to use Express Install, you must add support for it manually. Adobe recommends that you use the Express Install functionality in the wrapper template at /templates/swfobject directory as a base.

Adding Express Install support from the wrapper template involves adding JavaScript to your main wrapper file, as well as deploying the swfobject.js file. In addition, you must deploy the playerProductInstall.swf file with your application. This file is located in the SWF file's output directory when you build a project in Flash Builder, or the /templates/swfobject directory if you use the SDK.

You can also use the Flash Player Detection Kit to add Express Install support to your custom wrapper.

Flash Player Detection Kit

Adding deep linking to a custom wrapper

Support for deep linking, also known as history management, is included by default in the HTML that is wrapper generated by Flash Builder. If you write your own wrapper, however, you must add it manually or use the HTML template file as a base.

To add deep linking support, you reference the history.js and history.css files in your wrapper. The following sample wrapper references these files in the /history subdirectory:

```
<!-- index.html -->
<!-- saved from url=(0014)about:internet -->
<html>
<body>
    <link rel="stylesheet" type="text/css" href="history/history.css" />
    <script type="text/javascript" src="history/history.js"></script>
    <script src="mysource.js"></script>
</body>
</html>
```

The history.js file records actions for deep linking. The history.css file defines styles for the history files. To support deep linking in your application built with Flex, you must deploy the following files with your wrapper:

- history.js
- historyFrame.html
- history.css

These files are generated by Flash Builder in the /history directory. If you are using the SDK, you can get these files from the /templates/swfobject/history directory.

If you do not add deep linking support to your wrapper, you cannot use the BrowserManager class in applications built with Flex.

“Deep linking” on page 2022

About the object and embed tags

The `<object>` and `<embed>` tags embed SWF files in HTML. The wrapper generated by Flash Builder hides the details of these tags from you for most common use cases.

Adobe recommends using SWFObject 2 rather than the `<object>` and `<embed>` tags to embed your SWF file, but these tags are useful in some cases, such as if you want to create a custom wrapper or if there is a likelihood that your users will have JavaScript disabled in their browsers.

For browsers with scripting disabled, the default HTML template uses the `<object>` and `<embed>` tags to embed your application. These tags are children of the `<noscript>` tag, which means that the browser executes them when scripting is disabled on the client. When you compile a project in Flash Builder, Flex Builder sets the values of the tokens within these tags for you. When you compile an application with the SDK, you must manually edit the template and set the values of these tags.

You can also use the `<object>` and `<embed>` tags tags in simple HTML wrappers. For more complex wrappers, or wrappers that support features such as Express Install, you should use the SWFObject 2 functionality as described in “About SWFObject 2” on page 2555.

The `<object>` and `<embed>` tags support a set of properties that add additional functionality to the wrapper. These properties let you change the appearance of the SWF file on the page or change some of its properties such as the title or language. If you want to customize your wrapper, you can add these properties to the wrapper.

The `<object>` tag is supported by Internet Explorer 3.0 or later on Windows platforms or any browser that supports the use of the Flash ActiveX control. The `<embed>` tag is supported by Netscape Navigator 2.0 or later, or browsers that support the use of the Netscape-compatible plug-in version of Flash Player.

When an ActiveX-enabled browser loads the HTML page, it reads the values set on the `<object>` and ignores the `<embed>` tag. When browsers using the Flash plug-in load the HTML page, they read the values set on the `<embed>` tag and ignore the `<object>` tag. Make sure that the properties for each tag are identical, unless you want different results depending on the user's browser.

The following are required attributes of the `<object>` tag:

- `height`
- `width`
- `classid`

All other properties are optional and you set their values in separate, named `<param>` tags.

Although the `movie` property is technically an optional tag, without it, there is no reference to the SWF file you want the client to load. Therefore, your wrapper should always set the `movie` parameter in the `<object>` tag.

