1 Create a function that calls the `removeChildAt` method of the editor's tool bar Container subcontrol, specifying the control to remove.

2 Call the method in the RichTextEditor control's `initialize` event listener.

The following example removes the alignment buttons from a RichTextEditor control, and shows the default appearance of a second RichTextEditor control:

```
<?xml version="1.0"?>
<!-- textcontrols/RTERemoveAlignButtons.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    height="700">
    <fx:Script><![CDATA[
        public function removeAlignButtons():void {
            rt1.toolbar.removeChild(rt1.alignButtons);
        }
    ]]></fx:Script>

    <s:VGroup>
        <mx:RichTextEditor id="rt1"
            title="RichTextEditor With No Align Buttons"
            creationComplete="removeAlignButtons()"/>
        <mx:RichTextEditor id="rt2"
            title="Default RichTextEditor"/>
    </s:VGroup>

</s:Application>
```

Add a new subcontrol

1 Create an ActionScript function that defines the subcontrol. Also create any necessary methods to support the control's function.

2 Call the method in the RichTextEditor control's `initialize` event listener, as in the following tag:

```
<mx:RichTextEditor id="rt" initialize="addMyControl()"
```

The following example adds a find-and-replace dialog box to a RichTextEditor control. It consists of two files: the application, and a custom TitleWindow control that defines the find-and-replace dialog (which also performs the find-and-replace operation on the text). The application includes a function that adds a button to pop up the TitleWindow, as follows:

```
<?xml version="1.0"?>
<!-- textcontrols/CustomRTE.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
            import mx.controls.*;
            import mx.containers.*;
            import flash.events.*;
            import mx.managers.PopUpManager;
            import mx.core.IFlexDisplayObject;
            /* The variable for the pop-up dialog box. */
            public var w:IFlexDisplayObject;
            /* Add the Find/Replace button to the Rich Text Editor control's
               tool bar container. */
            public function addFindReplaceButton():void {
                var but:Button = new mx.controls.Button();
                but.label = "Find/Replace";
                but.addEventListener("click",findReplaceDialog);
                rt.toolbar.addChild(but);
            }
            /* The event listener for the Find/Replace button's click event
               creates a pop-up with a MyTitleWindow custom control. */
            public function findReplaceDialog(event:Event):void {
            var w:MyTitleWindow = MyTitleWindow(PopUpManager.createPopUp(this, MyTitleWindow,
true));
                w.height=200;
                w.width=340;
                /* Pass the a reference to the textArea subcomponent
                   so that the custom control can replace the text. */
                w.RTETextArea = rt.textArea;
                PopUpManager.centerPopUp(w);
            }
        ]]>
    </fx:Script>
    <mx:RichTextEditor id="rt" width="95%"
        title="RichTextEditor"
        text="This is a short sentence."
        initialize="addFindReplaceButton()"/>
</s:Application>
```

The following MyTitleWindow.mxml file defines the custom myTitleWindow control that contains the find-and-replace interface and logic:

```
<?xml version="1.0"?>
<!-- textcontrols/MyTitleWindow.mxml -->
<!-- A TitleWindow that displays the X close button. Clicking the close button
only generates a CloseEvent event, so it must handle the event to close the control. -->
<mx:TitleWindow
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    title="Find/Replace"
    showCloseButton="true"
    close="closeDialog();">

    <fx:Script>
        <![CDATA[
            import mx.controls.TextArea;
            import mx.managers.PopUpManager;
            /* Reference to the RichTextArea textArea subcomponent.
               It is set by the application findReplaceDialog method
               and used in the replaceAndClose method, below. */
            public var RTETextArea:TextArea;
            /* The event handler for the Replace button's click event.
               Replace the text in the RichTextEditor TextArea and
               close the dialog box. */
            public function replaceAndClose():void{
                RTETextArea.text = RTETextArea.text.replace(ti1.text, ti2.text);
                PopUpManager.removePopUp(this);
            }
            /* The event handler for the TitleWindow close button. */
            public function closeDialog():void {
                PopUpManager.removePopUp(this);
            }
        ]]>
    </fx:Script>
    <!-- The TitleWindow subcomponents: the find and replace inputs,
         their labels, and a button to initiate the operation. -->
    <mx:Label text="Find what:"/>
    <mx:TextInput id="ti1"/>

    <mx:Label text="Replace with:"/>
    <mx:TextInput id="ti2"/>

    <mx:Button label="Replace" click="replaceAndClose();"/>
</mx:TitleWindow>
```

Using the Flex AIR components

When building an Adobe® AIR® application in Flex, you can use any of the controls and other components that are part of Flex. In addition, Flex includes a set of components that are specifically for AIR applications.

Flex AIR components overview

The Flex AIR components can be divided into the following groups:

File system controls

The file system controls are a set of user-interface controls that provide information about and tools to interact with the file system of the local computer on which the AIR application is running. These include controls for displaying lists of files in tree or grid format, controls for choosing directories or files from a list or combo box, and so on.

- "About file system controls" on page 835
- "FileSystemComboBox control" on page 836
- "FileSystemTree control" on page 837
- "FileSystemList control" on page 838
- "FileSystemDataGrid control" on page 839
- "FileSystemHistoryButton control" on page 840
- "Displaying a directory structure with Flex AIR" on page 841

HTML control

The HTML control is used to display an HTML web page within a Flex application. For example, you could use it to combine HTML and Flex content in a single application. You cannot use the HTML control in a mobile Flex application.

- "About the HTML control" on page 842

FlexNativeMenu control

The FlexNativeMenu control provides the ability to use MXML to declaratively define the structure of a native menu. You can use it to define an application menu (on OS X), a window's menu (on Windows), a context menu, and so forth.

- "About the FlexNativeMenu control" on page 843

Window containers

The window containers are two components that can be used as containers for defining the layout of windows in applications. There are two window containers: the WindowedApplication, a substitute for the Application container to use as the main or initial window of an AIR application; and the Window, for application windows that are opened after the initial window of the application.

- "About the AIR window containers" on page 861.
- "WindowedApplication container" on page 861
- "Window container" on page 862

About file system controls

The Flex file system components combine the functionality of other Flex controls, such as Tree, DataGrid, ComboBox, and so forth, with pre-built awareness of the file system on the application user's computer. These controls duplicate the functionality of user interface controls that are commonly used in desktop applications for browsing and selecting files and directories. You can use one or two of them to directly include file-related functionality in a screen of your application. Or you can combine several of them together to create a full-featured file browsing or selection dialog box.

Each of the Flex file system controls, except the FileSystemHistoryButton control, displays a view of the contents of a particular directory in the computer's file system. For instance, the FileSystemTree displays the directory's contents in a hierarchical tree (using the Flex Tree control) and the FileSystemComboBox displays the directory and its parent directories in the menu of a ComboBox control.

***Note:** The File class includes methods for accessing the file and directory selection dialog boxes built-in to the operating system. For example, the File.browseForOpen() method presents the user with a dialog box for opening a file. The File class also includes the `browseForDirectory()`, `browseForOpenMultiple()`, and `browseForSave()` methods. It is often better and easier to use these methods that to construct your own file selection user interface. For more information, see Letting the user browse to select a file and Letting the user browse to select a directory.*

For any of the Flex file system controls except the FileSystemHistoryButton control, you use the control's `directory` property to change the currently selected directory for a control. You can also use the `directory` property to retrieve the current directory, such as if the user selects a directory in the control.

FileSystemComboBox control

A FileSystemComboBox defines a combo box control for selecting a location in a file system. The control always displays the selected directory in the combo box's text field. When the combo box's drop-down list is displayed, it shows the hierarchy of directories that contain the selected directory, up to the computer root directory. The user can select a higher-level directory from the list. In this sense, the FileSystemComboBox control's behavior is different from the FileSystemTree, FileSystemList, and FileSystemDataGrid controls that display the directories and files that are contained by the current directory.

For more information on the FileSystemComboBox control, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Creating a FileSystemComboBox control

You use the `<mx:FileSystemComboBox>` tag to define a FileSystemComboBox control in MXML. Specify an `id` value if you intend to refer to a component elsewhere in your MXML, either in another tag or in an ActionScript block.

You specify the currently displayed directory using the control's `directory` property. The `directory` property can be set in MXML by binding the value to a property or variable, or by setting the property in ActionScript. When you set the `directory` property, the data provider of the underlying combo box is automatically populated. By default the `directory` property is set to the root "Computer" directory, which has no ancestor directories and hence shows no selectable directories in the combo box's drop-down list.

The following example shows four variations on the basic FileSystemComboBox. Each combo box is initially set to the user's desktop directory, in the application's `creationComplete` handler. The distinct characteristics of the combo boxes are as follows:

- The first combo box simply displays the selected directory.
- The second combo box's `showIcons` property is set to `false`, so no icon appears next to the items in the combo box's list.
- The third combo box's `indent` property is set to 20, which is larger than the default. As a result, the items in the combo box's list are more indented than normal.
- The fourth combo box has an event handler defined for the `directoryChange` event. When the selected directory in the combo box changes, it calls the `setOutput()` method, which writes the selected directory's path to a TextArea control named `output`.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- aircomponents/src/FSComboBoxSimple.mxml -->
<s:WindowedApplication xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    creationComplete="init();">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import flash.filesystem.File;

            private function init():void {
                fcb.directory = File.desktopDirectory;
                fcbIndent.directory = File.desktopDirectory;
                fcbNoIcons.directory = File.desktopDirectory;
                fcbChange.directory = File.desktopDirectory;
            }

            private function setOutput():void {
                output.text = fcbChange.directory.nativePath;
            }
        ]]>
    </fx:Script>

    <mx:FileSystemComboBox id="fcb"/>
    <mx:FileSystemComboBox id="fcbNoIcons"
        showIcons="false"/>
    <mx:FileSystemComboBox id="fcbIndent"
        indent="20"/>
    <mx:FileSystemComboBox id="fcbChange"
        directoryChange="setOutput();"/>
    <s:TextArea id="output"
        width="200" height="50"/>
</s:WindowedApplication>
```

FileSystemComboBox user interaction

The FileSystemComboBox supports the same user interaction as a standard combo box control. The control displays a directory in its selection field. The user clicks the button (or uses the keyboard) to open a drop-down list containing the names of the hierarchy of directories that contain the selected directory. The user can then select one of the directories, which causes the drop-down list to close and the selected directory to become the current directory. When the user selects a directory, the control dispatches the `directoryChange` event, and its `directory` property changes to the newly selected directory.

FileSystemTree control

A FileSystemTree control displays the contents of a file system directory as a tree. The tree can display the directory's files, its subdirectories, or both. For files, file names can be displayed with or without extensions.

For more information on the FileSystemTree control, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Creating a FileSystemTree control

You use the `<mx:FileSystemTree>` tag to define a FileSystemTree control in MXML. Specify an `id` value if you intend to refer to a component elsewhere in your MXML, either in another tag or in an ActionScript block.

You specify the currently displayed directory using the control's `directory` property. You can set the directory property in MXML by binding the value to a property or variable, or by setting the property in ActionScript. When you set the `directory` property, the data provider of the underlying tree control is automatically populated. The specified directory isn't displayed in the tree—its child files or directories are shown as the top-level nodes of the tree. By default the `directory` property is set to the root "Computer" directory. Consequently, its children (the drive or drives attached to the computer) are displayed as the top branches of the tree.

The following example demonstrates creating a FileSystemTree control that displays all files and folders, which is the default. In addition, hidden files are shown by setting the `showHidden` property to `true`.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- aircomponents/src/FSTreeSimple.mxml -->
<s:WindowedApplication
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <mx:FileSystemTree showHidden="true"/>
</s:WindowedApplication>
```

FileSystemTree user interaction

The FileSystemTree control supports the same types of user interaction as the standard Flex Tree control. In addition, the FileSystemTree control provides several additional events for file-related functionality. If the user double-clicks a closed directory node or clicks its disclosure icon, the control dispatches a `directoryOpening` event. If the user double-clicks an open directory node or clicks its disclosure icon, the control dispatches a `directoryClosing` event. If the user double-clicks a file node, the control dispatches a `fileChoose` event.

FileSystemList control

A FileSystemList control displays the contents of a file system directory as selectable items in a scrolling list (a Flex List control). The displayed contents can include subdirectories and files, with additional filtering options as well. A FileSystemList control can be linked to a FileSystemHistoryButton control, meaning that the button can be used to move to a previously displayed directory.

For more information on the FileSystemList control, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Creating a FileSystemList control

You use the `<mx:FileSystemList>` tag to define a FileSystemList control in MXML, as the following example shows. Specify an `id` value if you intend to refer to a component elsewhere in your MXML, either in another tag or in an ActionScript block.

You specify the currently displayed directory using the control's `directory` property. The directory property can be set in MXML by binding the value to a property or variable, or by setting the property in ActionScript. When you set the `directory` property, the data provider of the underlying list control is automatically populated. The specified directory isn't displayed in the list—its child files or directories are shown as the items in the list. By default the `directory` property is set to the root "Computer" directory. In that case its children, which are the drive or drives attached to the computer, are displayed as the items in the list.

The following example demonstrates creating a FileSystemList control that displays all files and folders (the default). The sample also includes a button for navigating up one level in the directory hierarchy. The button is enabled if the currently displayed directory has a parent directory because the button's `enabled` property is bound to the FileSystemList control's `canNavigateUp` property. The button navigates up one level by calling the FileSystemList control's `navigateUp()` method when it is clicked.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- aircomponents/src/FSListSimple.mxml -->
<s:WindowedApplication xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <mx:FileSystemList id="fileList"/>
    <s:Button label="Up"
        click="fileList.navigateUp();"
        enabled="{fileList.canNavigateUp}"/>
</s:WindowedApplication>
```

FileSystemList user interaction

The FileSystemList control provides standard scrolling list functionality for files: a user can scroll through the list of files and select one or multiple files or directories. When the user double-clicks a directory, the FileSystemList control automatically sets that directory as the control's `directory` property. It then becomes the directory whose contents are displayed in the list.

FileSystemDataGrid control

A FileSystemDataGrid displays file information in a data-grid format. The file information displayed includes the file name, creation date, modification date, type, and size. Data grid columns displaying this information are automatically created in the underlying DataGrid control, and can be removed or customized in the same way that you customize DataGrid columns. The displayed contents can include subdirectories and files, with additional filtering options as well. A FileSystemList control can be linked to a FileSystemHistoryButton control, meaning that the button can be used to move to a previously displayed directory.

For more information on the FileSystemDataGrid control, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Creating a FileSystemDataGrid control

You use the `<mx:FileSystemDataGrid>` tag to define a FileSystemDataGrid control in MXML, as the following example shows. Specify an `id` value if you intend to refer to a component elsewhere in your MXML, either in another tag or in an ActionScript block.

You specify the currently displayed directory using the control's `directory` property. You can set the directory property in MXML by binding the value to a property or variable, or by setting the property in ActionScript. When you set the `directory` property the data provider of the underlying data grid control is automatically populated. The specified directory isn't displayed in the grid—its child files or directories are shown as the rows in the grid. By default the `directory` property is set to the root "Computer" directory. In that case its children, the drive or drives attached to the computer, are displayed as the items in the grid.

The following example demonstrates creating a FileSystemDataGrid control that displays all files and folders (the default). The sample also includes a button for navigating up one level in the directory hierarchy. The button is enabled if the currently displayed directory has a parent directory because the button's `enabled` property is bound to the FileSystemDataGrid control's `canNavigateUp` property. The button navigates up one level by calling the FileSystemDataGrid control's `navigateUp()` method when it is clicked.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- aircomponents/src/FSDataGridSimple.mxml -->
<s:WindowedApplication xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <mx:FileSystemDataGrid id="fileGrid"/>
    <s:Button label="Up"
        click="fileGrid.navigateUp();"
        enabled="{fileGrid.canNavigateUp}"/>
</s:WindowedApplication>
```

FileSystemDataGrid user interaction

The FileSystemDataGrid control includes standard DataGrid functionality such as scrolling through the grid, selecting grid rows, reordering grid columns, and sorting grid data by clicking the grid headers.

In addition, the FileSystemDataGrid provides some file-specific functionality. A FileSystemDataGrid allows a user to navigate to other directories using the mouse or keyboard. The user can change the directory by double-clicking a subdirectory, by pressing Enter or Ctrl-Down when a subdirectory is selected, by pressing Ctrl-Up when the control isn't displaying the COMPUTER directory, by pressing Ctrl-Left when there is a “previous” directory to navigate back to, or by pressing Ctrl-Right when there is a “next” directory to navigate forward to.

If the user attempts to change the directory being displayed, the control dispatches a cancelable `directoryChanging` event. If the event isn’t canceled, the control displays the contents of the new directory and its `directory` property changes. Whenever the `directory` property changes for any reason, the controls dispatches a `directoryChange` event.

FileSystemHistoryButton control

The FileSystemHistoryButton control lets the user move backwards or forwards through the navigation history of another control. It works in conjunction with a FileSystemList or FileSystemDataGrid control, or any similar control with a property containing an array of File objects. The FileSystemHistoryButton is a PopUpMenuButton. It has a button for navigating back or forward one step in the history. It also has a list of history steps from which one step can be chosen.

To link a FileSystemHistoryButton to a control, bind the button’s `dataProvider` property to one of the control’s properties. The property must contain an array of File objects representing a sequence of directories in a file system browsing history. For instance, you can bind the `dataProvider` property to the `forwardHistory` or `backHistory` property of a FileSystemList or FileSystemDataGrid control. The button can then be used to navigate the display history of that control if you set the `click` and `itemClick` event handlers of the button to call the `navigateForward()` or `navigateBack()` method of the control.

For more information on the FileSystemHistoryButton control, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Creating a FileSystemHistoryButton control

You use the `<mx:FileSystemHistoryButton>` tag to define a FileSystemHistoryButton control in MXML. Specify an `id` value if you intend to refer to a component elsewhere in your MXML, either in another tag or in an ActionScript block.

You specify the property to which the button is bound by setting the `dataProvider` property.

The following example demonstrates creating two FileSystemHistoryButton controls that are linked to the display history of a FileSystemList control. Each button's `enabled` property is bound to the FileSystemList control's `canNavigateBack` or `canNavigateForward` property. As a result, the button is enabled if the currently displayed directory can navigate in the appropriate direction. When the user clicks a button, its event listener calls the FileSystemList control's `navigateBack()` or `navigateForward()` method. This causes the FileSystemList control to navigate to the previous or next directory.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- aircomponents/src/FSHistoryBSimple.mxml -->
<s:WindowedApplication xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:HGroup>
        <mx:FileSystemHistoryButton label="Back"
            dataProvider="{fileList.backHistory}"
            enabled="{fileList.canNavigateBack}"
            click="fileList.navigateBack();"
            itemClick="fileList.navigateBack(event.index)"/>
        <mx:FileSystemHistoryButton label="Forward"
            dataProvider="{fileList.forwardHistory}"
            enabled="{fileList.canNavigateForward}"
            click="fileList.navigateForward();"
            itemClick="fileList.navigateForward(event.index)"/>
    </s:HGroup>
    <mx:FileSystemList id="fileList"/>
</s:WindowedApplication>
```

FileSystemHistoryButton user interaction

The FileSystemHistoryButton is based on the Flex PopUpMenuButton, so their core functionality is the same. When the user clicks the main button the click event is dispatched (normally moving backward or forward one step in the history). In addition, by clicking the pull-down menu button, a list of the history steps is displayed. This allows the user to navigate directly to a specific step in the history.

Displaying a directory structure with Flex AIR

The following example uses the WindowedApplication container and the FileSystemTree and FileSystemDataGrid controls. In this example, the FileSystemTree control displays a directory structure. Clicking a directory name in the FileSystemTree control causes the FileSystemDataGrid control to display information about the files in the selected directory:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- aircomponents/src/FSDirApp.mxml -->
<s:WindowedApplication xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    width="750" height="500">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <mx:HDividedBox>
        <mx:FileSystemTree id="tree"
            width="200" height="100%"
            directory="{new File('C:\\')}"
            enumerationMode="directoriesOnly"
            change="dataGrid.directory = File(tree.selectedItem);"/>
        <mx:FileSystemDataGrid id="dataGrid"
            width="100%" height="100%"
            directory="{new File('C:\\')}"/>
    </mx:HDividedBox>
</s:WindowedApplication>
```

About the HTML control

An HTML control displays HTML web pages in your application. It is designed to be used to render specific external HTML content within your AIR application. It offers functionality like a lightweight web browser, including loading HTML pages, navigation history, and the ability to access the raw HTML content.

You cannot use the HTML control in a mobile Flex application. To show HTML in a mobile Flex application, use the StageWebView class instead. Blogger Judah Frangipane describes how to do this. There is also an Adobe Developer Connection article that shows you how to create a basic web browser in a mobile Flex application.

The HTML control is not designed or intended to be used as a replacement for the Text or TextArea controls. Those controls are more appropriate for displaying formatted text or for use as an item renderer for displaying short runs of text.