The following example shows the required properties as attributes of the `<object>` tag, and two optional properties, `movie` and `quality`, as `<param>` child tags:

```
<object classid="clsid:d27cdb6e-ae6d-11cf-96b8-444553540000" width="100" height="100">
    <param name="movie" value="moviename.swf">
    <param name="quality" value="high">
</object>
```

For the `<embed>` tag, all settings are attributes that appear between the angle brackets of the opening `<embed>` tag. The `<embed>` tag requires the `height` and `width` attributes. The `<embed>` tag does not require a `classid` attribute. As with the `movie` parameter of the `<object>` tag, the `src` attribute of the `<embed>` tag provides the reference to the application. Without it, there would be no SWF file, so you should consider it a required attribute.

The following example shows a simple `<embed>` tag with the optional `quality` attribute:

```
<embed src="moviename.swf" width="100" height="100" quality="high"></embed>
```

To use both tags together, position the `<embed>` tag just before the closing `</object>` tag, as the following example shows:

```
<object classid="clsid:d27cdb6e-ae6d-11cf-96b8-444553540000" width="100" height="100">
    <param name="movie" value="moviename.swf">
    <param name="quality" value="high">
    <embed src="moviename.swf" width="100" height="100" quality="high"></embed>
</object>
```

When you define parameters for the `<object>` tag, also add them as tag properties to the `<embed>` tag so that the SWF file appears the same on the page regardless of the client's browser.

If you are using the included HTML wrapper template, you will need to replace tokens such as `${height}` and `${width}` with absolute values before deploying the wrapper. For more information, see "About the HTML template" on page 2553.

Not all properties are supported by both the `<object>` and the `<embed>` tags. For example, the `id` property is used only by the `<object>` tag, just as the `name` property is used only by the `<embed>` tag.

In some cases, the `<object>` and `<embed>` tag properties duplicate properties that you can set on the `<s:Application>` tag in the application source code. For example, you can set the `height` and `width` properties of the SWF file on the `<object>` and `<embed>` tags or you can set them on the `<s:Application>` tag.

The following table describes the supported `<object>` and `<embed>` tag properties:

Property	Type	Description
`align`	String	Specifies the position of the SWF file. The `align` property supports the following values: • `bottom`: Vertically aligns the bottom of the SWF file with the current baseline. This is typically the default value. • `middle`: Vertically aligns the middle of the SWF file with the current baseline. • `top`: Vertically aligns the top of the SWF file with the top of the current text line. • `left`: Horizontally aligns the SWF file to the left margin. • `right`: Horizontally aligns the SWF file to the right margin.
`allowNetworking`	String	Restricts communication between the HTML page and the SWF file. This property affects more APIs than the `allowScriptAccess` property. The `allowNetworking` property supports the following values: • `all`: No networking restrictions. Flash Player behaves normally. This is typically the default. • `internal`: SWF files cannot call browser navigation or browser interaction APIs (such as the `ExternalInterface.call()`, `fscommand()`, and `navigateToURL()` methods), but can call other networking APIs. • `none`: SWF files cannot call networking or SWF-to-SWF file communication APIs. In addition to the APIs restricted by the `internal` value, these include other methods such as `URLLoader.load()`, `Security.loadPolicyFile()`, and `SharedObject.getLocal()`. For more information, see ActionScript 3.0 Developer's Guide.
`allowScriptAccess`	String	Controls the ability to perform outbound scripting from within the SWF file. The `allowScriptAccess` property can prevent a SWF file hosted from one domain from accessing a script in an HTML page that comes from another domain. Valid values are as follows: • `always`: Outbound scripting always succeeds. • `samedomain:` Outbound scripting succeds only if the application is from the same domain as the HTML page. • `never`: Outbound scripting always fails. Using this value is deprecated and not recommended, and should not be necessary if you do not serve untrusted SWF files from your own domain. If you do need to serve untrusted SWF files, Adobe recommends that you create a distinct subdomain and place all untrusted content there. This property affects the following operations: • `ExternalInterface.call()` • `fscommand()` • `navigateToURL()`, when used with `javascript` or another scripting scheme • `navigateToURL()`, when used with window name of `_self`, `_parent`, or `_top`. For more information, see ActionScript 3.0 Developer's Guide.
`archive`	String	Specifies a space-separated list of URIs for archives containing resources used by the application, which may include the resources specified by the `classid` and `data` properties. Preloading archives can result in reduced load times for applications. Archives specified as relative URIs are interpreted relative to the `codebase` property.