Creating an HTML control

You use the `<mx:HTML>` tag to define an HTML control in MXML. Specify an `id` value if you intend to refer to a component elsewhere in your MXML, either in another tag or in an ActionScript block.

You specify the location of the HTML page to display by setting the `location` property.

The following example demonstrates the use of an HTML control in a simple application. The HTML control's `location` property is set to "http://labs.adobe.com/", so that URL is opened in the control when it loads. In addition, when the "back" and "forward" are clicked they call the control's `historyBack()` and `historyForward()` methods. A TextInput control allows the user to enter a URL location. When a third "go" button is clicked, the HTML control's `location` property is set to the `text` property of the input text field.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- aircomponents/src/HTMLSimple.mxml -->
<s:WindowedApplication xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <mx:ControlBar width="100%">
        <s:Button label="&lt; Back"
            click="content.historyBack();"/>
        <s:Button label="Forward &gt;"
            click="content.historyForward();"/>
        <s:TextInput id="address"
            text="{content.location}" width="100%"/>
        <s:Button label="Go!"
            click="content.location = address.text"/>
    </mx:ControlBar>
    <s:Group width="100%" height="100%">
        <mx:HTML id="content" location="http://labs.adobe.com/"/>
    </s:Group>
</s:WindowedApplication>
```

HTML control user interaction

For a user interacting with an HTML control, the experience is like using a web browser with only the content window and no menu bar or navigation buttons. The HTML page content displays in the control. The user can interact with the content through form fields and buttons and by clicking hyperlinks. Some of these interactions, such as clicking a link or submitting a form, would normally cause a browser to load a new page. These actions cause the HTML control to display the content of the new page and also change the value of the control's `location` property.

About the FlexNativeMenu control

A FlexNativeMenu component is a Flex wrapper for the NativeMenu class. The FlexNativeMenu allows you to use MXML and a data provider to define the structure of a menu. The FlexNativeMenu component does not have any visual representation that is rendered by Flex. Instead, a FlexNativeMenu instance defines a native operating system menu such as an application menu (OS X), a window menu (Windows), a context menu, or any other native menu that can be created in AIR.

The FlexNativeMenu component is designed to be like the Flex Menu and MenuBar components. Developers who have worked with those components should find the FlexNativeMenu familiar.

For more information on the FlexNativeMenu control, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Creating a FlexNativeMenu control

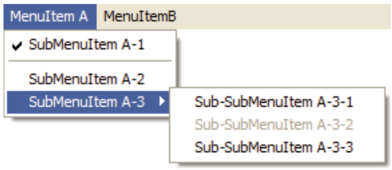
You define a FlexNativeMenu control in MXML by using the `<mx:FlexNativeMenu>` tag. Specify an `id` value if you intend to refer to a component elsewhere in your MXML application, either in another tag or in an ActionScript block. Because the FlexNativeMenu control have any visual representation, if you want to use it as the direct child of a container in MXML, you must insert it in an `<fx:Declaration>` block.

You specify the data for the FlexNativeMenu control by using the `dataProvider` property. The FlexNativeMenu control uses the same types of data providers as does the MenuBar control and the Menu control. Several of the XML attributes or object property names have meaning to the FlexNativeMenu control. For more information on structuring FlexNativeMenu data providers, see "Defining FlexNativeMenu menu structure and data" on page 849.

You can assign any name to node tags in the XML data. In subsequent examples, each node is named with the generic `<menuitem>` tag, but you can use `<node>`, `<subNode>`, `<person>`, `<address>`, and so on.

Creating an application or window menu

When you create an application or window menu using the FlexNativeMenu control, the top-level objects or nodes in the data provider correspond to the top-level menu items. In other words, they define the items that display in the menu bar itself. Items nested inside one of those top-level items define the items within the menu. Likewise, those menu items can contain items, in which case the menu item is a submenu. When the user selects the menu item it expands its own menu items. For example, the following image shows a window menu with three menu items (plus an additional separator menu item). The item with the label "SubMenuItem A-3" in turn contains three menu items, so SubMenuItem A-3 is treated as a submenu. (The code to create this menu is provided later.)



For an MXML application using the Flex WindowedApplication container as the root MXML node, you can assign a FlexNativeMenu to the WindowedApplication instance's `menu` property. The menu is used as the application menu on OS X and the window menu of the initial window on Windows. Likewise, to specify a window menu for an additional window defined using the Flex Window container, assign a FlexNativeMenu to the Window instance's `menu` property. In that case the menu displays on Windows only and is ignored on OS X.

***Note:** Mac OS X defines a menu containing standard items for every application. Assigning a FlexNativeMenu object to the* `menu` *property of the WindowedApplication component replaces the standard menu rather than adding additional menus to it.*

The following application defines a FlexNativeMenu as the `menu` property of a WindowedApplication container. Consequently, the specified menu is used as the application menu on Mac OS and the window menu of the initial window on Windows. This code creates the menu shown in the previous image:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- aircomponents/src/NativeMSimple.mxml -->
<s:WindowedApplication xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:menu>
        <mx:FlexNativeMenu dataProvider="{myMenuData}"
            labelField="@label"
            showRoot="false"/>
    </s:menu>

    <fx:Declarations>
        <fx:XML format="e4x" id="myMenuData">
            <root>
                <menuitem label="MenuItem A">
                    <menuitem label="SubMenuItem A-1" type="check" toggled="true"/>
                    <menuitem type="separator"/>
                    <menuitem label="SubMenuItem A-2"/>
                    <menuitem label="SubMenuItem A-3">
                        <menuitem label="Sub-SubMenuItem A-3-1"/>
                        <menuitem label="Sub-SubMenuItem A-3-2" enabled="false"/>
                        <menuitem label="Sub-SubMenuItem A-3-3"/>
                    </menuitem>
                </menuitem>
                <menuitem label="MenuItemB">
                    <menuitem label="SubMenuItem B-1"/>
                    <menuitem label="SubMenuItem B-2"/>
                </menuitem>
            </root>
        </fx:XML>
    </fx:Declarations>
</s:WindowedApplication>
```

in this example, the FlexNativeMenu control is used as the value of the `WindowedApplication.menu` property, so it does not have to be in an `<fx:Declaration>` block. However, if it was the direct child of the WindowedApplication container, it must be in an `<fx:Declaration>` block. For an example defining the FlexNativeMenu control in an `<fx:Declaration>` block, see “Handling FlexNativeMenu control events” on page 858.

Creating a context menu

Creating a context menu in a Flex AIR application involves two steps. You create the FlexNativeMenu instance that defines the menu structure. You then assign that menu as the context menu for its associated control. Because a context menu consists of a single menu, the top-level menu items serve as the items in the single menu. Any menu item that contains child menu items defines a submenu within the single context menu.

The FlexNativeMenu is a replacement for the context menu that you use with browser-based Flex applications (the flash.ui.ContextMenu class). You can use one type of menu or the other, but you can’t specify both types for a single component.

To assign a FlexNativeMenu component as the context menu for a visual Flex control, call the FlexNativeMenu instance’s `setContextMenu()` method, passing the visual control as the `component` parameter (the only parameter):

```
menu.setContextMenu(someComponent);
```

The same FlexNativeMenu can be used as the context menu for more than one object, by calling `setContextMenu()` multiple times using different `component` parameter values. You can also reverse the process (that is, remove an assigned context menu) using the `unsetContextMenu()` method.

The following example demonstrates creating a FlexNativeMenu component and setting it as the context menu for a Label control:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- aircomponents/src/NativeMList.mxml -->
<s:WindowedApplication xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    creationComplete="init();">

    <fx:Script>
        <![CDATA[
            import mx.controls.FlexNativeMenu;

            private var myMenu:FlexNativeMenu;

            private function init():void
            {
                myMenu = new FlexNativeMenu();
                myMenu.dataProvider = menuData;
                myMenu.labelField = "@label";
                myMenu.showRoot = false;
                myMenu.setContextMenu(lbl);
            }
        ]]>
    </fx:Script>

    <fx:Declarations>
        <!-- The XML data provider -->
        <fx:XML format="e4x" id="menuData">
            <root>
                <menuitem label="MenuItem A"/>
                <menuitem label="MenuItem B"/>
                <menuitem label="MenuItem C"/>
            </root>
        </fx:XML>
    </fx:Declarations>

    <mx:Label id="lbl" x="100" y="10"
        text="Right-click here to open menu"/>
</s:WindowedApplication>
```

In addition to context menus for visual components within an application window, an AIR application supports two other special context menus: dock icon menus (OS X) and system tray icon menus (Windows). To set either of these menus, you define the menu's structure using the FlexNativeMenu component, then you assign the FlexNativeMenu instance to the WindowedApplication container's `dockIconMenu` or `systemTrayIconMenu` property.

Before setting the `dockIconMenu` or `systemTrayIconMenu` property you may want to determine whether the user's operating system supports a dock icon or a system tray icon, using the NativeApplication class's static `supportsDockIcon` and `supportsSystemTrayIcon` properties. Doing so isn't necessary, but can be useful. For instance, you might want to customize a menu depending on whether it is used as the context menu for a dock icon or for a system tray icon.

Finally, while a dock icon exists automatically for an application, you must explicitly specify a system tray icon in order for the icon to appear. (Naturally, the icon must exist in order for the user to be able to right-click the icon to activate the context menu).

The following example defines a FlexNativeMenu that is used as a context menu. If the user's operating system supports a system tray icon, the code creates an icon and displays it in the system tray. The code then assigns the FlexNativeMenu instance as the context menu for the system tray and dock icon menus.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- aircomponents/src/NativeMContextM.mxml -->
<s:WindowedApplication xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    creationComplete="init();">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            import flash.desktop.DockIcon;
            import flash.desktop.InteractiveIcon;
            import flash.desktop.NativeApplication;
            import flash.desktop.SystemTrayIcon;
            import flash.display.Shape;
            import mx.controls.FlexNativeMenu;

            private var myMenu:FlexNativeMenu;

            private function init():void {
                // Create the menu
                myMenu = new FlexNativeMenu();
                myMenu.dataProvider = menuData;
                myMenu.labelField = "@label";
                myMenu.showRoot = false;

                var icon:InteractiveIcon;
                icon = NativeApplication.nativeApplication.icon;

                // If we need a system tray icon, create one and display it
                if (NativeApplication.supportsSystemTrayIcon)
                {
                    var iconData:BitmapData = createSystemTrayIcon();
                    SystemTrayIcon(icon).bitmaps = new Array(iconData);
                }

                // Use this approach if you want to assign the same menu
                // to the dock icon and system tray icon
                this.systemTrayIconMenu = this.dockIconMenu = myMenu;

                // Use this approach if you want to assign separate menus
//              if (NativeApplication.supportsDockIcon)
//              {
//                  this.dockIconMenu = myMenu;
//              }
//              else if (NativeApplication.supportsSystemTrayIcon)
//              {
//                  this.systemTrayIconMenu = myMenu;
//              }
            }
            private function createSystemTrayIcon():BitmapData {
                // Draw the icon in a Graphic
                var canvas:Shape = new Shape();
                canvas.graphics.beginFill(0xffff00);
                canvas.graphics.drawCircle(24, 24, 24);
                canvas.graphics.endFill();
                canvas.graphics.beginFill(0x000000);
                canvas.graphics.drawEllipse(13, 13, 9, 12);
                canvas.graphics.drawEllipse(27, 13, 9, 12);
                canvas.graphics.endFill();
                canvas.graphics.lineStyle(3, 0x000000);
                canvas.graphics.moveTo(11, 32);
                canvas.graphics.curveTo(24, 46, 37, 32);

                var result:BitmapData = new BitmapData(48, 48, true, 0x00000000);
                result.draw(canvas);

                return result;
            }
        ]]>
    </fx:Script>

     <fx:Declarations>
        <!-- The XML data provider -->
        <fx:XML format="e4x" id="menuData">
            <root>
                <menuitem label="MenuItem A"/>
                <menuitem label="MenuItem B"/>
                <menuitem label="MenuItem C"/>
            </root>
        </fx:XML>
     </fx:Declarations>

    <s:Label text="Right-click on the dock icon (Mac OS X) or system tray icon (Windows)"/>
</s:WindowedApplication>
```

***Note:** Mac OS X defines a standard menu for the application dock icon. When you assign a FlexNativeMenu as the dock icon's menu, the items in that menu are displayed above the standard items. You cannot remove, access, or modify the standard menu items.*

Creating a pop-up menu

A pop-up menu is like a context menu, but the pop-up menu isn't necessarily associated with a particular Flex component. To open a pop-up menu, create a FlexNativeMenu instance and set its `dataProvider` property to populate the menu. To open the menu on the screen, call its `display()` method:

```
myMenu.display(this.stage, 10, 10);
```

The `display()` method has three required parameters: the Stage instance that defines the coordinates within which the menu is placed, the x coordinate where the menu is placed, and the y coordinate for the menu. For an example of using the `display()` method to create a pop-up menu, see "Example: An Array FlexNativeMenu data provider" on page 852.

One important thing to keep in mind is that the `display()` method operates immediately when it's called. Several property changes cause the FlexNativeMenu's data provider to invalidate (such as changes to the data provider, changing the `labelField`, and so forth). When the `display()` method is called immediately after making such changes, those changes aren't reflected in the menu that appears on the screen. For example, in the following code listing when the button is clicked no menu appears because the menu is created and the data provider is specified in the same block of code in which the `display()` method is called:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- aircomponents/src/NativeMDisplay.mxml -->
<s:WindowedApplication xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Script>
        <![CDATA[
            import mx.controls.FlexNativeMenu;

            private function createAndShow():void
            {
                var myMenu:FlexNativeMenu = new FlexNativeMenu();
                myMenu.dataProvider = menuData;
                myMenu.labelField = "@label";
                myMenu.showRoot = false;
                // calling display() here has no result, because the data provider
                // has been set but the underlying NativeMenu hasn't been created yet.
                myMenu.display(this.stage, 10, 10);
            }
        ]]>
    </fx:Script>

     <fx:Declarations>
        <!-- The XML data provider -->
        <fx:XML format="e4x" id="menuData">
            <root>
                <menuitem label="MenuItem A"/>
                <menuitem label="MenuItem B"/>
                <menuitem label="MenuItem C"/>
            </root>
        </fx:XML>
     </fx:Declarations>
    <!-- Button control to create and open the menu. -->
    <s:Button x="300" y="10"
        label="Open Menu"
        click="createAndShow();"/>
</s:WindowedApplication>
```

Defining FlexNativeMenu menu structure and data

The techniques for defining structure and data for a FlexNativeMenu are like the techniques for structuring all Flex menu controls. Consequently, this section does not provide comprehensive information on structuring Flex menus, but instead focuses on differences between FlexNativeMenu structure versus other Flex menu components.

The `dataProvider` property of a FlexNativeMenu defines the structure of the menu. To change a menu's structure at runtime, change the data provider and the menu updates itself accordingly. Menus typically use a hierarchical data provider such as nested arrays or XML. However, a simple menu may consist of a single flat structure of menu items.

A FlexNativeMenu instance uses a data descriptor to parse and manipulate the data provider's contents. By default, a FlexNativeMenu control uses a DefaultDataDescriptor instance as its descriptor. However, you can customize menu data parsing by creating your own data descriptor class and setting it as the FlexNativeMenu control's `dataDescriptor` property. The DefaultDataDescriptor supports a data provider that is an XML object or XMLList object, an array of objects, an object with a `children` property containing an array of objects, or a collection that implements the ICollectionView interface such as an ArrayCollection or XMLListCollection instance.

Specifying and using menu entry information

Information in a FlexNativeMenu control's data provider determines how each menu entry appears and is used. To access or change the menu contents, you modify the contents of the data provider.

The FlexNativeMenu class uses the methods of the IMenuDataDescriptor interface to access and manipulate information in the data provider that defines the menu behavior and contents. Flex includes the DefaultDataDescriptor class that implements this interface. A FlexNativeMenu control uses the DefaultDataDescriptor class if you do not specify another class in the `dataDescriptor` property.

Menu entry types

Each data provider entry can specify an item type and type-specific information about the menu item. Menu-based classes support the following item types (`type` field values):

Menu item type	Description
normal	The default type. Selecting an item with the `normal` type triggers an `itemClick` event. Alternatively, if the item has children, the menu dispatches a `menuShow` event and opens a submenu.
check	Selecting an item with the `check` type toggles the menu item's `toggled` property between `true` and `false` values and triggers an `itemClick` event. When the menu item is in the `true` state, it displays a check mark in the menu next to the item's label.
separator	Items with the `separator` type provide a simple horizontal line that divides the items in a menu into different visual groups.

Unlike other Flex menu controls, the FlexNativeMenu component does not support radio-button menu items (type `radio`).

Menu attributes

Menu items can specify several attributes that determine how the item is displayed and behaves. The following table lists the attributes you can specify, their data types, their purposes, and how the data provider must represent them if the menu uses the DefaultDataDescriptor class to parse the data provider:

Attribute	Type	Description
`altKey`	Boolean	Specifies whether the Alt key is required as part of the key equivalent for the item.
`commandKey`	Boolean	Specifies whether the Command key is required as part of the key equivalent for the item.
`controlKey`	Boolean	Specifies whether the Control key is required as part of the key equivalent for the item.
`enabled`	Boolean	Specifies whether the user can select the menu item (`true`), or not (`false`). If not specified, Flex treats the item as if the value were `true`. If you use the default data descriptor, data providers must use an `enabled` XML attribute or object field to specify this characteristic.

Attribute	Type	Description
keyEquivalent	String	Specifies a keyboard character which, when pressed, triggers an event as though the menu item was selected. The menu's keyEquivalentField or keyEquivalentFunction property determines the name of the field in the data that specifies the key equivalent, or a function for determining the key equivalents. (If the data provider is in E4X XML format, you must specify one of these properties to assign a key equivalent.)
label	String	Specifies the text that appears in the control. This item is used for all menu item types except separator. The menu's labelField or labelFunction property determines the name of the field in the data that specifies the label, or a function for determining the labels. (If the data provider is in E4X XML format, you must specify one of these properties to display a label.) If the data provider is an array of strings, Flex uses the string value as the label.
mnemonicIndex	Integer	Specifies the index position of the character in the label that is used as the mnemonic for the menu item. The menu's mnemonicIndexField or mnemonicIndexFunction property determines the name of the field in the data that specifies the mnemonic index, or a function for determining mnemonic index. (If the data provider is in E4X XML format, you must specify one of these properties to specify a mnemonic index in the data.) Alternatively, you can indicate that a character in the label is the menu item's mnemonic by including an underscore immediately to the left of that character.
shiftKey	String	Specifies whether the Shift key is required as part of the key equivalent for the item.
toggled	Boolean	Specifies whether a check item is selected. If not specified, Flex treats the item as if the value were false and the item is not selected. If you use the default data descriptor, data providers must use a toggled XML attribute or object field to specify this characteristic.
type	String	Specifies the type of menu item. Meaningful values are separator and check. Flex treats all other values, or nodes with no type entry, as normal menu entries. If you use the default data descriptor, data providers must use a type XML attribute or object field to specify this characteristic.

Unlike other Flex menu controls, the FlexNativeMenu component does not support the groupName or icon attributes. In addition, it supports the additional attribute keyEquivalent and the key equivalent modifier attributes altKey, commandKey, controlKey, and shiftKey.

The FlexNativeMenu component ignores all other object fields or XML attributes, so you can use them for application-specific data.

Considerations for XML-based FlexNativeMenu data providers

In a simple case for creating a single menu or menu bar using the FlexNativeMenu control, you might use an <fx:XML> or <fx:XMLList> tag and standard XML node syntax to define the menu data provider. When you use an XML-based data provider, keep the following rules in mind:

- With the <fx:XML> tag you must have a single root node, and you set the showRoot property of the FlexNativeMenu control to false. (Otherwise, your FlexNativeMenu would have only the root node as a menu item.) With the <fx:XMLList> tag you define a list of XML nodes, and the top-level nodes define the top-level menu items.
- If your data provider has label, keyEquivalent, or mnemonicIndex attributes, the default attribute names are not recognized by the DefaultDataDescriptor class. Set the FlexNativeMenu control's labelField , keyEquivalentField, or mnemonicIndexField property and use the E4X @ notation to specify the attribute name, such as:

```
  labelField="@label"
  keyEquivalentField="@keyEquivalent"
  mnemonicIndexField="@mnemonicIndex"
```

Example: An Array FlexNativeMenu data provider

The following example uses a FlexNativeMenu component to display a popup menu. It demonstrates how to define the menu structure using an Array of plain objects as a data provider. For an application that specifies an identical menu structure in XML, see “Example: An XML FlexNativeMenu data provider” on page 853.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- aircomponents/src/NativeMArray.mxml -->
<s:WindowedApplication xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    creationComplete="init();">

    <fx:Script>
        <![CDATA[
            import mx.controls.FlexNativeMenu;

            private var myMenu:FlexNativeMenu;

            private function init():void {
                myMenu = new FlexNativeMenu();
                myMenu.dataProvider = menuData;
                myMenu.showRoot = false;
            }

            // Method to show the menu.
            private function show():void {
                myMenu.display(this.stage, 10, 10);
            }

            // The Array data provider
            [Bindable]
            public var menuData:Array = [
                {label: "MenuItem A"},
                {label: "MenuItem B", type: "check", toggled: true},
                {label: "MenuItem C", enabled: false},
                {type: "separator"},
                {label: "MenuItem D", children: [
                    {label: "SubMenuItem D-1"},
                    {label: "SubMenuItem D-2"},
                    {label: "SubMenuItem D-3"}
                    ]}
                ];
        ]]>
    </fx:Script>

    <!-- Button control to create and open the menu. -->
    <s:Button x="300" y="10"
        label="Open Menu"
        click="show();"/>
</s:WindowedApplication>
```

Example: An XML FlexNativeMenu data provider

The following example displays a popup menu using a FlexNativeMenu component. It shows how to define the menu structure using XML as a data provider. For an application that specifies an identical menu structure using an Array of objects as a data provider, see “Example: An Array FlexNativeMenu data provider” on page 852.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- aircomponents/src/NativeMxml.mxml -->

        </fx:XML>
     </fx:Declarations>

    <!-- Button control to create and open the menu. -->
    <s:Button x="300" y="10"
        label="Open Menu"
        click="show();"/>
</s:WindowedApplication>
```

Specifying menu item keyboard equivalents

You can specify a key equivalent (sometimes called an accelerator) for a menu command. When the key or key combination is pressed the FlexNativeMenu dispatches an `itemClick` event, as though the user had selected the menu item. The key equivalent string is automatically displayed beside the menu item name in the menu. The format depends on the user's operating system and system preferences. In order for the command to be invoked, the menu containing the command must be part of the application menu (OS X) or the window menu of the active window (Windows).

***Note:** Key equivalents are only triggered for application and window menus. If you add a key equivalent to a context or pop-up menu, the key equivalent is displayed in the menu label but the associated menu command is never invoked.*

About key equivalents

A key equivalent consists of two parts:

Primary key A string containing the character that serves as the key equivalent. If a data provider object has a `keyEquivalent` field, the DefaultDataDescriptor automatically uses that value as the key equivalent. You can specify an alternative data provider field by setting the FlexNativeMenu component's `keyEquivalentField` property. You can specify a function to use to determine the key equivalent by setting the FlexNativeMenu component's `keyEquivalentFunction` property.

Modifier keys One or more modifier keys that are also part of the key equivalent combination, such as the control key, shift key, command key, and so forth. If a data provider item includes an `altKey`, `commandKey`, `controlKey`, or `shiftKey` object field or XML attribute set to `true`, the specified key or keys become part of the key equivalent combination, and the entire key combination must be pressed to trigger the command. Alternatively, you can specify a function for the FlexNativeMenu component's `keyEquivalentModifiersFunction`, and that function is called to determine the key equivalent modifiers for each data provider item.

If you specify more than one key equivalent modifier, all the specified modifiers must be pressed in order to trigger the command. For instance, for the menu item generated from the following XML the key equivalent combination is Control-Shift-A (rather than Control-A OR Shift-A):

```
<menuitem label="Select All" keyEquivalent="a" controlKey="true" shiftKey="true"/>
```

Note that this can result in impossible key combinations if the menu item specifies multiple modifiers that are only available on one operating system. For example, the following item results in a menu item with the key equivalent Command-Shift-G:

```
<menuitem label="Ungroup" keyEquivalent="g" commandKey="true" shiftKey="true"/>
```

On Mac OS X, this command works as expected. On Windows, the key equivalent Shift-G is displayed in the menu. However, pressing Shift-G does not trigger the command because the Command key is still considered a required part of the command, even though that key doesn't exist in Windows.

To use different key combinations for the same menu item on different platforms, you can specify a `keyEquivalentModifiersFunction` function for the FlexNativeMenu instance. This function can provide alternative logic for processing the menu item data. For an example using the `keyEquivalentModifiersFunction`, see "Example: Using custom logic for multi-platform key equivalent menu commands" on page 855.

Example: FlexNativeMenu key equivalent commands

The following example uses a FlexNativeMenu to define a menu that includes keyboard equivalents for the menu commands. Note that while this example only uses keys and modifier keys that are available on Windows and Mac OS X, it uses the Control key as a modifier on both platforms. However, the Command key would be more in line with the common convention on Mac OS X. For an example that uses the `keyEquivalentModifiersFunction` property to create menus that use the common cross-platform conventions, see "Example: Using custom logic for multi-platform key equivalent menu commands" on page 855.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- aircomponents/src/NativeMKeyEquiv.mxml -->
<s:WindowedApplication xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:menu>
        <mx:FlexNativeMenu dataProvider="{menuData}"
            labelField="@label"
            keyEquivalentField="@keyEquivalent"
            showRoot="false"
            itemClick="trace('click:', event.label);"/>
    </s:menu>
    <fx:Declarations>
        <fx:XML format="e4x" id="menuData">
            <root>
                <menuitem label="File">
                    <menuitem label="New" keyEquivalent="n" controlKey="true"/>
                    <menuitem label="Open" keyEquivalent="o" controlKey="true"/>
                    <menuitem label="Save" keyEquivalent="s" controlKey="true"/>
                    <menuitem label="Save As..." keyEquivalent="s" controlKey="true"
shiftKey="true"/>
                    <menuitem label="Close" keyEquivalent="w" controlKey="true"/>
                </menuitem>
                <menuitem label="Edit">
                    <menuitem label="Cut" keyEquivalent="x" controlKey="true"/>
                    <menuitem label="Copy" keyEquivalent="c" controlKey="true"/>
                    <menuitem label="Paste" keyEquivalent="v" controlKey="true"/>
                </menuitem>
            </root>
        </fx:XML>
    </fx:Declarations>
</s:WindowedApplication>
```

Example: Using custom logic for multi-platform key equivalent menu commands

The following example creates the same menu structure as the previous example. However, instead of using the same keyboard combination (for example, Control-O) regardless of the user's operating system, in this example a `keyEquivalentModifiersFunction` function is defined for the FlexNativeMenu. The function is used to create keyboard equivalents that follow platform conventions by using the Control key on Windows but substituting the Command key on Mac OS X.

In the data provider data, the `controlKey="true"` attribute is still used. The function that determines the key equivalent modifiers uses the value of the `controlKey` field or XML attribute to specify the Control key on Windows and the Command key on OS X, and if the `controlKey` attribute is `false` (or not specified) then neither modifier is applied.

Specifying menu item mnemonics

A menu item mnemonic is a key associated with a menu item which, when pressed while the menu is displayed, is equivalent to selecting that menu item with the mouse. Typically, the operating system indicates a menu item’s mnemonic by underlining that character in the name of the menu item. Mnemonics for menu items are supported in Windows. In Mac OS X, when a menu is activated a user types the first letter or letters of a menu item’s label, then presses return to select the item.

The simplest way to specify a mnemonic for a menu item in a FlexNativeMenu component is to include an underscore character (“_”) in the menu item’s label field, immediately to the left of the letter that serves as the mnemonic for that menu item. For instance, if the following XML node is used in a data provider for a FlexNativeMenu, the mnemonic for the command is the first character of the second word (the letter “A”):

```
<menuitem label="Save _As"/>
```

When the native menu is created, the underscore character is not included in the label. Instead, the character following the underscore becomes the mnemonic for the menu item. To include a literal underscore character in a menu item’s name, use two underscore characters (“__”). This sequence is converted to one underscore in the menu item label.

As an alternative to using underscore characters in label names, you can provide an integer index position for the mnemonic character in a `mnemonicIndex` field in the data provider objects. You can also use another Object property or XML attribute by setting the FlexNativeMenu component’s `mnemonicIndexField` property. To use complex logic for assigning mnemonics, you can specify a function for the FlexNativeMenu component’s `mnemonicIndexFunction` property. Each of these properties provides a mechanism to define an integer (zero-based) index position for the menu items’ mnemonics.

Handling FlexNativeMenu control events

User interaction with a FlexNativeMenu is event-driven. When the user selects a menu item or opens a menu or submenu, the menu dispatches an event. You can register event listeners to define the actions that are carried out in response to the user’s selection. Event handling with the FlexNativeMenu component shares similarities with other Flex menu components, but also has key differences. For information about Flex menu component events, see Menu-based control events.

The FlexNativeMenu component defines two specific events, both of which dispatch event objects that are instances of the FlexNativeMenuEvent class:

Event	Description
`itemClick`	(FlexNativeMenuEvent.ITEM_CLICK) Dispatched when a user selects an enabled menu item of type normal or check. This event is not dispatched when a user selects a menu item that opens a submenu or a disabled menu item.
`menuShow`	(FlexNativeMenuEvent.MENU_SHOW) Dispatched when the entire menu or a submenu opens (including a top-level menu of an application or window menu).

The event object passed to the event listener is of type FlexNativeMenuEvent and contains the following menu-specific properties:

Property	Description
`index`	The index of the item in the menu or submenu that contains it. Only available for the `itemClick` event.
`item`	The item in the data provider for the menu item associated with the event. Only available for the `itemClick` event.
`label`	The label of the item. Only available for the `itemClick` event.
`nativeMenu`	A reference to the underlying NativeMenu object where the event occurred.
`nativeMenuItem`	A reference to the underlying NativeMenuItem object that triggered the event. Only available for the `itemClick` event.

To access properties of an object-based menu item, you specify the `item` property of the event object, as follows:

```
ta1.text = event.item.extraData;
```

To access attributes of an E4X XML-based menu item, you specify the menu item attribute name in E4X syntax, as follows:

```
ta1.text = event.item.@extraData;
```

***Note:** If you set an event listener on a submenu of a FlexNativeMenu component, and the menu data provider's structure changes (for example, if an element is removed), the event listener might no longer exist. To ensure that the event listener is available when the data provider structure changes, use the events of the FlexNativeMenu control, not a submenu.*

The standard approach to handling FlexNativeMenu events is to register an event listener with the FlexNativeMenu component. Any time an individual menu item is selected or submenu is opened, the FlexNativeMenu dispatches the appropriate event. Your listener code can use the event object's `item` property or other properties to determine on which menu item the interaction occurred, and perform actions in response.

The following example lets you experiment with FlexNativeMenu control events. It lets you display two menus, one with an XML data provider and one with an Array data provider. A TextArea control displays information about each event as a user opens the menus, opens submenus, and selects menu items. The example shows some of the differences in how you handle XML and object-based menus. It also indicates some of the types of information that are available about each FlexNativeMenu event.

            }
            // The event listener for the object-based Menu events.
            private function menuShowInfo2(event:FlexNativeMenuEvent):void {
                ta1.text = "event.type: " + event.type;

                // The label field is null for menuShow events.
                ta1.text += "\nevent.label: " + event.label;

                // The index value is -1 for menuShow events.
                ta1.text += "\nevent.index: " + event.index;

                // The item field is null for menuShow events.
                if (event.item)
                {
                    ta1.text += "\nItem label: " + event.item.label
                    ta1.text += "\nItem toggled: " + event.item.toggled;
                    ta1.text += "\ntype: " + event.item.type;
                }
            }
            // The object-based data provider, an Array of objects.
            // Its contents are identical to that of the XML data provider.
            public var objMenuData:Array = [
                {label: "MenuItem A", children: [
                    {label: "SubMenuItem A-1", enabled: false},
                    {label: "SubMenuItem A-2"}
                ]},
                {label: "MenuItem B", type: "check", toggled: true},
                {label: "MenuItem C", type: "check", toggled: false},
                {type: "separator"},
                {label: "MenuItem D", children: [
                    {label: "SubMenuItem D-1"},
                    {label: "SubMenuItem D-2"},
                    {label: "SubMenuItem D-3"}
                ]}
            ];
        ]]>
    </fx:Script>

    <fx:Declarations>
        <!-- The XML-based menu data provider.
        The <fx:XML tag requires a single root. -->
        <fx:XML id="xmlMenuData" format="e4x">
            <xmlRoot>
                <menuitem label="MenuItem A" >
                    <menuitem label="SubMenuItem A-1" enabled="false"/>
                    <menuitem label="SubMenuItem A-2"/>
                </menuitem>

        click="createAndShow2();"/>
    <!-- Text area to display the event information -->
    <s:TextArea x="10" y="70"
        width="200" height="250"
        id="ta1"/>
</s:WindowedApplication>
```

About the AIR window containers

Flex containers define the content, sizing, and positioning for a specific part of an application. For AIR applications, Flex includes two specific window components that serve as containers whose content area is an operating system window. Both the WindowedApplication and the Window containers can be used to define the contents of an operating system window. They also provide the means to define and control characteristics of the window itself, such as the window's size, its position on the user's screen, and the presence of window chrome.

Spark and MX window containers

Flex supplies a Spark and a MX version of the WindowedApplication and the Window containers. The Spark components are located in the spark.components package. The MX components are located in the mx.core package.

The biggest difference between the two component sets is that you use skins to set many of the visual characteristics of the Spark components, and styles to set them for the MX components. Adobe recommends that you use the Spark components in your application when possible.

WindowedApplication container

The WindowedApplication container defines an application container that you use to create Flex applications for AIR that use the native operating system chrome. The WindowedApplication container adds window-related functionality and desktop application-specific functionality to the Flex Application container, which you can use when you build AIR applications.

The WindowedApplication container serves two roles. First, it provides the entry point into the main application, which in turn executes other application logic. In that sense it serves as the core of the entire application, just as the Application container does for a browser-based Flex application. Second, the WindowedApplication container represents the first native window of the application.

If the application only uses one native window, the WindowedApplication is the base stage that contains all other content. If your application opens additional native windows, each window has its own stage and display list.

The native window defined by the WindowedApplication is no different from any other application window in this respect. This is different from a browser-based Flex application, where all of an application's windows are drawn by Flex within the same stage (the Application container).

For example, in a Flex AIR application, registering a `keyDown` event listener on the WindowedApplication container only dispatches events when a key is pressed while the initial window has focus. If the application has multiple native windows and another of the windows has focus when the key is pressed, the event is not dispatched. This behavior differs from a non-AIR Flex application, in which a `keyDown` listener registered with the Application container receives notification of all key presses while the application has focus.

For more information on the WindowedApplication container, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Creating and using a WindowedApplication container

The WindowedApplication container defines an AIR application object that includes its own window controls. In an MXML AIR application, a Spark `<s:WindowedApplication>` or MX `<mx:WindowedApplication>` tag replaces the Application tag in a Flex application.

WindowedApplication container example

The following application shows a simple use of the WindowedApplication container:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- aircomponents/src/WindowSimple.mxml -->
<s:WindowedApplication xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

       <s:Label text="Hello World" />
</s:WindowedApplication>
```

Window container

The Window container is a Flex container that is used to define the content and layout of operating system windows that are opened after an application launches. In other words, it is used for windows other than the initial or main window of the application, which is a WindowedApplication container.

In addition to the functionality that the Window container shares with the WindowedApplication container, a Window container allows you to define the main characteristics of the window. The characteristics you can specify include the type of window, the type of chrome, whether certain actions (such as resizing and maximizing) are permitted for the window, and more.

These characteristics are accessed as properties that can be set when the container is initially created, before the actual operating system window is displayed. However, once the actual window is opened, the properties can no longer be set and can only be read.

For more information about the Window container, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Creating and using a Window container

The Window container defines an AIR application object that includes its own window controls. In an MXML AIR application, you use a `<s:Window>` tag as the top-level tag of an MXML component, with the window's content defined in the body of the MXML component document. However, unlike other MXML components, a Window-based component cannot be used in another MXML document. Instead, you create an instance of the MXML component in ActionScript.

Because several of the properties of the Window container can only be set before the window is opened, they can be set as properties in the `<s:Window>` MXML tag. They can also be set using ActionScript, either in an `<fx:Script>` block in the window's MXML document or in code that creates an instance of the window.

Once the window's initial properties are set, you call the Window container's `open()` method to cause the operating system window to appear on the user's display.

Window container example

The following example shows a basic use of the Window container. The example includes two MXML files. The first uses a WindowedApplication container and is the initial window of the application. The second uses the Window container to define a secondary window for the application. In this example, the main window simulates a "splash screen" for the application. After a set time (4 seconds) it closes the splash screen and opens the second window. In order to make a splash screen window with no window chrome, in the application.xml file the `systemChrome` tag is set to `none`.

The following code defines the main application MXML file, which contains the initial window (the splash screen) that opens automatically when the application is run:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- aircomponents/src/WindowSplash.mxml -->
<s:WindowedApplication xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    creationComplete="init();">

    <fx:Script>
        <![CDATA[
            import myComponents.DocumentWindow;
            private const LOAD_DELAY:int = 4;
            private var timeElapsed:int = 0;
            private var loadTimer:Timer;

            private var docWindow:myComponents.DocumentWindow;

            private function init():void {
                // center the window on the screen
                var screenBounds:Rectangle = Screen.mainScreen.bounds;
                nativeWindow.x = (screenBounds.width - nativeWindow.width) / 2;
                nativeWindow.y = (screenBounds.height - nativeWindow.height) / 2;

                // start the timer, which simulates a loading delay
                loadTimer = new Timer(1000);
                loadTimer.addEventListener(TimerEvent.TIMER, incrementTime);
                loadTimer.start();

                updateStatus();
            }
            private function incrementTime(event:TimerEvent):void {
                timeElapsed++;

                updateStatus();

                // if the loading delay has passed, stop the timer,
                // close the splash screen, and open the document window
                if ((LOAD_DELAY - timeElapsed) == 0)
                {
                    loadTimer.stop();
                    loadTimer.removeEventListener(TimerEvent.TIMER, incrementTime);
                    loadTimer = null;

                    nativeWindow.close();

                    // open a new instance of the document window
                    docWindow = new DocumentWindow();
                    docWindow.open();
                }
            }

            private function updateStatus():void {
                var timeRemaining:uint = LOAD_DELAY - timeElapsed;
                var timeRemainingMsg:String = timeRemaining.toString() + " second";
                if (timeRemaining != 1) { timeRemainingMsg += "s"; }
                timeRemainingMsg += " remaining.";

                loadStatusMessage.text = "initializing... " + timeRemainingMsg;
            }
        ]]>
    </fx:Script>

    <s:VGroup horizontalCenter="0" verticalCenter="0">
        <s:Label text="My Splash Screen"
            fontFamily="Courier New"
            fontSize="36"/>
        <s:Label id="loadStatusMessage"
            text="initializing..."/>
    </s:VGroup>
</s:WindowedApplication>
```

The `incrementTime()` method is called each second and when the appropriate time is reached, a DocumentWindow instance is created and its `open()` method is called. The DocumentWindow class is defined in a separate MXML document. Its base MXML tag is the `<s:Window>` tag, so it is a subclass of the Window class (the Window container). Here is the source code for the DocumentWindow MXML file:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- aircomponents/src/myComponents/DocumentWindow.mxml -->
<s:Window xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    width="550" height="450">
    <s:Label text="This is a document window."
        horizontalCenter="0" verticalCenter="0"/>
</s:Window>
```

Controlling window chrome

The window that a WindowedApplication or Window container defines conforms to the standard behavior of the operating system. The user can move the window by dragging the title bar and resize the window by dragging on any side or corner of the window. The containers also include a set of properties that allow you to control window sizing, including `minimumHeight`, `minimumWidth`, `maximumHeight`, and `maximumWidth`.

The WindowedApplication container and the Window container allow you to control the presence and the appearance of the window *chrome*.

For the MX WindowedApplication or Window containers only, you can hide the chrome by setting the `showFlexChrome` style to `false`.

Setting the chrome

Flex provides several options for setting the chrome:

- Use the chrome defined by your operating system. The system chrome consists of a border and title bar. The title bar contains the close, minimize, maximize, and restore buttons. For an Apple computer, the restore button is omitted.
- Use the Flex chrome. The Flex chrome is defined by a set of skin files. The Flex chrome contains all of the elements of the system chrome, and adds a gripper to the lower-right corner of the container that you can use to resize the window. The Flex chrome also adds a status bar to the bottom of the window.
- Use the WindowedApplicationSkin class. The WindowedApplicationSkin skin class contains only a border and a status bar.
- Create your own skin files to define the chrome.

The title bar area of the chrome includes a title message and an icon that can be set and modified by using the `title` and `titleIcon` properties of the WindowedApplication or Window container. You can show or hide the status bar by using the `showStatusBar` property.

How the chrome is represented depends on the setting of the `systemChrome` attribute, which is defined in the application .xml file for a WindowedApplication container, or in the Window container's `systemChrome` property. If `systemChrome` is set to "standard" in the application .xml file (or `flash.display.NativeWindowSystemChrome.STANDARD` in ActionScript) the operating system renders the chrome.

If `systemChrome` is set to "none" (`NativeWindowSystemChrome.NONE`) the Window and WindowedApplication container can either use the Flex chrome, use the WindowedApplicationSkin class to define the chrome, or define no chrome at all. When you do not use any chrome, the application shows only a background color.