Property	Type	Description
base	String	Specifies the base directory or URL used to resolve relative path statements in ActionScript.
bgcolor	String	Specifies the background color of the application.
border	int	Specifies the width of the SWF file’s border, in pixels. The default value for this property depends on the user agent.
classid	String	Defines the classid of Flash Player. This identifies the ActiveX control for the browser. Internet Explorer 3.0 or later on Windows 9x, Windows 2000, Windows NT, Windows ME, and Windows XP prompt the user with a dialog box asking if they would like to auto-install Flash Player if it's not already installed. This process can occur without the user having to restart the browser. This property is used for the <object> tag only. For the <object> tag, you set the value of this property as an attribute of the <object> tag and not as a <param> tag.
codetype	String	Defines the content type of data expected when downloading the application specified by the classid property The codetype property is optional but recommended when the classid property is specified; it lets the browser avoid loading unsupported content types. The default value of the codetype property is the value of the type property.
data	String	Specifies the location of the application’s data; for example, instance image data for objects that define images.
declare	Boolean	Makes the current SWF file’s definition a declaration only. The SWF file must be instantiated by a subsequent object definition referring to this declaration.
devicefont	Boolean	Specifies whether static text objects for which the deviceFont option is not selected are drawn using a device font anyway, if the needed fonts are available from the operating system.
dir	String	Specifies the base direction of text in an element’s content and attribute values. It also specifies the directionality of tables. Valid values are LTR (left-to-right text or table) and RTL (right-to-left text or table).
flashVars	String	Sends variables to the application. The format is a set of name-value pairs, each separated by an ampersand (&). Most browsers support string sizes of up to 64 KB (65535 bytes) in length. The default value of this property is typically an empty string. The value of this property is URL encoded prior to being sent to the application. For more information on using flashVars to pass variables to applications built with Flex, see “Communicating with the wrapper” on page 226.
height	int	The height of the application SWF file. For the <object> tag, you set the value of this property as an attribute of the <object> tag and not as a <param> child tag.
hspace	int	Specifies the amount of white space inserted to the left and right of the SWF file. The default value is typically not specified, but is generally a small, nonzero length.
id	String	Identifies the SWF file to the host environment (a web browser, for example) so that it can be referenced by using a scripting language such as VBScript or JavaScript. The id property is only used with the <object> tag. It is equivalent to the name property used with the <embed> tag.
lang	String	Specifies the base language of an element’s property values and text content. The default value is typically unknown. The browser can use language information specified using the lang property to control rendering in a variety of ways.