The Flex chrome is defined by the SparkChromeWindowedApplicationSkin skin class in the spark.skins.spark package. The following example sets the `skinClass` style of the WindowedApplication to specify to use the Flex chrome. This example assumes that you set `systemChrome` to "none" in the application's .xml file:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- aircomponents/src/WindowSimpleChrome.mxml -->
<s:WindowedApplication xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Style>
        @namespace "library://ns.adobe.com/flex/spark";
        WindowedApplication
        {
            skinClass:ClassReference("spark.skins.spark.SparkChromeWindowedApplicationSkin");
        }
    </fx:Style>

    <s:Label text="Hello World" />
</s:WindowedApplication>
```

Flex includes a simple skin class for the WindowedApplication and Window containers that defines just a border and status bar, but no gripper button, title bar, or title bar buttons. The following example assigns this skin to the WindowedApplication container. This example assumes that you set `systemChrome` to “none” in the application’s .xml file:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- aircomponents/src/WindowSimpleChromeWindowed.mxml -->
<s:WindowedApplication xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Style>
        @namespace "library://ns.adobe.com/flex/spark";
        WindowedApplication
        {
            skinClass:ClassReference("spark.skins.spark.WindowedApplicationSkin");
        }
    </fx:Style>

    <s:Label text="Hello World" />
</s:WindowedApplication>
```

Defining custom skin classes

The SparkChromeWindowedApplicationSkin class references additional skin classes to draw the gripper, title bar, and title bar buttons. Different operating systems can use the same skin file for some skins, but use different skin files for other skins. The following table describes these classes:

Skin	Microsoft Window skin file	Apple Macintosh skin file
The skin for the close button in the title bar.	CloseButtonSkin.mxml	MacCloseButtonSkin.mxml
The skin for the gripper button for resizing the window.	GripperSkin.mxml	GripperSkin.mxml
The skin for the maximize button in the title bar.	MaximizeButtonSkin.mxml	MacMaximizeButtonSkin.mxml
The skin for the minimize button in the title bar.	MinimizeButtonSkin.mxml	MacMinimizeButtonSkin.mxml
The title bar skin.	TitleBarSkin.mxml	MacTitleBarSkin.mxml
The skin for the restore button in the title bar.	RestoreButtonSkin.mxml	No restore button available.

To customize these skins, define your own skin class based on the SparkChromeWindowedApplicationSkin class, and then reference your custom skin classes from it.

Dynamically repeating controls and containers

Repeater components let you dynamically repeat MXML content at run time.

Adobe® Flex® also supports list controls, which provide better performance when you display large amounts of data. For more information about the HorizontalList, TileList, and List controls, see "MX data-driven controls" on page 943.

About Repeater components

Repeater components are useful for repeating a small set of simple user interface components, such as RadioButton controls and other controls typically used in Form containers. Repetition is generally controlled by an array of dynamic data, such as an Array object returned from a web service, but you can use static arrays to emulate simple `for` loops.

Although Repeater components look like containers in your code, they are not containers and have none of the automatic layout functionality of containers. Their sole purpose is to specify a series of subcomponents to include in your application one or more times based on the contents of a specified data provider. To align items that a repeater generates or perform any other layout task, place the Repeater component and its contents inside a container and apply the layout to that container.

Using the Repeater component

You use the `<mx:Repeater>` tag to declare a Repeater component that handles repetition of one or more user interface components based on dynamic or static data arrays at run time. The repeated components can be controls or containers. Using a Repeater component requires data binding to allow for run-time-specific values. For more information about data binding, see "Storing data" on page 889.

You can use the `<mx:Repeater>` tag anywhere a control or container tag is allowed, as long as you wrap the repeater tag in a MX container, such as VBox, HBox, Panel, or Canvas. If you use a container such as Canvas that uses absolute positioning, you must manually position each repeated element so that they do not overlap.

To repeat user interface components, you place their tags within the `<mx:Repeater>` tag. All components derived from the UIComponent class can be repeated with the exception of the `Application` container tag. Components that are not based on UIComponent class cannot be children of the Repeater control.

You can also use more than one `<mx:Repeater>` tag in an MXML document, and you can nest `<mx:Repeater>` tags.

Declaring the Repeater component in MXML

You declare the Repeater component in the `<mx:Repeater>` tag, inside a MX container. The following table describes the Repeater component's properties:

Property	**Description**
`id`	Instance name of the corresponding Repeater component.
`dataProvider`	An implementation of the ICollectionView interface, IList interface, or Array class, such as an ArrayCollection object. You must specify a `dataProvider` value or the Repeater component will not execute. Generally, you specify the value of the `dataProvider` property as a binding expression because the value is not known until run time.
`startingIndex`	Number that specifies the element in the data provider at which the repetition starts. The data provider array is zero-based, so to start at the second element of the array, specify a starting index of one. If the `startingIndex` is not within the range of the `dataProvider` property, no repetition occurs.
`count`	Number that specifies how many repetitions occur. If the `dataProvider` property has fewer items than the number in the `count` property, the repetition stops with the last item.
`currentIndex`	Number that specifies the element of the `dataProvider` item currently being processed. The data provider array is zero-based, so when the third element is being processed, the current index is two. This property changes as the Repeater component executes, and is -1 after the execution is complete. It is a read-only property that you cannot set in the `<mx:Repeater>` tag.
`currentItem`	Reference to the item that is being processed in the `dataProvider` property. This property changes as the Repeater component executes, and is null after the execution is complete. It is a read-only property that you cannot set in the `<mx:Repeater>` tag. After a Repeater component finishes repeating, you do not use the `currentItem` property to get the current item. Instead, you call the `getRepeaterItem()` method of the repeated component itself. For more information, see "Referencing repeated components" on page 873.
`recycleChildren`	Boolean value that, when set to `true`, binds new data items into existing Repeater children, incrementally creates new children if there are more data items, and destroys extra children that are no longer required. For more information, see "How a Repeater component executes" on page 883.

The following table describes the Repeater component's events:

Event	**Description**
`repeat`	Dispatched each time an item is processed and `currentIndex` and `currentItem` are updated.
`repeatEnd`	Dispatched after all the subcomponents of a repeater are created.
`repeatStart`	Dispatched when Flex begins processing the `dataProvider` property and begins creating the specified subcomponents.

Basic principles of the Repeater component

The simplest repeating structures you can create with a Repeater component are static loops that execute a set number of times. The following Repeater component emulates a simple for loop that executes four times, printing a simple line of text and incrementing the counter by one each time:

```
<?xml version="1.0"?>
<!-- repeater/StaticLoop.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns="*">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            [Bindable]
            public var myArray:Array=[1,2,3,4];
        ]]>
    </fx:Script>
    <fx:Declarations>
        <mx:ArrayCollection id="myAC" source="{myArray}"/>
    </fx:Declarations>
    <!-- Notice that the Repeater is inside a MX container. -->
    <mx:VBox>
        <mx:Repeater id="myrep" dataProvider="{myAC}">
            <mx:Label id="Label1" text="This is loop #{myrep.currentItem}"/>
        </mx:Repeater>
    </mx:VBox>

</s:Application>
```

In actuality, the counter is not the data within the array, but the position within the array. As long as the array contains four elements, you can provide any data within the array itself, and the Repeater component still executes four times. The following example illustrates this principle:

```
<?xml version="1.0"?>
<!-- repeater/StaticLoop2.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
            [Bindable]
            public var myArray:Array=[10,20,30,40];
        ]]>
    </fx:Script>
    <fx:Declarations>
        <mx:ArrayCollection id="myAC" source="{myArray}"/>
    </fx:Declarations>
    <!-- Notice that the Repeater is inside a MX container. -->
    <mx:VBox>
        <mx:Repeater id="myrep" dataProvider="{myAC}">
            <mx:Label id="Label1" text="This is loop #{myrep.currentIndex+1}"/>
        </mx:Repeater>
    </mx:VBox>

</s:Application>
```

Notice that this example prints the current index plus one, not the index itself. This is because the first element of the array is assigned an index value of zero (0).

You can also use the `startingIndex` and `count` properties to adjust the starting point and total number of executions. The `count` property sets a maximum on the number of times the Repeater component executes. The `count` property is often—but not always—an exact measure of the number of times that the content within the Repeater component will execute. This number is because the Repeater component stops after the last element of the data provider is reached, regardless of the value of the `count` property.

The following example shows how the `count` and `startingIndex` properties affect a Repeater component:

```
<?xml version="1.0"?>
<!-- repeater\StartingIndexCount.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            [Bindable]
            public var myArray:Array=[100,200,300,400,500,600];
        ]]>
    </fx:Script>
    <fx:Declarations>
        <mx:ArrayCollection id="myAC" source="{myArray}"/>
    </fx:Declarations>
    <mx:VBox>
        <mx:Repeater id="myrep" dataProvider="{myAC}" count="6">
            <mx:Label id="Label1"
                text="Value: {myrep.currentItem}, Loop #{myrep.currentIndex+1} of
{myrep.count}"/>
        </mx:Repeater>
    </mx:VBox>
    <mx:HRule/>
    <mx:VBox>
        <mx:Repeater id="myrep2" dataProvider="{myAC}"
                count="4" startingIndex="1">
            <mx:Label id="Label2"
                text="Value: {myrep2.currentItem}, Loop #{myrep2.currentIndex-
myrep2.startingIndex+1} of {myrep2.count}"/>
        </mx:Repeater>
    </mx:VBox>
    <mx:HRule/>
    <mx:VBox>
        <mx:Repeater id="myrep3" dataProvider="{myAC}" count="6"
                startingIndex="3">
            <mx:Label id="Label3"
                text="Value: {myrep3.currentItem}, Loop #{myrep3.currentIndex-
myrep3.startingIndex+1} of {myrep3.count}"/>
        </mx:Repeater>
    </mx:VBox>
</s:Application>
```

The first Repeater component loops through each element of the data provider, starting with the first and stopping after the last. The second Repeater component starts at the second element of the data provider and iterates four times, ending at the fifth element. The third Repeater component starts with the fourth element and continues until the end of the data provider array, and then stops. Only three iterations occur despite the fact that the `count` property is set to 6.

Creating dynamic loops with the Repeater component

Instead of a static data written directly into your application, your application might work with dynamic data providers. Dynamic data is defined in an `<fx:Model>` tag and drawn from an XML file, a web service, a remote object, or some other source. The data is collected and evaluated at run time to determine the number and value of elements in the data provider and how the Repeater component behaves.

In the following example, an `<mx:Repeater>` tag repeats a RadioButton control for each product in an XML file:

```
<?xml version="1.0"?>
<!-- repeater\DynamicLoop.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    initialize="catalogService.send();">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Declarations>
        <mx:HTTPService id="catalogService" url="assets/repeater/catalog.xml"
                resultFormat="e4x"/>
        <mx:XMLListCollection id="myXC"
                source="{catalogService.lastResult.product}"/>
    </fx:Declarations>
    <mx:VBox>
        <mx:Repeater id="r" dataProvider="{myXC}">
            <mx:RadioButton id="Radio" label="{r.currentItem.name}"
                    width="150"/>
        </mx:Repeater>
    </mx:VBox>
</s:Application>
```

Assume that catalog.xml contains the following:

```
<?xml version="1.0"?>
<!-- assets\catalog.xml -->
<products>
  <product>
    <name>Name</name>
    <price>Price</price>
    <freeship>Free Shipping?</freeship>
  </product>
  <product>
    <name>Whirlygig</name>
    <price>5</price>
    <freeship>false</freeship>
  </product>
  <product>
    <name>Tilty Thingy</name>
    <price>15</price>
    <freeship>true</freeship>
  </product>
<product>
    <name>Really Big Blocks</name>
    <price>25</price>
    <freeship>true</freeship>
  </product>
</products>
```

You can still use the `count` property to restrict the number of iterations performed. You can use the `startingIndex` property to skip entries at the beginning of the data provider.

In the preceding example, the first product entry in the XML file contains metadata that other applications use to create column headers. Because it doesn't make sense to include that entry in the radio buttons, start the Repeater component at the second element of the data provider, as in the following code example:

```
<?xml version="1.0"?>
<!-- repeater\StartSecondElement.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    initialize="catalogService.send();">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Declarations>
        <mx:HTTPService id="catalogService" url="assets/repeater/catalog.xml"
                resultFormat="e4x"/>
        <mx:XMLListCollection id="myXC"
                source="{catalogService.lastResult.product}"/>
    </fx:Declarations>

    <mx:VBox>
        <mx:Repeater id="r" dataProvider="{myXC}"
                startingIndex="1">
            <mx:RadioButton id="Radio" label="{r.currentItem.name}"
                width="150"/>
        </mx:Repeater>
    </mx:VBox>
</s:Application>
```

Referencing repeated components

To reference individual instances of a repeated component, you use indexed `id` references, as the following example shows:

```
<?xml version="1.0"?>
<!-- repeater\RefRepeatedComponents.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            public function labelTrace():void {
                for (var i:int = 0; i < nameLabel.length; i++)
                    trace(nameLabel[i].text);
            }
        ]]>
    </fx:Script>
    <fx:Declarations>
        <fx:Model id="catalog" source="../assets/repeater/catalog.xml"/>
        <s:ArrayCollection id="myAC" source="{catalog.product}"/>
    </fx:Declarations>

    <s:Label id="title" text="Products:"/>

    <s:VGroup>
        <mx:VBox>
            <mx:Repeater id="r" dataProvider="{myAC}" startingIndex="1">
                <mx:Label id="nameLabel"
                    text="{r.currentItem.name}: ${r.currentItem.price}"
                    width="200"/>
            </mx:Repeater>
        </mx:VBox>
        <s:Button label="Trace" click="labelTrace();"/>
    </s:VGroup>
</s:Application>
```

In this example, the `id` of the repeated Label control is `nameLabel`; each `nameLabel` instance created has this `id`. You reference the individual Label instances as `nameLabel[0]`, `nameLabel[1]`, and so on. You reference the total number of `nameLabel` instances as `nameLabel.length`. The `for` loop traces the `text` property of each Label control in the `nameLabel` Array object. The `labelTrace()` method prints the name and price of each product in the system log, provided you've defined it in the `mm.cfg` file.

Referencing repeated child components

When a container is repeated and indexed in an array, its children are also indexed. For example, for the following MXML code, you reference the child Label controls of the VBox container `vb[0]` as `nameLabel[0]` and `shipLabel[0]`. The syntax for referencing the children is the same as the syntax for referencing the parent.

```
<?xml version="1.0"?>
<!-- repeater\RefRepeatedChildComponents.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[

            public function labelTrace():void {
                for (var i:int = 0; i < nameLabel.length; i++)
                    trace(nameLabel[i].text);
            }
        ]]>
    </fx:Script>
    <fx:Declarations>
        <fx:Model id="catalog" source="../assets/repeater/catalog.xml"/>
    </fx:Declarations>

    <s:Label id="title" text="Products:"/>
    <mx:VBox>
        <mx:Repeater id="r" dataProvider="{catalog.product}"
                startingIndex="1">
            <mx:VBox id="vb">
                <mx:Label id="nameLabel"
                    text="{r.currentItem.name}: ${r.currentItem.price}"
                    width="200"/>
                <mx:Label id="shipLabel"
                    text="Free shipping: {r.currentItem.freeship}"/>
                <mx:Spacer/>
            </mx:VBox>
        </mx:Repeater>
    </mx:VBox>
    <s:Button label="Trace" click="labelTrace();"/>
</s:Application>
```

Referencing nested Repeater components

When `<mx:Repeater>` tags are nested, the inner `<mx:Repeater>` tags are indexed Repeater components. For example, for the following MXML code, you access the nested Repeater components as `r2[0]`, `r2[1]`, and so on. The syntax for referencing the children is same as the syntax for referencing the parent.

```
<?xml version="1.0"?>
<!-- repeater\RefNestedComponents.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <fx:Script>
    <![CDATA[

      public function labelTrace():void {
        for (var i:int = 0; i < nameLabel.length; i++)
         for (var j:int = 0; j < nameLabel[i].length; j++)
          trace(nameLabel[i][j].text);
      }
    ]]>
  </fx:Script>
  <fx:Declarations>
      <fx:Model id="data">
        <color>
          <colorName>Red</colorName>
          <colorName>Yellow</colorName>
          <colorName>Blue</colorName>
        </color>
      </fx:Model>
      <fx:Model id="catalog" source="../assets/repeater/catalog.xml"/>
      <s:ArrayCollection id="myAC1" source="{catalog.product}"/>
      <s:ArrayCollection id="myAC2" source="{data.colorName}"/>
  </fx:Declarations>
  <s:Label id="title" text="Products:"/>
  <mx:VBox>
      <mx:Repeater id="r" dataProvider="{myAC1}" startingIndex="1">
        <mx:Repeater id="r2" dataProvider="{myAC2}">
          <mx:Label id="nameLabel" text="{r2.currentItem} {r.currentItem.name}:
${r.currentItem.price}" width="250"/>
        </mx:Repeater>
      </mx:Repeater>
  </mx:VBox>
  <s:Button label="Trace" click="labelTrace();"/>
</s:Application>
```

This application places the full list of products with color and price into the system log when you click the Button control (provided you have defined the log file in the mm.cfg file).

In the previous example, the instances of the Label control are multiply indexed because they are inside multiple Repeater components. For example, the index `nameLabel[1][2]` contains a reference to the Label control produced by the second iteration of `r` and the third iteration of `r2`.

Using the getRepeaterItem() method in an event handler for the Repeater component

When a Repeater component is busy repeating, each repeated object that it creates can bind at that moment to the Repeater component's `currentItem` property, which is changing as the Repeater component repeats. You cannot give each instance its own event handler by writing something like `click="doSomething({r.currentItem})"` because binding expressions are not allowed in event handlers, and all instances of the repeated component must share the same event handler.

Repeated components and repeated Repeater components have a `getRepeaterItem()` method that returns the item in the `dataProvider` property that was used to produce the object. When the Repeater component finishes repeating, you can use the `getRepeaterItem()` method to determine what the event handler should do based on the `currentItem` property. To do so, you pass the `event.currentTarget.getRepeaterItem()` method to the event handler. The `getRepeaterItem()` method takes an optional index that specifies which Repeater components you want when nested Repeater components are present; the 0 index is the outermost Repeater component. If you do not specify the index argument, the innermost Repeater component is implied.

Note: *After a Repeater component finishes repeating, you do not use the* `Repeater.currentItem` *property to get the current item. Instead, you call the* `getRepeaterItem()` *method of the repeated component itself.*

The following example illustrates the `getRepeaterItem()` method. When the user clicks each repeated Button control, the corresponding `colorName` value from the data model appears in the Button control label.

```
<?xml version="1.0"?>
<!-- repeater\GetItem.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <fx:Script>
    <![CDATA[
      public function clicker(cName:String):void {
         foolabel.text=cName;
       }
    ]]>
  </fx:Script>
  <s:Label id="foolabel" text="foo"/>
  <fx:Declarations>
      <fx:Model id="data">
        <color>
          <colorName>Red</colorName>
          <colorName>Yellow</colorName>
          <colorName>Blue</colorName>
        </color>
      </fx:Model>
      <s:ArrayCollection id="myAC" source="{data.colorName}"/>
  </fx:Declarations>
  <mx:VBox>
      <mx:Repeater id="myrep" dataProvider="{myAC}">
        <mx:Button click="clicker(event.currentTarget.getRepeaterItem());"
          label="{myrep.currentItem}"/>
      </mx:Repeater>
  </mx:VBox>
</s:Application>
```

The code in the following example uses the `getRepeaterItem()` method to display a specific URL for each Button control that the user clicks. The Button controls must share a common data-driven click handler, because you cannot use binding expressions inside event handlers. However, the `getRepeaterItem()` method lets you change the functionality for each Button control.

```
<?xml version="1.0"?>
<!-- repeater\DisplayURL.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <fx:Script>
    <![CDATA[
      [Bindable]
      public var dp:Array = [
        { label: "Flex", url: "http://www.adobe.com/flex" },
        { label: "Flash", url: "http://www.adobe.com/flash" }
      ];
    ]]>
  </fx:Script>
  <fx:Declarations>
      <s:ArrayCollection id="myAC" source="{dp}"/>
  </fx:Declarations>
  <mx:VBox>
      <mx:Repeater id="r" dataProvider="{myAC}">
        <mx:Button label="{r.currentItem.label}"
           click="navigateToURL(
            new URLRequest(event.currentTarget.getRepeaterItem().url), '_blank');"/>
      </mx:Repeater>
  </mx:VBox>
</s:Application>
```

When executed, this example yields two buttons: one for Flex and one for Adobe® Flash®. When you click the button of your choice, the relevant product page loads in a new browser window.

Accessing specific instances of repeated components

Repeated components and repeated Repeater components have three properties that you can use to dynamically keep track of specific instances of repeated objects, to determine which Repeater component produced them, and to determine which `dataProvider` items were used by each Repeater component. The following table describes these properties:

Property	Description
instanceIndices	Array that contains the indices required to reference the component from its document. This Array is empty unless the component is in one or more Repeater components. The first element corresponds to the outermost Repeater component. For example, if the `id` is `b` and `instanceIndices` is `[2,4]`, you would reference it on the document as `b[2][4]`.
repeaters	Array that contains references to the Repeater components that produced the component. The Array is empty unless the component is in one or more Repeater components. The first element corresponds to the outermost Repeater component.
repeaterIndices	Array that contains the indices of the items in the `dataProvider` properties of the Repeater components that produced the component. The Array is empty unless the component is within one or more Repeater components. The first element corresponds to the outermost Repeater component. For example, if `repeaterIndices` is `[2,4]`, the outer Repeater component used its `dataProvider[2]` data item and the inner Repeater component used its `dataProvider[4]` data item. This property differs from `instanceIndices` if the `startingIndex` of any of the Repeater components is not 0. For example, even if a Repeater component starts at `dataProvider` item 4, the document reference of the first repeated component is `b[0]`, not `b[4]`.

The following example application uses the `repeaters` property to display the `id` value of the Repeater components in an Alert control when the user clicks one of the Button controls labelled by the index value of the outer Repeater component and inner Repeater component, respectively. It uses the `repeaters` property to get the `id` value of the inner Repeater component:

```
<?xml version="1.0"?>
<!-- repeater\RepeatersProp.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <fx:Script>
    <![CDATA[
      import mx.controls.Alert;
      [Bindable]
      public var myArray:Array=[1,2];
    ]]>
  </fx:Script>
  <fx:Declarations>
    <s:ArrayCollection id="myAC" source="{myArray}"/>
  </fx:Declarations>

  <mx:VBox>
      <mx:Repeater  id="repeater1" dataProvider="{myAC}">
        <mx:Repeater  id="repeater2" dataProvider="{myAC}">
          <mx:Button
            label="[{repeater1.currentIndex},{repeater2.currentIndex}]"
            click="Alert.show(event.target.repeaters[1].id);"/>
        </mx:Repeater>
      </mx:Repeater>
  </mx:VBox>
</s:Application>
```

The following example application uses the `instanceIndices` property to set the `text` property of a TextInput control when the user clicks the corresponding Button control in the set of repeated Button and TextInput controls. You need to use the `instanceIndices` property because you must get the correct object dynamically; you cannot get it by its `id` value.

The following example shows how to use the `instanceIndices` property to set the `text` property of a TextInput control when the user clicks a Button control. The argument `event.target.instanceIndices` gets the index of the corresponding TextInput control.

```
<?xml version="1.0"?>
<!-- repeater\InstanceIndicesProp.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <fx:Script>
    <![CDATA[
      [Bindable]
      public var myArray:Array=[1,2,3,4,5,6,7,8];
    ]]>
  </fx:Script>
  <fx:Declarations>
    <mx:ArrayCollection id="myAC" source="{myArray}"/>
  </fx:Declarations>

  <mx:Box>
      <mx:Repeater id="list" dataProvider="{myAC}" count="4" startingIndex="2">
        <mx:HBox>
          <mx:Button label="Click Me"
            click="myText[event.target.instanceIndices].text=
            event.target.instanceIndices.toString();"/>
          <mx:TextInput id="myText"/>
        </mx:HBox>
      </mx:Repeater>
  </mx:Box>
</s:Application>
```

The following code shows how to use the `repeaterIndices` property instead of the `instanceIndices` property to set the `text` property of a TextInput control when the user clicks a Button control. The value of `event.target.repeaterIndices` is based on the current index of the Repeater component. Because the `startingIndex` property of the Repeater component is set to 2, it does not match the `event.target.instanceIndices` value, which always starts at 0.

```
<?xml version="1.0"?>
<!-- repeater\RepeaterIndicesProp.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <fx:Script>
    <![CDATA[
      [Bindable]
      public var myArray:Array = [1,2,3,4,5,6,7,8];
    ]]>
  </fx:Script>
  <mx:Box>
      <mx:Repeater id="list" dataProvider="{myArray}"
        startingIndex="2" count="4">
            <mx:HBox>
                <mx:Button id="b" label="Click Me"
                    click="myText[event.target.repeaterIndices-list.startingIndex].text=
                    event.target.repeaterIndices.toString();"/>
                <mx:TextInput id="myText"/>
            </mx:HBox>
      </mx:Repeater>
  </mx:Box>
</s:Application>
```

In this case, clicking the button prints the current element of the data provider, not the current iteration of the loop.

***Note:** The value of the `repeaterIndices` property is equal to the `startingIndex` property on the first iteration of the Repeater component. Subtracting the `startingIndex` value from the `repeaterIndices` value always yields the `instanceIndices` value.*

Using a Repeater component in a custom MXML component

You can use the `<mx:Repeater>` tag in an MXML component definition in the same way that you use it in an application file. When you use the MXML component as a tag in another MXML file, the repeated items appear. You can access an individual repeated item by its array index number, just as you do for a repeated item defined in the application file.

In the following example, a Button control in an MXML component called `childComp` is repeated for every element in an Array object called dp:

```
<?xml version="1.0"?>
<!-- repeater\myComponents\CustButton.mxml -->
<mx:VBox
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
  <fx:Script>
    <![CDATA[
      [Bindable]
      public var dp:Array=[1,2,3,4];
    ]]>
  </fx:Script>
  <fx:Declarations>
      <s:ArrayCollection id="myAC" source="{dp}"/>
  </fx:Declarations>

  <mx:Box>
      <mx:Repeater id="r" dataProvider="{myAC}">
        <mx:Button id="repbutton" label="button {r.currentItem}"/>
      </mx:Repeater>
  </mx:Box>
</mx:VBox>
```

The application file in the following example uses the childComp component to display four Button controls, one for each element in the array. The `getLabelRep()` function displays the label text of the second Button in the array.

```
<?xml version="1.0"?>
<!-- repeater\RepeatCustButton.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:MyComp="myComponents.*">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <fx:Script>
    <![CDATA[
      import mx.controls.Alert;
      public function getLabelRep():void {
        Alert.show(comp.repbutton[1].label);
      }
    ]]>
  </fx:Script>

  <MyComp:CustButton id="comp"/>
  <s:Button label="Get label of Repeated element" width="200"
    click="getLabelRep();"/>
</s:Application>
```

Dynamically creating components based on data type

You can use a Repeater component to dynamically create different types of components for specific items in a set of data. A Repeater component broadcasts a `repeat` event as it executes, and this event is broadcast after the `currentIndex` and `currentItem` properties are set. You can call an event handler function on the `repeat` event, and dynamically create different types of components based on the individual data items.

How a Repeater component executes

A Repeater component executes initially when it is instantiated. If the Repeater component's dataProvider property exists, it proceeds to instantiate its children, and they instantiate their children, recursively.

The Repeater component re-executes whenever its dataProvider, startingIndex, or count properties are set or modified either explicitly in ActionScript, or implicitly by data binding. If the dataProvider property is bound to a web service result, the Repeater component re-executes when the web service operation returns the result. A Repeater component also re-executes in response to paging through the dataProvider property by incrementally increasing the startingIndex value, as the following example shows:

```
r.startingIndex += r.count;
```

When a Repeater component re-executes, it destroys any children that it previously created (assuming the recycleChildren property is set to false), and then reinstantiates its children based on the current dataProvider property. The number of children in the container might change, and the container layout changes to accommodate any changes to the number of children.

Recreating children in a Repeater component

The recycleChildren property controls whether children of a Repeater component are recreated when the Repeater component re-executes. When you set the recycleChildren property to false, the Repeater component recreates all the objects when you swap one dataProvider with another, or sort, which causes a performance lag. Only set this property to true if you are confident that modifying your dataProvider will not recreate the Repeater component's children.

The default value of the recycleChildren property is false, to ensure that you do not leave stale state information in a repeated instance. For example, suppose you use a Repeater component to display photo images, and each Image control has an associated NumericStepper control for how many prints you want to order. Some of the state information, the image, comes from the dataProvider, while other state information, the print count, is set by user interaction. If you set the recycleChildren property to true and page through the photos by incrementally increasing the Repeater component's startingIndex value, the Image controls bind to the new images, but the NumericStepper controls keep the old information.

Considerations when using a Repeater component

Consider the following when you use a Repeater component:

- You must wrap a Repeater control in a MX container tag such as HBox, VBox, Box, Panel, or Canvas. The Repeater control cannot be a top-level child of the Application tag, and it cannot be a child of Spark containers such as Group, VGroup, or HGroup. If you are using nested repeaters, only the outer Repeater must be wrapped in a MX container.
- You cannot use a Repeater component to iterate through a two-dimensional Array object that is programmatically generated. This is because the elements of an Array object do not trigger changeEvent events, and therefore cannot function as binding sources at run time. Binding copies initial values during instantiation after variables are declared in an <mx:Script> tag, but before initialize handlers are executed.
- Run-time changes to an array used as a data provider are not reflected in the Repeater component. Use a collection if you need to allow run-time modification.
- Forgetting curly braces ({ }) in a dataProvider property is a common mistake when using a Repeater component. If the Repeater component doesn't execute, make sure that the binding is correct.
- If repeated objects are displayed out of order and you are using adjacent or nested Repeater components, you might need to place a dummy UIComponent immediately after the Repeater that is displaying objects incorrectly.

The code in the following example contains adjacent `<mx:Repeater>` tags and uses an `<mx:Spacer>` tag to create a dummy UIComponent:

```
<mx:VBox>
    <mx:Repeater id="r1">
        ...
    </mx:Repeater>
    <mx:Repeater id="r2">
        ...
    </mx:Repeater>
    <mx:Spacer height="0" id="dummy"/>
</mx:VBox>
```

The code in the following example contains nested `<mx:Repeater>` tags and uses an `<mx:Spacer>` tag to create a dummy UIComponent:

```
<mx:VBox>
    <mx:Repeater id="outer">
        <mx:Repeater id="inner">
            ...
        </mx:Repeater>
        <mx:Spacer id="dummy" height="0"/>
    </mx:Repeater>
</mx:VBox>
```

Chapter 5: Using data-driven UI components

Representing data

Data representation is a combination of features that provide a powerful way to validate, format, store, and pass data between objects.

About data representation

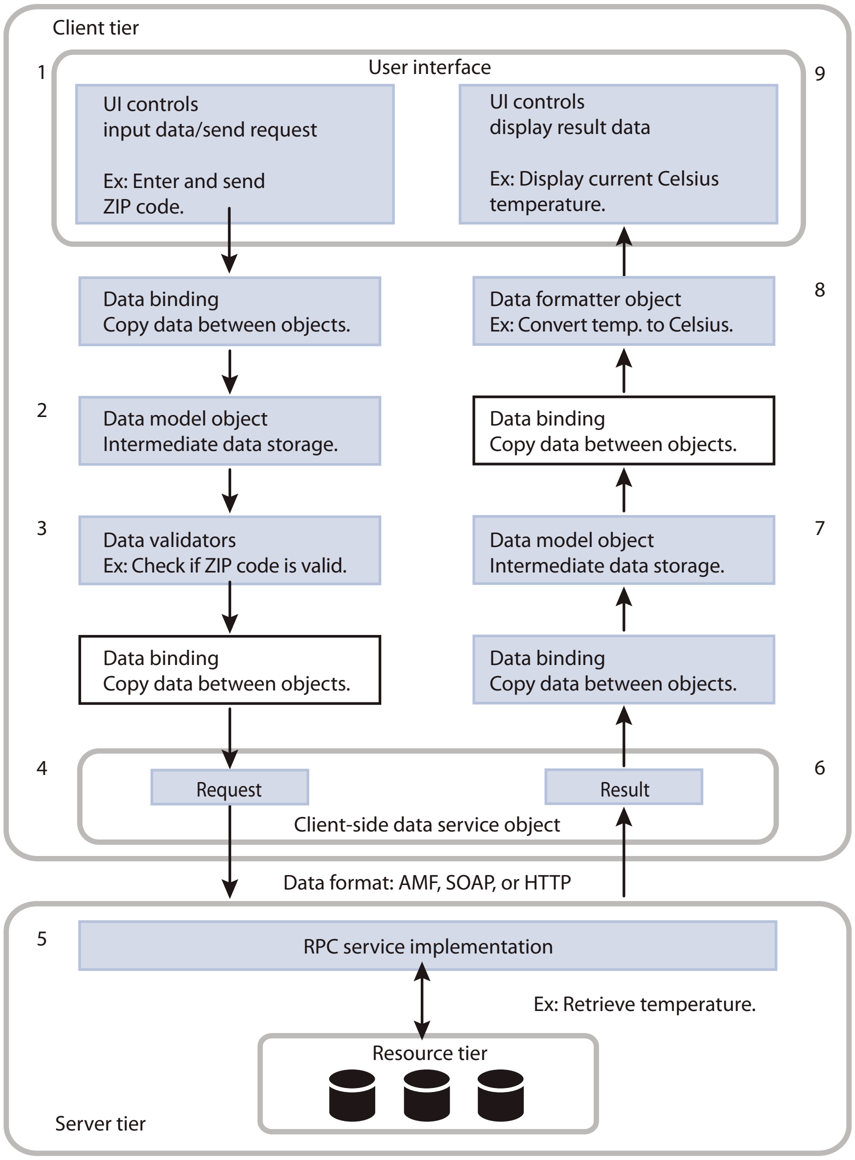
Adobe® Flex™ provides the following set of features for representing data in your applications: data binding, validation, and formatting. These features work in conjunction with the Adobe® LiveCycle™ Data Services ES features for working with remote data. Together, they allow you to perform the following tasks:

- Pass data between client-side objects.
- Store data in client-side objects.
- Validate data before passing it between client-side objects.
- Format data before displaying it.

The following steps describe a simple scenario in which a user provides input data and requests information in an Adobe Flex application:

1. The user enters data in input fields and submits a request by clicking a Button control.
2. (Optional) *Data binding* passes data to a data model object, which provides intermediate data storage. This allows data to be manipulated and passed to other objects in the application.
3. (Optional) One or more *data validator* objects validate the request data. Validator objects check whether the data meets specific criteria.
4. The data is passed to a server-side object.
5. The server-side object processes the request and returns data or a fault object if a valid result cannot be returned.
6. (Optional) Data binding passes data to a data model object, which provides intermediate data storage. This allows data to be manipulated and passed to other objects in the application.
7. (Optional) One or more *data formatter* objects format result data for display in the user interface.
8. Data binding passes data into user interface controls for display.

The following diagram illustrates what happens in Flex for two different user input examples. In one example, the user enters ZIP code data, and Flex validates the format. In the other example, the user requests the current temperature in Celsius.



Client tier
User interface
1
UI controls
input data/send request
Ex: Enter and send
ZIP code.
UI controls
display result data
Ex: Display current Celsius
temperature.
9
Data binding
Copy data between objects.
Data formatter object
Ex: Convert temp. to Celsius.
8
2
Data model object
Intermediate data storage.
Data binding
Copy data between objects.
3
Data validators
Ex: Check if ZIP code is valid.
Data model object
Intermediate data storage.
7
Data binding
Copy data between objects.
Data binding
Copy data between objects.
4
Request
Result
6
Client-side data service object
Data format: AMF, SOAP, or HTTP
5
RPC service implementation
Ex: Retrieve temperature.
Resource tier
Server tier

Data binding

The data binding feature provides a syntax for automatically copying the value of a property of one client-side object to a property of another object at run time. Data binding is usually triggered when the value of the source property changes. You can use data binding to pass user input data from user interface controls to a data service. You can also use data binding to pass results returned from a data service to user interface controls.

The following example shows a Text control that gets its data from an HSlider control's `value` property. The property name inside the curly braces ({ }) is a binding expression that copies the value of the source property, `mySlider.value`, into the Text control's `text` property.

```
<mx:HSlider id="mySlider"/>
<mx:Text text="{mySlider.value}"/>
```

For more information, see “Data binding” on page 299.

Data models

The data model feature lets you store data in client-side objects. A *data model* is an ActionScript object that contains properties for storing data, and that optionally contains methods for additional functionality. Data models are useful for partitioning the user interface and data in an application.

You can use the data binding feature to bind user interface data into a data model. You can also use the data binding feature to bind data from a data service to a data model.

You can define a simple data model in an MXML tag. When you require functionality beyond storage of untyped data, you can use an ActionScript class as a data model.

The following example shows an MXML-based data model with properties of TextInput controls bound into its fields:

```
<?xml version="1.0"?>
<!-- datarep\DatarepModelTag.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Declarations>
         <fx:Model id="reg">
           <registration>
              <name>{nme.text}</name>
              <email>{email.text}</email>
              <phone>{phone.text}</phone>
              <zip>{zip.text}</zip>
              <ssn>{ssn.text}</ssn>
          </registration>
        </fx:Model>
    </fx:Declarations>

    <s:TextInput id="nme"/>
    <s:TextInput id="email"/>
    <s:TextInput id="phone"/>
    <s:TextInput id="zip"/>
    <s:TextInput id="ssn"/>
</s:Application>
```

For more information about data models, see “Storing data” on page 889.

Data validation

The data validation feature lets you ensure that data meets specific criteria before the application uses the data. *Data validators* are ActionScript objects that check whether data in a component is formatted correctly. You can apply a data validator to a property of any component. For models in a remote procedure call (RPC) component declaration, properties to which a validator component is applied are validated just before the request is sent to an RPC service destination. Only valid requests are sent.

The following example shows MXML code that uses the standard ZipCodeValidator component, represented by the `<mx:ZipCodeValidator>` tag, to validate the format of the ZIP code that a user enters. The `source` property of the ZipCodeValidator validator indicates the property that it validates.

```
<?xml version="1.0"?>
<!-- datarep\Validate.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Declarations>
        <fx:Model id="zipModel">
            <root>
                <zip>{input.text}</zip>
            </root>
        </fx:Model>
        <mx:ZipCodeValidator source="{zipModel}"
            property="zip"
            listener="{input}"
            trigger="{input}"/>
    </fx:Declarations>
    <s:TextInput id="input"
        text="enter zip"
        width="80"/>
    <s:TextInput
        text="click here to validate"/>
</s:Application>
```

For more information about validator components, see “Validating Data” on page 1964.

Data formatting

The data formatting feature lets you change the format of data before displaying it in a user interface control. For example, when a data service returns a string that you want to display in the (xxx)xxx-xxxx phone number format, you can use a formatter component to ensure that the string is reformatted before it is displayed.

A *data formatter component* is an object that formats raw data into a customized string. You can use data formatter components with data binding to reformat data that is returned from a data service.

The following example formats the value of the `text` property of a TextInput control into a long date format:

```
<?xml version="1.0"?>
<!-- datarep\Format.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Declarations>
        <!-- Declare a DateTimeFormatter and define the dateStyle.-->
        <s:DateTimeFormatter id="dateTimeFormatter" dateStyle="long"/>
    </fx:Declarations>
    <s:Label text="Enter date (mm/dd/yyyy):"/>
    <s:TextInput id="dob" text="12/08/1980" width="300"/>
    <s:Label text="Formatted date: "/>
    <s:TextInput id="formattedDate"
        text="" editable="false" width="300"/>

    <!-- Format and update the date.-->
    <s:Button label="Format Input"
        click="formattedDate.text=dateTimeFormatter.format(dob.text);"/>
</s:Application>
```

For more information about data formatters, see “Formatting Data” on page 2004.

Storing data

You use the data model feature to store data in an application before it is sent to the server, or to store data sent from the server before using it in the application.

About data models

A *data model* is an ActionScript object that contains properties that you use to store application-specific data. Communication between an Adobe® Flex™ application and the server is required only to retrieve data not yet available to the Flex application and to update a server-side data source with new data from the Flex application.

You can use a data model for data validation, and it can contain client-side business logic. You can define a data model in MXML or ActionScript. In the model-view-controller (MVC) design pattern, the data model represents the model tier.

When you plan an application, you determine the kinds of data that the application must store and how that data must be manipulated. This helps you decide what types of data models you need. For example, suppose you decide that your application must store data about employees. A simple employee model might contain name, department, and e-mail address properties.

Defining a data model

You can define a data model in an MXML tag, an ActionScript function, or an ActionScript class. In general, you should use MXML-based models for simple data structures, and use ActionScript for more complex structures and client-side business logic.

***Note:** The `<fx:Model>` and `<fx:XML>` tags are Flex compiler tags and do not correspond directly to ActionScript classes. The ActionScript 3.0 Reference for the Adobe Flash Platform contains information about these tags and other compiler tags.*

You can place an `<fx:Model>` tag or an `<fx:XML>` tag in a Flex application file or in an MXML component file. The tag should have an `id` value, and it cannot be the root tag of an MXML component.

Declare an `<fx:Model>` tag or an `<fx:XML>` tag in an `<fx:Declarations>` tag. You define these tags in an `<fx:Declarations>` tag because they are not visual components.