Property	Type	Description
menu	Boolean	Changes the appearance of the menu that appears when users right-click over an application in Flash Player. Set to true to display the entire menu. Set to false to display only the About and Settings options on the menu. The default value is typically true.
movie	String	Specifies the location of the SWF file. The movie property is only used with the <object> tag. It is equivalent to the src property used with the <embed> tag.
name	String	Identifies the SWF file to the host environment (a web browser, typically) so that it can be referenced by using a scripting language. The name property is only used with the <embed> tag. It is equivalent to the id property used with the <object> tag.
quality	String	Defines the quality of playback in Flash Player. Valid values of quality are low, medium, high, autolow, autohigh, and best. The default value is typically best. The low setting favors playback speed over appearance and never uses anti-aliasing. The autolow setting emphasizes speed at first but improves appearance whenever possible. Playback begins with anti-aliasing turned off. If Flash Player detects that the processor can handle it, anti-aliasing is turned on. The autohigh setting emphasizes playback speed and appearance equally at first, but sacrifices appearance for playback speed if necessary. Playback begins with anti-aliasing turned on. If the actual frame rate drops below the specified frame rate, anti-aliasing is turned off to improve playback speed. Use this setting to emulate the View > Antialias setting in Flash. The medium setting applies some anti-aliasing and does not smooth bitmaps. The high setting favors appearance over playback speed and always applies anti-aliasing. The best setting provides the best display quality and does not consider playback speed. All output is anti-aliased and all bitmaps are smoothed.
salign	String	Positions the SWF file within the browser. Valid values are L, T, R, B, TL, TR, BL, and BR. L, R, T, and B align the SWF file along the left, right, top, or bottom edge, respectively, of the browser window and crop the remaining three sides as needed. TL and TR align the SWF file to the top-left and top-right corner, respectively, of the browser window and crop the bottom and remaining right or left side as needed. BL and BR align the SWF file to the bottom-left and bottom-right corner, respectively, of the browser window and crop the top and remaining right or left side as needed.
scale	String	Defines how the browser fills the screen with the SWF file. The default value is typically showall. Valid values of the scale property are showall, noborder, and exactfit. Set to showall to make the entire SWF file visible in the specified area without distortion, while maintaining the original aspect ratio of the SWF file. Borders may appear on two sides of the SWF file. Set to noborder to scale the SWF file to fill the specified area, without distortion but possibly with some cropping, while maintaining the original aspect ratio of the SWF file. Set to exactfit to make the entire SWF file visible in the specified area without trying to preserve the original aspect ratio. Distortion may occur.
src	String	Specifies the location of the SWF file. The src property is only used with the <embed> tag. It is equivalent to the movie property used with the <object> tag.

Property	Type	Description
standby	String	Defines a message that the browser displays while loading the object's implementation and data.
style	String	Specifies style information for the SWF file. The syntax of the value of the style property is determined by the default style sheet language. In CSS, property declarations have the form "name:value" and are separated by a semicolon. Styles set with this property do not affect components or the Application container in the application. Rather, they apply to the SWF file as it appears on the HTML page.
supportembed	Boolean	Determines whether the Netscape-specific <embed> tag is supported. The supportembed property is optional, and the default value is typically true. Set to false to prevent the <embed> tag from being read by the browser.
tabindex	int	Specifies the position of the SWF file in the tabbing order for the current document. This value must be a number between 0 and 32767. User agents should ignore leading zeros.
title	String	Displays information about the SWF file. Values of the title property can be rendered by browsers or other user agents in different ways. For example, some browsers display the title as a ToolTip. Audio user agents might speak the title information in a similar context.
type	String	Specifies the content type for the data specified by the data property. The type property is optional but recommended when data is specified; it prevents the browser from loading unsupported content types. If the value of this property differs from the HTTP Content-Type returned by the server, the HTTP Content-Type takes precedence.
usemap	String	Associates an image map with the SWF file. The image map is defined by a map element. The value of usemap must match the value of the name attribute of the associated map element.
vspace	int	Specifies the amount of white space inserted above and below the SWF file. The default value is typically not specified, but is generally a small, nonzero length.
width	int	The width of the application SWF file. For the <object> tag, you set the value of this property as an attribute of the <object> tag and not as a <param> tag.
wmode	String	Sets the Window Mode property of the SWF file for transparency, layering, and positioning in the browser. Valid values of wmode are window, opaque, and transparent. Set to window to play the SWF in its own rectangular window on a web page. Set to opaque to hide everything on the page behind it. Set to transparent so that the background of the HTML page shows through all transparent portions of the SWF file. This can slow animation performance. To make sections of your SWF file transparent, you must set the alpha property to 0. To make your application's background transparent, set the backgroundAlpha property on the <fx:Application> tag to 0. The wmode property is not supported in all browsers and platforms.

The <object> and <embed> tags can also take additional properties that are not supported by applications built with Flex. These unsupported properties are listed in "Unsupported Flash Player properties" on page 2570.

Unsupported Flash Player properties

Some optional Flash Player properties do not apply to applications built with Flex. These are properties that involve movie frames and looping. The following properties have no effect when used with Flex:

- `loop`
- `play`