The <fx:Model> tag

The most common type of MXML-based model is the <fx:Model> tag, which is compiled into an ActionScript object of type mx.utils.ObjectProxy, which contains a tree of objects when your data is in a hierarchy, with no type information. The leaves of the Object tree are scalar values. Because models that are defined in `<fx:Model>` tags contain no type information or business logic, you should use them only for the simplest cases. Define models in ActionScript classes when you need the typed properties or you want to add business logic.

The following example shows an employee model declared in an `<fx:Model>` tag:

```
<?xml version="1.0"?>
<!-- Models\ModelsModelTag.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <fx:Declarations>
        <fx:Model id="employeemodel">
            <employee>
                <name>
                    <first/>
                    <last/>
                </name>
                <department/>
                <email/>
            </employee>
        </fx:Model>
    </fx:Declarations>
</s:Application>
```

An `<fx:Model>` child tag with no value is considered null. If you want an empty string instead, you can use a binding expression as the value of the tag, as the following example shows:

```
<?xml version="1.0"?>
<!-- Models\ModelTagEmptyString.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <fx:Declarations>
        <fx:Model id="employeemodel">
            <employee>
                <name>
                    <!--Fill the first property with empty string.-->
                    <first>{""}</first>
                    <!--Fill the last property with empty string.-->
                    <last>{""}</last>
                </name>
                <!--department is null-->
                <department/>
                <!--email is null-->
                <email/>
            </employee>
        </fx:Model>
    </fx:Declarations>
</s:Application>
```

The <fx:XML> tag

An <fx:XML> tag represents literal XML data. Setting the `format` property to `e4x` creates an XML object, which implements the powerful XML-handling standards defined in the ECMAScript for XML specification (ECMA-357 edition 2) (known as E4X). For backward compatibility, when the `format` property is not explicitly set to `e4x`, the type of the object created is flash.xml.XMLNode.

***Note:** You currently cannot use a node within an `<fx:XML>` data model as a binding source.*

Script-based models

As an alternative to using an MXML-based model, you can define a model as a variable in an <fx:Script> tag. The following example shows a very simple model defined in an ActionScript script block. It would be easier to declare this model in an `<fx:Model>` tag.

```
<?xml version="1.0"?>
<!-- Models\ScriptModel.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <fx:Script>
        <![CDATA[
            [Bindable]
            public var myEmployee:Object={
                name:{
                    first:null,
                    last:null
                    },
                department:null,
                email:null
            };
        ]]>
    </fx:Script>
</s:Application>
```

There is no advantage to using a script-based model instead of an MXML-based model. As with MXML-based models, you cannot type the properties of a script-based model. To type properties, you must use a class-based model.

Class-based models

Using an ActionScript class as a model is a good option when you want to store complex data structures with typed properties, or when you want to execute client-side business logic by using application data. Also, the type information in a class-based model is retained on the server when the model is passed to a server-side data service.

The following example shows a model defined in an ActionScript class. This model is used to store shopping cart items in an e-commerce application. It also provides business logic in the form of methods for adding and removing items, getting an item count, and getting the total price.

```
package
{

[Bindable]
public class ShoppingCart {
    public var items:Array = [];

    public var total:Number = 0;

    public var shippingCost:Number = 0;

    public function ShoppingCart() {
    }

    public function addItem(item:Object, qty:int = 1,
        index:int = 0):void {
        items.splice(index, 0, { id: item.id,
        name: item.name,
        description: item.description,
        image: item.image,
        price: item.price,
        qty: qty });
        total += parseFloat(item.price) * qty;
}

    public function removeItemAt(index:Number):void {
        total -= parseFloat(items[index].price) * items[index].qty;
        items.splice(index, 1);
        if (getItemCount() == 0)
        shippingCost = 0;
}

    public function getItemCount():int {
        return items.length;
    }

    public function getTotal():Number {
        return total;
    }
}
}
```

Note: *You can use properties of any recognized type in a class-based model. For example, you could create an Employee class, and then define properties of type Employee in another class that imports Employee.*

You declare a class-based model as an ActionScript component tag in an MXML file, as the following example shows:

```
<local:ShoppingCart id="cart" xmlns:local="*"/>
```

This component is in the same directory as the MXML file, as indicated by the XML namespace value `*`. For more information about specifying the location of components, see “Using XML namespaces” on page 10.

Specifying an external source for an <fx:Model> tag or <fx:XML> tag

You can specify an external source for an <fx:Model> or <fx:XML> tag in a `source` property. Separating the content of a model from the MXML that defines the user interface improves the maintainability and reusability of an application. Adobe recommends this way of adding static XML content to a Flex application.

The external source file can contain static data and data binding expressions, just like a model defined in the body of the `<fx:Model>` or `<fx:XML>` tag. The file referenced in a `source` property resides on the server and not on the client machine. The compiler reads the `source` value and compiles the source into the application; the `source` value is not read at run time. To retrieve XML data at run time, you can use the `<mx:HTTPService>` tag; for more information, see Accessing Server-Side Data with Flex.

Using `<fx:Model>` and `<fx:XML>` tags with external sources is an easy way to reuse data model structures and data binding expressions. You can also use them to prepopulate user interface controls with static data by binding data from the model elements into the user interface controls.

The `source` property accepts the names of files relative to the current web application directory, as well as URLs with HTTP:// prefixes. In the following example, the content of the myEmployee1 data model is an XML file named content.xml in the local web application directory. The content of the myEmployee2 data model is a fictional HTTP URL that returns XML.

```
<fx:Model source="employees.xml" id="employee1"/>

<fx:Model source="http://www.somesite1.com/employees.xml" id="employee2"/>
```

The source file must be a valid XML document with a single root node. The following example shows an XML file that could be used as the source of the `<fx:Model source="employees.xml" id="Model1"/>` tag.

```
<?xml version="1.0"?>
<employees>
    <employee>
        <name>John Doe</name>
        <phone>555-777-66555</phone>
        <email>jdoe@fictitious.com</email>
        <active>true</active>
    </employee>
    <employee>
        <name>Jane Doe</name>
        <phone>555-777-66555</phone>
        <email>jndoe@fictitious.com</email>
        <active>true</active>
    </employee>
</employees>
```

Using validators with a data model

To validate the data stored in a data model, you use validators. In the following example, the `<mx:EmailValidator>`, `<mx:PhoneNumberValidator>`, `<mx:ZipCodeValidator>`, and `<mx:SocialSecurityValidator>` tags declare validators that validate the e-mail, phone, zip, and ssn fields of the registration data model. The validators generate error messages when a user enters incorrect data in TextInput controls that are bound to the data model fields.

```
<?xml version="1.0"?>
<!-- Models\ModelWithValidator.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <fx:Declarations>

            listener="{zip}"/>
        <mx:SocialSecurityValidator source="{reg}" property="ssn"
            trigger="{submit}"
            triggerEvent="click"
            listener="{ssn}"/>
    </fx:Declarations>

    <!-- Form contains user input controls. -->
    <s:Form>
        <s:FormItem label="Name" required="true">
            <s:TextInput id="username" width="200"/>
        </s:FormItem>
        <s:FormItem label="Email" required="true">
            <s:TextInput id="email" width="200"/>
        </s:FormItem>
        <s:FormItem label="Phone" required="true">
            <s:TextInput id="phone" width="200"/>
        </s:FormItem>
        <s:FormItem label="Zip" required="true">
            <s:TextInput id="zip" width="60"/>
        </s:FormItem>
        <s:FormItem label="Social Security" required="true">
            <s:TextInput id="ssn" width="200"/>
        </s:FormItem>
        <s:FormItem>
        <!-- User clicks Button to trigger validation. -->
            <s:Button id="submit" label="Validate"/>
        </s:FormItem>
    </s:Form>
</s:Application>
```

This example cleanly separates the user interface and application-specific data. You could easily extend it to create a three-tier architecture by binding data from the registration data model into an RPC service request. You could also bind user input data directly into an RPC service request, which itself is a data model, as described in Accessing Server-Side Data with Flex.

For more information about validators, see “Validating Data” on page 1964.

Using a data model as a value object

You can use a data model as a value object, which acts as a central repository for a set of data returned from method calls on one or more objects. This makes it easier to manage and work with data in an application.

In the following example, the tentModel data model stores the results of a web service operation. The TentDetail component is a custom MXML component that gets its data from the tentModel data model and displays details for the currently selected tent.

```
...
<!-- Data model stores data from selected tent. -->
<fx:Model id="tentModel">
    <tent>
        <name>{selectedTent.name}</name>
        <sku>{selectedTent.sku}</sku>
        <capacity>{selectedTent.capacity}</capacity>
        <season>{selectedTent.seasonStr}</season>
        <type>{selectedTent.typeStr}</type>
        <floorarea>{selectedTent.floorArea}</floorarea>
        <waterproof>{getWaterProof(selectedTent.waterProof)}</waterproof>
        <weight>{getWeight(selectedTent)}</weight>
        <price>{selectedTent.price}</price>
    </tent>
</fx:Model>
...
    <TentDetail id="detail" tent="{tentModel}"/>
...
```

The following example shows the MXML source code for the TentDetail component. References to the `tent` property, which contains the tentModel data model, and the corresponding `tentModel` properties are highlighted in boldface.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- Models\myComponents\TentDetail.mxml-->
<s:Panel xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    title="Tent Details">

            </s:FormItem>
            <s:FormItem label="Weather" styleName="flabelColor">
                <s:Label text="{tent.waterproof}"
                    styleName="productSpec"/>
            </s:FormItem>
            <s:FormItem label="Weight" styleName="flabelColor">
                <s:Label text="{tent.weight}"
                    styleName="productSpec"/>
            </s:FormItem>
        </s:Form>
    </s:VGroup>
</s:Panel>
```

Binding data into an XML data model

Flex compiles the `<fx:XML>` tag into literal XML data in an ActionScript xml.XMLNode or XML object. This is different from the `<fx:Model>` tag, which Flex compiles into an Action object that contains a tree of ActionScript objects. To bind data into an `<fx:XML>` data model, you can use the curly braces syntax the same way you do with other data models. However, you cannot use a node within the data model as a binding source.

Adobe does not recommend using the `<mx:Binding>` tag for this type of binding because doing so requires you to write an appropriate ActionScript XML command as the `destination` property of the `<mx:Binding>` tag. For more information about the `<fx:XML>` tag, see “Defining a data model” on page 889.

The following example shows an `<fx:XML>` data model with binding destinations in curly braces:

```
<?xml version="1.0"?>
<!-- Models\XMLBinding.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Declarations>
        <fx:XML id="myEmployee" format="e4x">
            <employee>
                <name>
                    <first>{firstName.text}</first>
                    <last>{lastName.text}</last>
                    </name>
                <department>{department.text}</department>
                <email>{email.text}</email>
            </employee>
        </fx:XML>
    </fx:Declarations>
    <s:TextInput id="firstName"/>
    <s:TextInput id="lastName"/>
    <s:TextInput id="department"/>
    <s:TextInput id="email"/>
</s:Application>
```

Data providers and collections

A *collection* object contains a data object, such as an Array or an XMList object, and provides a set of methods that let you access, sort, filter, and modify the data items in that data object. Several controls, known as *data provider controls*, have a `dataProvider` property that you populate with a collection.

The mx.collections.ArrayCollection and mx.collections.XMLListCollection classes are specific collection implementations that you can use with any data provider control in the Flex framework. Most data provider controls also support using the mx.collections.ArrayList class. This class is similar to the ArrayCollection class, except that is uses less memory, but does not have as many features.

For more information on Flex components that use data providers, see “Spark list-based controls” on page 514, “MX data-driven controls” on page 943, and “Menu-based controls” on page 985.

About collections and data provider components

Data provider components require data for display or user interaction. To provide this data, you assign a collection, which is usually an ArrayCollection, ArrayList, or XMLListCollection object, to the data provider component’s `dataProvider` property.

Optionally, for MX controls only, you can assign a raw data object such as an Array, XML, or XMLList object to the data provider component’s `dataProvider` property; however, this is not considered a best practice because of the limitations noted in “About data provider components” on page 901.

The source of data in a collection object can be local or a remote source, such as a web service or a PHP page that you call with a Flex data access component.

About collections

Collections are objects that provide a uniform way to access and represent the data contained in a data source object, such as an Array or an XMLList object. Collections provide a level of abstraction between components and the data objects that you use to populate them.

The standard collection types in the Flex framework, the ArrayCollection and XMLListCollection classes, extend the mx.collections.ListCollectionView class, which implements the mx.collections.ICollectionView and mx.collections.IList interfaces. These interfaces provide the underlying functionality for viewing and modifying data objects. An ArrayCollection object takes an Array as its source object. An XMLListCollection object take an XMLList object as its source object.

Collections provide the following features:

- Ensure that a component is properly updated when the underlying data changes. Components are not updated when noncollection data objects change. (They *are* updated to reflect the new data the next time they are refreshed.) If the data provider is a collection, the components are updated immediately after the collection change occurs.
- Provide mechanisms for handling paged data from remote data sources that may not initially be available and may arrive over a period of time.
- Provide a consistent set of operations on the data, independent of those provided by the raw data source. For example, you can insert and delete objects by using an index into the collection, independently of whether the underlying data is, for example, in an Array or an Object.
- Provide a specific *view* of the data that can be in sorted order, or filtered by a developer-supplied method. This is only a view of the data; it does not change the data.
- Use a single collection to populate multiple components from the same data source.
- Use collections to switch data sources for a component at run time, and to modify the content of the data source so that changes are reflected by all components that use the data source.
- Use collection methods to access data in the underlying data source.

***Note:** If you use a raw data object, such as an Array, as the value of an MX control's data provider, Flex automatically wraps the object in a collection wrapper (either an ArrayCollection or XMLListCollection). The control does not automatically detect changes that are made directly to the raw object. A change in the length of an array, for example, does not result in an update of the control. You can, however, use an object proxy, a listener interface, or the* `itemUpdated()` *method to notify the view of certain changes. For Spark controls, you cannot use a raw object as the value of the control's data provider. You must specify an object that implements the IList interface. Classes that implement IList include ArrayCollection, ArrayList, and XMLListCollection.*

Another type of collection, ArrayList, extends the IList interface but not the ICollectionView interface. As a result, it is more lightweight and provides most of the same functionality as the ArrayCollection class. It does not, however, support sorting, filtering, or cursors.

Collection interfaces

Collections use the following interfaces to define how a collection represents data and provides access to it. The standard Flex framework collections, the ArrayCollection and XMLListCollection classes, implement both the ICollectionView interface and the IList interface. The IList and ICollectionView interfaces provide alternate methods for accessing and changing data. The IList interface is simpler; it provides add, set, get, and remove operations that operate directly on linear data.

Interface	Description
IList	A direct representation of items organized in an ordinal fashion. The interface presents the data from the source object in the same order as it exists in that object, and provides access and manipulation methods based on an index. The IList class does not provide sorting, filtering, or cursor functionality.
ICollectionView	A view of a collection of items. You can modify the view to show the data in sorted order and to show a subset of the items in the source object, as specified by a filter function. A class that implements this interface can use an IList interface as the underlying collection. The interface provides access to an IViewCursor object for access to the items.
IViewCursor	Enumerates an object that implements the ICollectionView interface bidirectionally. The *view cursor* provides find, seek, and bookmarking capabilities, and lets you modify the underlying data (and the view) by inserting and removing items.

The ICollectionView interface (also called the *collection view*) provides a more complex set of operations than the IList interface, and is appropriate when the underlying data is not organized linearly. Its data access techniques, however, are more complex than those of the IList interface, so you should use the IList interface if you need only simple, indexed access to a linear collection. The collection view can represent a subset of the underlying data, as determined by a sort or filter operation.

Collection classes

The following table describes the public classes in the mx.collections.* and spark.collections.* packages. It does not include constant, event, and error classes. For complete reference information on collection-related classes, see the MX collections, Spark collections, and collections.errors packages, and the CollectionEvent and CollectionEventKind classes in the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Class	Description
ArrayCollection	A standard collection for working with Arrays. Implements the IList and ICollectionView interfaces.
ArrayList	A standard collection for working with Arrays. Implements the IList interface. You can use this class instead of the ArrayCollection class if you do not need to sort, filter, or use cursors in your collection.
AsyncListView	A standard collections that handles `ItemPendingErrors` thrown by the `getItemAt()`, `removeItemAt()`, and `toArray()` methods.Use this class to support data paging when accessing data from a remote server.
XMLListCollection	A standard collection for working with XMLList objects. Implements the IList and ICollectionView interfaces, and a subset of XMLList methods.
CursorBookmark	Represents the position of a view cursor within a collection. You can save a view cursor position in a CursorBookmark object and use the object to return the view cursor to the position at a later time.
Sort	Provides the information and methods required to sort a collection.
SortField	Provides properties and methods that determine how a specific field affects data sorting in a collection.
ItemResponder	(Used only if the data source is remote.) Handles cases when requested data is not yet available.
ListCollectionView	Superclass of the ArrayCollection and XMLListCollection classes. Adapts an object that implements the IList interface to the ICollectionView interface so that it can be passed to anything that expects an IList or an ICollectionView.

About data provider components

Several Flex components, including all list-based controls, are called data provider components because they have a `dataProvider` property that consumes data from an ArrayCollection, ArrayList, XMLListCollection object, or a custom collection. For example, the value of an MX Tree control's `dataProvider` property determines the structure of the tree and any associated data assigned to each tree node, and a ComboBox control's `dataProvider` property determines the items in the control's drop-down list. Many standard controls, including the ColorPicker and MenuBar controls, also have a `dataProvider` property.

For Spark list-based controls, the value of the `dataProvider` property must implement the IList interface. Classes that implement IList include ArrayCollection, ArrayList, and XMLListCollection.

For the MX list-based controls, you can specify raw data objects, such as an Array of strings or objects or an XML object, the value of the `dataProvider` property. For MX controls, Flex automatically wraps the raw data in a collection.

Adobe recommends that you always specify a collection as the value of the `dataProvider` property. Using collections explicitly ensures data synchronization and provides both simpler and more sophisticated data access and manipulation tools than are available when you are using raw objects directly as data providers. Collections can also provide a consistent interface for accessing and managing data of different types. For more information about collections, see "About collections and data provider components" on page 898.

Although raw data objects for MX controls are automatically wrapped in an ArrayCollection object or XMLListCollection, they are subject to the following limitations:

- Raw objects are often not sufficient if you have data that changes, because the data provider component does not receive a notification of any changes to the base object. The component therefore does not get updated until it must be redrawn due to other changes in the application, or if the data provider is reassigned. At that time, it gets the data again from the updated raw object.
- Raw objects do not provide advanced tools for accessing, sorting, or filtering data. For example, if you use an Array as the data provider, you must use the native Adobe® Flash® Array methods to manipulate the data.

For detailed descriptions of the individual controls, see the pages for the controls in the *ActionScript 3.0 Reference for the Adobe Flash Platform*. For information on programming with many of the data provider components, see "MX data-driven controls" on page 943.

Data objects

The Flex framework supports the following types of data objects for populating data provider components:

Linear or list-based data objects are flat data structures consisting of some number of objects, each of which has the same structure; they are often one-dimensional Arrays or ActionScript object graphs, or simple XML structures. You can specify one of these data structures in an ArrayList, ArrayCollection or XMLListCollection object's `source` property or as the value of a data provider control's `dataProvider` property.

You can use list-based data objects with all data provider controls, but you do not typically use them with Tree and most menu-based controls, which typically use hierarchical data structures. For data that can change dynamically, you typically use an ArrayCollection, ArrayList, or XMLListCollection object to represent and manipulate these data objects rather than the raw data object. You can also use a custom object that implements the ICollectionView and/or IList interfaces. If you do not require sorting, cursors, and filtering, you can use a class that implements just the IList interface

Hierarchical data objects consist of cascading levels of often asymmetrical data. Often, the source of the data is an XML object, but the source can be a generic Object tree or trees of typed objects. You typically use hierarchical data objects with Flex controls that are designed to display hierarchical data:

- Tree
- Menu
- MenuBar
- PopUpMenuButton

A hierarchical data object matches the layout of a tree or cascading menu. For example, a tree often has a root node, with one or more branch or leaf child nodes. Each branch node can hold additional child branch or leaf nodes, but a leaf node is an endpoint of the tree.

The Flex hierarchical data provider controls use *data descriptor* interfaces to access and manipulate hierarchical data objects, and the Flex framework provides one class, the DefaultDataDescriptor class, which implements the required interfaces. If your data object does not conform to the structural requirements of the default data descriptor, you can create your own data descriptor class that implements the required interfaces.

You can use an ArrayCollection object or XMLListCollection object, or a custom object that implements the ICollectionView and IList interfaces to access and manipulate dynamic hierarchical data.

You can also use a hierarchical data object with controls that take linear data, such as the List control and the DataGrid control, by extracting specific data for linear display.

For more information on using hierarchical data providers, see “Hierarchical data objects” on page 927.

Specifying data providers in MXML applications

The Flex framework lets you specify and access data for data provider components in many ways. For example, you can bind a collection that contains data from a remote source to the `dataProvider` property of a data provider component; you can define the data provider in a `dataProvider` child tag of a data provider component; or you can define the data provider in ActionScript.

All access techniques belong to one of the following patterns, whether data is local or is provided from a remote source:

- Using a collection implementation, such as an ArrayList object, ArrayCollection object, or XMLListCollection object, directly. This pattern is particularly useful for collections where object reusability is not important.
- Using a collection interface. This pattern provides the maximum of independence from the underlying collection implementation.
- Using a raw data object, such as an Array, with an MX list-based control. This pattern is discouraged unless data is completely static.

Using a collection object explicitly

You can use a collection, such as an ArrayList, ArrayCollection, or XMLListCollection object, as a data provider explicitly in an MXML control by assigning it to the component’s `dataProvider` property. This technique is more direct than using an interface and is appropriate if the data provider is always of the same collection type.

For list-based controls, you often use an ArrayList object as the data provider, and populate the ArrayList object by using an Array that is local or from a remote data source. The following example shows an ArrayList object declared in line in a ComboBox control:

```
<?xml version="1.0"?>
<!-- dpcontrols\ArrayCollectionInComboBox.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <s:ComboBox id="myCB">
        <s:ArrayList id="stateArray">
            <fx:Object label="AL" data="Montgomery"/>
            <fx:Object label="AK" data="Juneau"/>
            <fx:Object label="AR" data="Little Rock"/>
        </s:ArrayList>
    </s:ComboBox>
</s:Application>
```

In this example, the default property of the ComboBox control, `dataProvider`, defines an ArrayList object. Because `dataProvider` is the default property of the ComboBox control, it is not declared. The default property of the ArrayList object, `source`, is an Array of Objects, each of which has a label and a data field. Because the ArrayList object's `source` property takes an Array object, it is not necessary to declare the `<fx:Array>` tag as the parent of the `<fx:Object>` tags.

The following example uses ActionScript to declare and create an ArrayList object:

```
<?xml version="1.0"?>
<!-- dpcontrols\ArrayCollectionInAS.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    initialize="initData();">

    <fx:Script>
        <![CDATA[
            import mx.collections.*;
            [Bindable]
            public var stateArray:ArrayList;

            public function initData():void {
                stateArray=new ArrayList(
                [{label:"AL", data:"Montgomery"},
                {label:"AK", data:"Juneau"},
                {label:"AR", data:"Little Rock"}]);
            }
        ]]>
    </fx:Script>
    <s:ComboBox id="myComboBox" dataProvider="{stateArray}"/>
</s:Application>
```

After you define the ComboBox control, the `dataProvider` property of the ComboBox control provides access to the collection that represents the underlying source object, and you can use the property to modify the data provider. If you add the following button to the preceding code, for example, you can click the button to add the label and data for Arizona to the end of the list in the ComboBox control, as in the following example:

```
<s:Button label="Add AZ"
    click="stateArray.addItem({'label':'AZ', 'data':'Phoenix'});"/>
```

In many cases, an ArrayList class is adequate for defining a non-XML data provider. However, for web services, remote objects, and uses that require cursors, filters, and sorts, you use the ArrayCollection class.

The following example shows an ArrayCollection object that is populated from a remote data source, in this case a remote object, as the data provider of a DataGrid control. Note that the `ArrayUtil.toArray()` method is used to ensure that the data sent to the ArrayCollection object is an Array.

```
<?xml version="1.0"?>
<!-- dpcontrols\ROParamBind22.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout gap="10"/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            import mx.controls.Alert;
            import mx.utils.ArrayUtil;
        ]]>
    </fx:Script>

    <fx:Declarations>
        <mx:RemoteObject
            id="employeeRO"
            destination="roDest"
            showBusyCursor="true"
            fault="Alert.show(event.fault.faultString, 'Error');">
            <mx:method name="getList">
                <mx:arguments>
                    <deptId>{dept.selectedItem.data}</deptId>
                </mx:arguments>
            </mx:method>
        </mx:RemoteObject>
        <mx:ArrayCollection id="employeeAC"
            source="{ArrayUtil.toArray(employeeRO.getList.lastResult)}"/>
    </fx:Declarations>
    <s:HGroup>
        <s:Label text="Select a department:"/>
        <s:ComboBox id="dept" width="150">
            <s:dataProvider>
                <mx:ArrayCollection>
```

```
                    <mx:source>
                        <fx:Object label="Engineering" data="ENG"/>
                        <fx:Object label="Product Management" data="PM"/>
                        <fx:Object label="Marketing" data="MKT"/>
                    </mx:source>
                </mx:ArrayCollection>
            </s:dataProvider>
        </s:ComboBox>
        <s:Button label="Get Employee List"
            click="employeeRO.getList.send()"/>
    </s:HGroup>

    <mx:DataGrid dataProvider="{employeeAC}" width="100%">
        <mx:columns>
            <mx:DataGridColumn dataField="name" headerText="Name"/>
            <mx:DataGridColumn dataField="phone" headerText="Phone"/>
            <mx:DataGridColumn dataField="email" headerText="Email"/>
        </mx:columns>
    </mx:DataGrid>
</s:Application>
```

Accessing data by using collection interfaces

If you know that a control's data can always be represented by a specific collection class, use an ArrayList, ArrayCollection, or XMLListCollection object explicitly, as shown above. If your code might be used with different types of collections—for example, if you might switch between object-based data and XML data from a remote data service—then you should use the ICollectionView interface in your application code, as the following example shows:

```
public var myICV:ICollectionView = indeterminateCollection;
...
<s:ComboBox id="cb1" dataProvider="{myICV}" initialize="sortICV()"/>
```

You can then manipulate the interface as needed to select data for viewing, or to get and modify the data in the underlying data object.

Using a raw data object as a data provider for an MX control

When the data is static, you can use a raw data object, such as an Array object, directly as a data provider for an MX control. For example, you could use an array for a static list of U.S. Postal Service state designators. Do not use the data object directly as the `dataProvider` property of a control if the object contents can change dynamically, for example in response to user input or programmatic processing.

Note: *For Spark list-based controls, you cannot use a raw object as the value of the control's data provider. You must specify an object that implements the IList interface. Classes that implement IList include ArrayCollection, ArrayList, and XMLListCollection.*

The result returned by an HTTP service or web service is often an Array, and if you treat that data as read-only, you can use the Array directly as a data provider. However, it is a better practice to use a collection explicitly. List-based controls turn Array-based data providers into collections internally, so there is no performance advantage to using an Array directly as the data provider. If you pass an Array to multiple controls, it is more efficient to convert the Array into a collection when the data is received, and then pass the collection to the controls.

The following example shows an MX ComboBox control that takes a static Array as its `dataProvider` value. As noted previously, using raw objects as data providers is not a best practice and should be considered only for data objects that will not change.

```
<?xml version="1.0"?>
<!-- dpcontrols/StaticComboBox.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Script>
        <![CDATA[
            [Bindable]
            public var myArray:Array = ["AL", "AK", "AR"];
        ]]>
    </fx:Script>

    <mx:ComboBox id="myCB0" dataProvider="{myArray}"/>
</s:Application>
```

In the preceding example, the Array specified as the `dataProvider` is automatically wrapped in an ArrayCollection object. This is the default type for data providers to be wrapped in. If the data provider were an XML or XMLList object, it would be wrapped in an XMLListCollection object. In this example, the ArrayCollection does not have an `id` property, but you can use ArrayCollection methods and properties directly through the `dataProvider` property, as the following example shows:

```
<mx:Button label="Add AZ"
    click="myCB0.dataProvider.addItem({'label':'AZ','data':'Phoenix'});"/>
```

Setting a data provider in ActionScript

You may set the `dataProvider` property of a control in ActionScript, as well as in MXML, as the following example shows:

```
<?xml version="1.0"?>
<!-- dpcontrols/DataGridValidateNow.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
   initialize="initData();">
   <fx:Script>
       <![CDATA[

            import mx.collections.ArrayList;
            [Bindable]
            private var DGArray:ArrayList = new ArrayList([
                {Artist:'Pavement', Album:'Slanted and Enchanted', Price:11.99},
                {Artist:'Pavement', Album:'Brighten the Corners', Price:11.99}]);

            // Initialize initDG ArrayList variable from the ArrayList.
            public function initData():void {
                myGrid.dataProvider = DGArray;
            }
        ]]>
   </fx:Script>
   <mx:DataGrid id="myGrid">
      <mx:columns>
         <mx:DataGridColumn dataField="Album"/>
         <mx:DataGridColumn dataField="Price"/>
      </mx:columns>
   </mx:DataGrid>
</s:Application>
```

In this example, you use the `intialize` event to set the `dataProvider` property of the DataGrid control.

In some situations, you might set the `dataProvider` property, and then immediately attempt to perform an action on the control based on the setting of the `dataProvider` property, as the following example shows:

```
<?xml version="1.0"?>
<!-- dpcontrols/DataGridValidateNowSelindex.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    initialize="initData();">
   <fx:Script>
       <![CDATA[
            import mx.collections.ArrayList;
            [Bindable]
            private var DGArray:ArrayList = new ArrayList([
                {Artist:'Pavement', Album:'Slanted and Enchanted', Price:11.99},
                {Artist:'Pavement', Album:'Brighten the Corners', Price:11.99}]);

            // Initialize initDG ArrayList variable from the ArrayList.
            public function initData():void {
                myGrid.dataProvider = DGArray;
                myGrid.validateNow();
                myGrid.selectedIndex=1;
            }
        ]]>
   </fx:Script>
   <mx:DataGrid id="myGrid">
      <mx:columns>
         <mx:DataGridColumn dataField="Album"/>
         <mx:DataGridColumn dataField="Price"/>
      </mx:columns>
   </mx:DataGrid>
</s:Application>
```

In this example, setting the `selectedindex` to 1 might fail because the DataGrid control is in the process of setting the `dataProvider` property. Therefore, you insert the `validateNow()` method after setting the data provider. The `validateNow()` method validates and updates the properties and layout of the control, and then redraws it, if necessary.

Do not insert the `validateNow()` method every time you set the `dataProvider` property because it can affect the performance of your application; it is only required in some situations when you attempt to perform an operation on the control immediately after setting its `dataProvider` property.

Example: Using a collection

The following sample code shows how you can use a standard collection, an ArrayCollection object, to represent and manipulate an Array for use in a control. This example shows the following features:

- Using an ArrayCollection to represent data in an Array
- Sorting the ArrayCollection
- Inserting data in the ArrayCollection

Note that if the example did not include sorting, it could use an ArrayList rather than an ArrayCollection as the data provider.

This example also shows the insertion's effect on the Array and the ArrayCollection representation of the Array:

```
<?xml version="1.0"?>
<!-- dpcontrols\SimpleDP.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx" width="600"
    initialize="sortAC();">
    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;
            import spark.collections.Sort;
            import spark.collections.SortField;

            // Function to sort the ArrayCollection in descending order.
            public function sortAC():void {
                var sortA:Sort = new Sort();
                sortA.fields=[new SortField("label")];
                myAC.sort=sortA;
                //Refresh the collection view to show the sort.
                myAC.refresh();
            }
            // Function to add an item in the ArrayCollection.
            // Data added to the view is also added to the underlying Array.
            // The ArrayCollection must be sorted for this to work.
            public function addItemToMyAC():void {
                myAC.addItem({label:"MD", data:"Annapolis"});
            }
        ]]>
    </fx:Script>
    <fx:Declarations>
        <!-- An ArrayCollection with an array of objects -->
        <mx:ArrayCollection id="myAC">
            <!-- Use an fx:Array tag to associate an id with the array. -->
            <fx:Array id="myArray">
                <fx:Object label="MI" data="Lansing"/>
                <fx:Object label="MO" data="Jefferson City"/>
                <fx:Object label="MA" data="Boston"/>
                <fx:Object label="MT" data="Helena"/>
                <fx:Object label="ME" data="Augusta"/>
                <fx:Object label="MS" data="Jackson"/>
                <fx:Object label="MN" data="Saint Paul"/>
            </fx:Array>
        </mx:ArrayCollection>
    </fx:Declarations>
    <s:HGroup width="100%">
        <!-- A ComboBox populated by the collection view of the Array. -->
        <s:ComboBox id="cb1" dataProvider="{myAC}"/>
        <s:Button id="b1" label="Add MD" click="addItemToMyAC();"/>
    </s:HGroup>
</s:Application>
```

Using simple data access properties and methods

Collections provide simple properties and methods for indexed access to linear data. These properties and methods are defined in the IList interface, which provides a direct representation of the underlying data object. Any operation that changes the collection also changes the data provider in a similar manner: if you insert an item as the third item in the collection, it is also the third item in the underlying data object, which is an Array when working with ArrayList or an ArrayCollection object. The underlying data object is an XMLList object when working with XMLListCollection objects.

Note: *If you use the ICollectionView interface to sort or filter a collection, do not use the IList interface to manipulate the data, because the results are indeterminate.*

Simple data access properties and methods let you do the following:

- Get, set, add, or remove an item at a specific index into the collection
- Add an item at the end of the collection
- Get the index of a specific item in the collection
- Remove all items in the collection
- Get the length of the collection

You can use this functionality directly on ArrayList, ArrayCollection, and XMLListCollection objects and also on the `dataProvider` property of any standard Flex data provider component.

The following sample code uses an ArrayList object to display an Array of elements in a ComboBox control. For an example that shows how to manage an ArrayCollection of objects with multiple fields, see “Example: Modifying data in a DataGrid control” on page 924.

In the following example the Array data source initially consists of the following elements:

```
"AZ", "MA", "MZ", "MN", "MO", "MS"
```

When you click the Button control, the application uses the `length` property of the ArrayList and several of its methods to do the following:

1. Change the data in the Array and the displayed data in the ComboBox control to a correct alphabetical list of the U.S. state abbreviations for states that start with M:

   ```
   MA, ME, MI, MN, MO, MS, MT
   ```

2. Display in a TextArea control information about the tasks it performed and the resulting Array.

The code includes comments that describe the changes to the data object.

```
<?xml version="1.0"?>
<!-- dpcontrols\UseIList.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    initialize="initData();">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import mx.collections.*;
            // The data provider is an Array of Strings
            public var myArray:Array = ["AZ", "MA", "MZ", "MN", "MO", "MS"];
            // Declare an ArrayList that represents the Array.
            [Bindable]
            public var myAL:ArrayList;
            //Initialize the ArrayList.
            public function initData():void {
                myAL = new ArrayList(myArray);
            }
            // The function to change the collection, and therefore
            // the Array.
            public function changeCollection():void {
                // Get the original collection length.
                var oldLength:int=myAL.length;
                // Remove the invalid first item, AZ.
                var removedItem:String=String(myAL.removeItemAt(0));
                // Add ME as the second item. (ILists used 0-based indexing.)
                myAL.addItemAt("ME", 1);
                // Add MT at the end of the Array and collection.
                myAL.addItem("MT");
                // Change the third item from MZ to MI.
                myAL.setItemAt("MI", 2);
                // Get the updated collection length.
                var newLength:int=myAL.length;
                // Get the index of the item with the value ME.
                var addedItemIndex:int=myAL.getItemIndex("ME");
                // Get the fifth item in the collection.
                var index4Item:String=String(myAL.getItemAt(4));
                // Display the information in the TextArea control.
                ta1.text="Start Length: " + oldLength + ". New Length: " +
                    newLength;
                ta1.text+=".\nRemoved " + removedItem;
                ta1.text+=".\nAdded ME at index " + addedItemIndex;
                ta1.text+=".\nThe item at index 4 is " + index4Item + ".";
                // Show that the base Array has been changed.
                ta1.text+="\nThe base Array is: " + myArray.join();
            }
        ]]>
    </fx:Script>
    <s:ComboBox id="myCB" dataProvider="{myAL}"/>
    <s:TextArea id="ta1" height="75" width="300"/>
    <s:Button label="rearrange list" click="changeCollection();"/>
</s:Application>
```

Working with data views

Classes that implement the ICollectionView interface, such as ArrayCollection and XMLListCollection, provide a *view* of the underlying data object as a collection of items. Although they are more complex, data views give you more flexibility than the simple data access methods and properties that are defined in the IList interface. Data views provide the following features:

- You can modify the data view to show the data in sorted order or to show a subset of the items in the data provider without changing the underlying data. For more information, see "Sorting and filtering data for viewing" on page 912.
- You can access the collection data by using a *cursor*, which lets you move through the collection, use bookmarks to save specific locations in the collection, and insert and delete items in the collection (and therefore in the underlying data source). For more information, see "Using a view cursor" on page 914.
- You can represent remote data that might not initially be available, or parts of the data set that might become available at different times. For more information, see "Collection change notification" on page 923 and "Remote data in data provider components" on page 939.

You can use data views directly on ArrayCollection and XMLListCollection objects and also on the `dataProvider` property of standard Flex data provider components *except* those that are subclasses of the NavBar class (ButtonBar, LinkBar, TabBar, and ToggleButtonBar). It is a better practice to work directly on the collection objects than on the `dataProvider` property.

Note that the ArrayList class implements the IList interface but not the ICollectionView interface.

Sorting and filtering data for viewing

Collections let you sort and filter data in the data view so that the data in the collection is a reordered subset of the underlying data. Data view operations have no effect on the underlying data object content, only on the subset of data that the collection view represents, and therefore on what is displayed by any control that uses the collection.

Sorting

A Sort object lets you sort data in a collection. You can specify multiple fields to use in sorting the data, require that the resulting entries be unique, and specify a custom comparison function to use for ordering the sorted output. You can also use a Sort object to find items in a collection. When you create a Sort object, or change its properties, you must call the `refresh()` method on the collection to show the results.

You use SortField objects to specify the fields to use in the sort. You create SortField objects and put them in the Sort class object's `fields` array.

To create case-insensitive sorts, use the `ignoreCase` property of the SortingCollator.

Filtering

You use a filter function to limit the data view in the collection to a subset of the source data object. The function must take a single Object parameter, which corresponds to a collection item, and must return a Boolean value specifying whether to include the item in the view. As with sorting, when you specify or change the filter function, you must call the `refresh()` method on the collection to show the filtered results. To limit a collection view of an array of strings to contain only strings starting with M, for example, use the following filter function:

```
public function stateFilterFunc(item:Object):Boolean {
    return item >= "M" && item < "N";
}
```

Example: Sorting and filtering an ArrayCollection

The following example shows the use of the filter function and a sort together. You can use the buttons to sort the collection, to filter the collection, or to do both. Use the Reset button to restore the collection view to its original state.

```
<?xml version="1.0"?>
<!-- dpcontrols\SortFilterArrayCollection.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    width="600">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;
            import spark.collections.Sort;
            import spark.collections.SortField;

            /* Function to sort the ICollectionView
               in ascending order. */
            public function sortAC():void {
                var sortA:Sort = new Sort();
                sortA.fields=[new SortField("label")];
                myAC.sort=sortA;
                //Refresh the collection view to show the sort.
                myAC.refresh();
            }
            /* Function to filter out all items with labels
               that are not in the range of M-N. */
            public function stateFilterFunc(item:Object):Boolean {
                return item.label >= "M" && item.label < "O";
            }

            /* Function to apply the filter function the ICollectionView. */
            public function filterAC():void {
                myAC.filterFunction=stateFilterFunc;
                /* Refresh the collection view to apply the filter. */
                myAC.refresh();
            }
            /* Function to Reset the view to its original state. */
            public function resetAC():void {
                myAC.filterFunction=null;
                myAC.sort=null;
                //Refresh the collection view.
                myAC.refresh();
            }
        ]]>
    </fx:Script>
    <fx:Declarations>
        <!-- An ArrayCollection with an array of objects. -->
        <mx:ArrayCollection id="myAC">
            <fx:Array id="myArray">
                <fx:Object label="LA" data="Baton Rouge"/>
                <fx:Object label="NH" data="Concord"/>
                <fx:Object label="TX" data="Austin"/>
                <fx:Object label="MA" data="Boston"/>
                <fx:Object label="AZ" data="Phoenix"/>
                <fx:Object label="OR" data="Salem"/>
                <fx:Object label="FL" data="Tallahassee"/>
                <fx:Object label="MN" data="Saint Paul"/>
                <fx:Object label="NY" data="Albany"/>
            </fx:Array>
        </mx:ArrayCollection>
    </fx:Declarations>
    <!-- Buttons to filter, sort, or reset the view in the second ComboBox
            control. -->
    <s:HGroup width="100%">
        <s:Button id="sortButton" label="Sort" click="sortAC();"/>
        <s:Button id="filterButton" label="Filter" click="filterAC();"/>
        <s:Button id="resetButton" label="Reset" click="resetAC();"/>
    </s:HGroup>
    <s:ComboBox id="cb1" dataProvider="{myAC}"/>
</s:Application>
```

For a more complex example of sorting a DataGrid control, which does both an initial sort of the data and a custom sort when you click a column heading, see “Create a custom sort for the Spark DataGrid control” on page 571.

Using a view cursor

You use a view cursor to traverse the items in a collection’s data view and to access and modify data in the collection. A *cursor* is a position indicator; it points to a particular item in the collection. Collections have a `createCursor()` method that returns a view cursor. View cursor methods and properties are defined in the IViewCursor interface.

You can use view cursor methods and properties to perform the following operations:

- Move the cursor backward or forward
- Move the cursor to specific items
- Get the item at a cursor location
- Add, remove, and change items
- Save a cursor position by using a bookmark, and return to it later

When you use standard Flex collection classes, ArrayCollection and XMLListCollection, you use the IViewCursor interface directly; as the following code snippet shows, you do not reference an object instance:

```
public var myAC:ICollectionView = new ArrayCollection(myArray);
public var myCursor:IViewCursor;
.
.
myCursor=myAC.createCursor();
```

Manipulating the view cursor

A view cursor object includes the following methods and properties for moving the cursor:

1 The `moveNext()` and `movePrevious()` methods move the cursor forward and backward by one item. Use the `beforeFirst` and `afterLast` properties to check whether you’ve reached the bounds of the view. The following example moves the cursor to the last item in the view:

```
while (! myCursor.afterLast) {
        myCursor.moveNext();
}
```

2 The `findAny()`, `findFirst()`, and `findLast()` methods move the cursor to an item that matches the parameter. Before you can use these methods, you must apply a Sort to the collection (because the functions use Sort methods).

If it is not important to find the first occurrence of an item or the last occurrence of an item in a nonunique index, the `findAny()` method can be somewhat more efficient than either the `findFirst()` or the `findLast()` method.

If the associated data is from a remote source, and not all of the items are cached locally, the find methods begin an asynchronous fetch from the remote source; if a fetch is already in progress, they wait for it to complete before making another fetch request.

The following example finds an item inside a collection of simple objects—in this case, an ArrayCollection of state ZIP code strings. It creates a default Sort object, applies it to an ArrayCollection object, and finds the first instance of the string `"MZ"` in a simple array of strings:

```
var sortD:Sort = new Sort();
// The null first parameter on the SortField constructor specifies a
// collection of simple objects (String, numeric, or Boolean values).
// The true second parameter specifies a case-insensitive sort.
sortD.fields = [new SortField(null, true)];
myAC.sort=sortD;
myAC.refresh();
myCursor.findFirst("MZ");
```

To find a complex object, you can use the `findFirst()` method to search on multiple sort fields. You cannot, however, skip fields in the parameter of any of the find methods. If an object has three fields, for example, you can specify any of the following field combinations in the parameter: 1, 1,2, or 1,2,3, but you cannot specify only fields 1 and 3.

Both of the following lines find an object with the label value `"ME"` and data value `"Augusta"`:

```
myCursor.findFirst({label:"ME"});
myCursor.findFirst({label:"ME", data:"Augusta"});
```

❖ The `seek()` method moves the cursor to a position relative to a bookmark. You use this method to move the cursor to the first or last item in a view, or to move to a bookmark position that you have saved.

Getting, adding, and removing data items

A view cursor object includes the following methods and properties for accessing and changing data in the view:

- The `current` property is a reference to the item at the current cursor location.
- The `insert()` method inserts an item before the current cursor location. However, if the collection is sorted (for example, to do a `find()` operation, the sort moves the item to the sorted order location, not to the cursor location.
- The `remove()` method removes the item at the current cursor location; if the removed item is not the last item, the cursor points to the location after the removed item.

The following example shows the results of using `insert()` and `remove()` on the `current` property:

```
<?xml version="1.0"?>
<!-- dpcontrols\GetAddRemoveItems.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    initialize="initData();">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            import mx.collections.*;
            public var myArray:Array = [{label:"MA", data:"Massachusetts"},
            {label:"MN", data:"Minnesota"}, {label:"MO", data:"Missouri"}];
            [Bindable]
            public var myAC:ArrayCollection;
            public var myCursor:IViewCursor;
            /* Initialize the ArrayCollection when you
               initialize the application. */
            public function initData():void {
                myAC = new ArrayCollection(myArray);
            }
            /* The function to change the collection,
               and therefore the Array. */
            public function testCollection():void {
                /* Get an IViewCursor object for accessing the collection data. */
                myCursor=myAC.createCursor();
                ta1.text="At start, the cursor is at: " + myCursor.current.label + ".";
                var removedItem:String=String(myCursor.remove());
                ta1.text+="\nAfter removing the current item, the cursor is at: "
                    + myCursor.current.label + ".";
                myCursor.insert({label:"ME", data:"Augusta"});
                ta1.text+="\nAfter adding an item, the cursor is at: "
                    + myCursor.current.label + ".";
            }
        ]]>
    </fx:Script>
    <s:ComboBox id="myCB" dataProvider="{myAC}"/>
    <s:TextArea id="ta1" height="75" width="350"/>
    <s:Button label="Run Test" click="testCollection();"/>
</s:Application>
```

Using bookmarks

You use a bookmark to save a cursor location for later use. You can also use the built-in `FIRST` and `LAST` bookmark properties to move the cursor to the first or last item in the data view.

Create and use a bookmark

1 Move the cursor to a desired location in the data view.

2 Assign the current value of the `bookmark` property to a variable, as in the following line:

```
var myBookmark:CursorBookmark=myCursor.bookmark;
```

3 Do some operations that might move the cursor.

4 When you must return to the bookmarked cursor location (or to a specific offset from the bookmarked location), call the IViewCursor `seek()` method, as in the following line:

```
myCursor.seek(myBookmark);
```

The following example counts the number of items in a collection between the selected item in a ComboBox control and the end of the collection, and then returns the cursor to the initial location:

```
<?xml version="1.0"?>
<!-- dpcontrols\UseBookmarks.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    initialize="run();">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;
            import mx.collections.IViewCursor;
            import mx.collections.CursorBookmark;
            import spark.collections.Sort;
            import spark.collections.SortField;
            private var myCursor:IViewCursor;
            // Initialize variables.
            public function run():void {
                // Initialize the cursor.
                myCursor=myAC.createCursor();
                // The findFirst() method, used in
                // countFromSelection() requires a
                // sorted view.
                var sort:Sort = new Sort();
                sort.fields=[new SortField("label")];
                myAC.sort=sort;
                //You must refresh the view to apply the sort.
                myAC.refresh();
            }
            // Count the items following the current
            // cursor location.
            public function countLast(theCursor:IViewCursor):int {
                var counter:int=0;
                // Set a bookmark at the current cursor location.
                var mark:CursorBookmark=theCursor.bookmark;
                // Move the cursor to the end of the Array.
                // The moveNext() method returns false when the cursor
                // is after the last item.
                    while (theCursor.moveNext()) {
                    counter++;
                }
                // Return the cursor to the initial location.
                theCursor.seek(mark);
                return counter;
            }
            // Function triggered by ComboBox change event.
            // Calls the countLast() function to count the
            // number of items to the end of the collection.
            public function countFromSelection():void {
                myCursor.findFirst(myCB.selectedItem);
                var count:int = countLast(myCursor);
                ta1.text += myCursor.current.label + " is " + count +
                                " from the last item.\n";
            }
        ]]>
    </fx:Script>
    <fx:Declarations>
        <!-- The data provider, an ArrayCollection with an array of objects. -->
        <mx:ArrayCollection id="myAC">
            <fx:Object label="MA" data="Boston"/>
            <fx:Object label="ME" data="Augusta"/>
            <fx:Object label="MI" data="Lansing"/>
            <fx:Object label="MN" data="Saint Paul"/>
            <fx:Object label="MO" data="Jefferson City"/>
            <fx:Object label="MS" data="Jackson"/>
            <fx:Object label="MT" data="Helena"/>
        </mx:ArrayCollection>
    </fx:Declarations>
    <s:ComboBox id="myCB"
        dataProvider="{myAC}" change="countFromSelection();"/>
    <s:TextArea id="ta1" height="200" width="175"/>
</s:Application>
```

Example: Updating an Array by using data view methods and properties

The following example uses the data view methods and properties of an ArrayCollection object to display an Array with the following elements in a ComboBox control:

```
"AZ", "MA", "MZ", "MN", "MO", "MS"
```

When you click the Update View button, the application uses the `length` property and several methods of the ICollectionView interface to do the following:

- Change the data in the array and the displayed data in the ComboBox control to a correct alphabetical list of the U.S. state abbreviations for the following states that start with the letter M:

  ```
  MA, ME, MI, MN, MO, MS, MT
  ```

- Save a bookmark that points to the ME item that it adds, and later restores the cursor to this position.
- Display in a TextArea control information about the tasks it performed and the resulting array.

When you click the Sort button, the application reverses the order of the items in the view, and limits the viewed range to ME–MO.

When you click the Reset button, the application resets the data provider array and the collection view.

```

```

Collection events and manual change notification

Collections use events to indicate changes to the collection. You can use these events to monitor changes and update the display accordingly.

Collection events

Collections use CollectionEvent, PropertyChangeEvent, and FlexEvent objects in the following ways:

- Collections dispatch a CollectionEvent (mx.events.CollectionEvent) event whenever the collection changes. All collection events have the `type` property value `CollectionEvent.COLLECTION_CHANGE`.
- The CollectionEvent object includes a `kind` property that indicates the way in which the collection changed. You can determine the change by comparing the `kind` property value with the CollectionEventKind constants; for example, `UPDATE`.
- The CollectionEvent object includes an `items` property that is an Array of objects whose type varies depending on the event kind. For ADD and REMOVE kind events, the array contains the added or removed items. For UPDATE events, the `items` property contains an Array of PropertyChangeEvent event objects. This object’s properties indicate the type of change and the property value before and after the change.
- The `PropertyChangeEvent` class `kind` property indicates the way in which the property changed. You can determine the change type by comparing the `kind` property value with the PropertyChangeEventKind constants; for example, `UPDATE`.
- View cursor objects dispatch a FlexEvent class event with the `type` property value of `mx.events.FlexEvent.CURSOR_UPDATE` when the cursor position changes.

You use collection events to monitor changes to a collection to update the display. For example, if a custom control uses a collection as its data provider, and you want the control to be updated dynamically and to display the revised data each time the collection changes, the control can monitor the collection events and update accordingly.

You could, for example, build a simple rental-car reservation system that uses collection events. This application uses `COLLECTION_CHANGE` event type listeners for changes to its `reservations` and `cars` data collections.

The CollectionEvent listener method, named `reservationsChanged`, tests the event `kind` field and does the following:

- If the event `kind` property is `ADD`, iterates through the objects in the event's `items` property and calls a function to update the reservation information display with boxes that display the time span of each reservation.
- If the event `kind` property is `REMOVE`, iterates through the objects in the event's `items` property and calls a function to remove the reservation box for each item.
- If the event `kind` property is `UPDATE`, iterates through the `PropertyChangeEvent` objects in the event's `items` property and calls the update function to update each item.
- If the event `kind` property is `RESET`, calls a function to reset the reservation information.

The following example shows the `reservationsChanged` CollectionEvent event listener function:

```
private function reservationsChanged(event:CollectionEvent):void {
    switch (event.kind) {
        case CollectionEventKind.ADD:
            for (var i:uint = 0; i < event.items.length; i++) {
                    updateReservationBox(Reservation(event.items[i]));
            }
            break;

        case CollectionEventKind.REMOVE:
            for (var i:uint = 0; i < event.items.length; i++) {
                removeReservationBox(Reservation(event.items[i]));
            }
            break;

        case CollectionEventKind.UPDATE:
            for (var i:uint = 0; i < event.items.length; i++) {
                if (event.items[i] is PropertyChangeEvent) {
                    if (PropertyChangeEvent(event.items[i]) != null) {
                         updateReservationBox(Reservation(PropertyChangeEvent(
                            event.items[i]).source));
                    }
                }
                else if (event.items[i] is Reservation) {
                    updateReservationBox(Reservation(event.items[i]));
                }
        }
        break;

        case CollectionEventKind.RESET:
            refreshReservations();
            break;
    }
}
```

The `updateReservationBox()` method either shows or hides a box that shows the time span of the reservation. The `removeReservationBox()` method removes a reservation box. The `refreshReservations()` method redisplays all current reservation information.

For more information on the application and the individual methods, see the sample code.

Collection change notification

Collections include the itemUpdated() method, which notifies a collection that the underlying data has changed and ensures that the collection's data view is up to date when items in the underlying data object do not implement the IEventDispatcher interface. This method takes the item that was modified, the property in the item that was updated, and its old and new values as parameters. Collections also provide the `enableAutoUpdate()` and `disableAutoUpdate()` methods, which enable and disable the automatic updating of the data view when the underlying data provider changes.

Using the itemUpdated() method

Use the `itemUpdated()` method to notify the collection of changes to a data provider object if the object does not implement the IEventDispatcher interface; in this case the object is not monitorable. Adobe Flash and Flex Objects and other basic data types do not implement this interface. Therefore you must use the `itemUpdated()` method to update the collection when you modify the properties of a data provider such as an Array or through the display object.

You can also use the `itemUpdated()` method if you must use an Array, rather than a collection, as an MX control's data provider. Then the component wraps the Array in a collection wrapper. The wrapper must be manually notified of any changes made to the underlying Array data object, and you can use the `itemUpdated()method` for that notification.

You do *not* have to use the `itemUpdated()` method if you add or remove items directly in a collection or use any of the ICollectionView or IList methods to modify the collection.

Also, specifying the `[Bindable]` metadata tag above a class definition, or above a variable declaration within the class, ensures that the class implements the IEventDispatcher interface, and causes the class to dispatch propertyChange events. If you specify the `[Bindable]` tag above the class declaration, the class dispatches propertyChange events for all properties; if you mark only specific properties as `[Bindable]`, the class dispatches events for only those properties. The collection listens for the propertyChange events. Therefore, if you have a collection called `myCollection` that consists of instances of a class that has a `[Bindable]myVariable` variable, an expression such as `myCollection.getItemAt(0).myVariable="myText"` causes the item to dispatch an event, and you do not have to use the `itemUpdated()` method. (For more information on the `[Bindable]` metadata tag and its use, see "Data binding" on page 299.)

The most common use of the `itemUpdate()` method is to notify a collection of changes to a custom class data source that you cannot make bindable or modify to implement the IEventDispatcher interface. The following schematic example shows how you could use the `itemUpdated()` method in such a circumstance.

Assume you have a class that you do not control or edit and that looks like the following:

```
public class ClassICantEdit {
    public var field1:String;
    public var field2:String;
}
```

You have an ArrayCollection that uses these objects, such as the following, which you populate with `classICantEdit` objects:

```
public var myCollection:ArrayCollection = new ArrayCollection();
```

You have a DataGrid control such as the following:

```
<s:DataGrid dataProvider="{myCollection}"/>
```

When you update a field in the `myCollection` ArrayCollection, as follows, the DataGrid control is not automatically updated:

```
myCollection.getItemAt(0).field1="someOtherValue";
```

To update the DataGrid control, you must use the collection's `itemUpdated()` method:

```
myCollection.itemUpdated(collectionOfThoseClasses.getItemAt(0));
```

Disabling and enabling automatic updating

A collection's disableAutoUpdate() method prevents events that represent changes to the underlying data from being broadcast by the view. It also prevents the collection from being updated as a result of these changes.

Use this method to prevent the collection, and therefore the control that uses it as a data provider, from showing intermediate changes in a set of multiple changes. The DataGrid class, for example, uses the `disableAutoUpdate()` method to prevent updates to the collection while a specific item is selected. When the item is no longer selected, the DataGrid control calls the `enableAutoUpdate()` method. Doing this ensures that, if a DataGrid control uses a sorted collection view, items that you edit do not jump around while you're editing.

You can also use the `disableAutoUpdate()` method to optimize performance in cases where multiple items in a collection are being edited at once. By disabling the auto update until all changes are made, a control like the DataGrid control can receive an update event as a single batch instead of reacting to multiple events.

The following code snippet shows the use of the `disableAutoUpdate()` and `enableAutoUpdate()` methods:

```
var obj:myObject = myCollection.getItemAt(0);
myCollection.disableAutoUpdate();
obj.prop1 = 'foo';
obj.prop2 = 'bar';
myCollection.enableAutoUpdate();
```

Example: Modifying data in a DataGrid control

The following example lets you add, remove, or modify data in a DataGrid control:

```
<?xml version="1.0"?>
<!-- dpcontrols\ModifyDataGridData.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    width="500" height="600" >
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import mx.events.*;
            import mx.collections.*;

            // Add event information to a log (displayed in the TextArea).
            public function collectionEventHandler(event:CollectionEvent):void {
                switch(event.kind) {
                    case CollectionEventKind.ADD:
                        addLog("Item "+ event.location + " added");
                        break;
                    case CollectionEventKind.REMOVE:
                        addLog("Item "+ event.location + " removed");
                        break;
                    case CollectionEventKind.REPLACE:
                        addLog("Item "+ event.location + " Replaced");
                        break;
                    case CollectionEventKind.UPDATE:
```

```
                    addLog("Item updated");
                    break;
            }
        }
        // Helper function for adding information to the log.
        public function addLog(str:String):void {
            log.text += str + "\n";
        }

        // Add a person to the ArrayCollection.
        public function addPerson():void {
            ac.addItem({first:firstInput.text, last:lastInput.text,
                email:emailInput.text});
                clearInputs();
        }

        // Remove a person from the ArrayCollection.
        public function removePerson():void {
            // Make sure an item is selected.
            if (dg.selectedIndex >= 0) {
                ac.removeItemAt(dg.selectedIndex);
        }
    }

    // Update an existing person in the ArrayCollection.
    public function updatePerson():void {
        // Make sure an item is selected.
        if (dg.selectedItem !== null) {
            ac.setItemAt({first:firstInput.text, last:lastInput.text,
                email:emailInput.text}, dg.selectedIndex);
        }
    }

    // The change event listener for the DataGrid.
    // Clears the text input controls and updates them with the contents
    // of the selected item.
    public function dgChangeHandler():void {
        clearInputs();
        firstInput.text = dg.selectedItem.first;
        lastInput.text = dg.selectedItem.last;
        emailInput.text = dg.selectedItem.email;
    }

    // Clear the text from the input controls.
    public function clearInputs():void {
        firstInput.text = "";
        lastInput.text = "";
        emailInput.text = "";
    }
    // The labelFunction for the ComboBox;
    // Puts first and last names in the ComboBox.
    public function myLabelFunc(item:Object):String {
        return item.first + " " + item.last;
    }
    ]]>
</fx:Script>
```

```
    <fx:Declarations>

Hierarchical data objects

You use hierarchical data objects with the controls that display a nested hierarchy of nodes and subnodes, such as tree branches and leaves, as well as Menu submenus and items. The following controls use hierarchical data objects:

- Menu
- MenuBar
- PopUpMenuButton
- Tree

The hierarchical components all use the same mechanism to work with the data provider. The following examples use the Tree control, but the examples apply to the other components.

About hierarchical data objects

The Flex framework, by default, supports two types of hierarchical data objects.

XML can be any of the following: Strings containing well-formed XML; or XML, XMLList, or XMLListCollection objects, including objects generated by the <fx:XML> and <fx:XMLList> compile-time tags. (These tags support data binding, which you cannot do directly in ActionScript.) Flex can automatically structure a Tree or menu-based control to reflect the nesting hierarchy of well-formed XML.

Objects can be any set of nested Objects or Object subclasses (including Arrays or ArrayCollection objects) that have a structure where the children of a node are in a `children` field. For more information, see "Creating a custom data descriptor" on page 931. You can also use the `<fx:Model>` compile-time tag to create nested objects that support data binding, but you must follow the structure defined in "Using the <fx:Model> tag with Tree and menu-based controls" on page 929.

You can add support for other hierarchical data provider structures, such as nested Objects where the children might be in fields with varying names.

Data descriptors and hierarchical data structure

Hierarchical data used in Tree and menu-based controls must be in a form that can be parsed and manipulated by using a data descriptor class. A *data descriptor* is a class that provides an interface between the hierarchical control and the data provider object. It implements a set of control-specific methods to determine the data provider contents and structure; to get, add, and remove data; and to change control-specific data properties.

Flex defines two data descriptor interfaces for hierarchical controls:

- ITreeDataDescriptor — Methods used by Tree controls
- IMenuDataDescriptor — Methods for Menu, MenuBar, and PopUpMenuButton controls

The Flex framework provides a DefaultDataDescriptor class that implements both interfaces. You can use the `dataDescriptor` property to specify a custom data descriptor class that handles data models that do not conform to the default descriptor structure.

Data descriptor methods and source requirements

The following table describes the methods of both interfaces, and the behavior of the DefaultDataDescriptor class. The first line of each interface/method entry indicates whether the method belongs to the ITreeDataDescriptor interface, the IMenuDataDescriptor interface, or both interfaces, and therefore indicates whether the method is used for trees, menus, or both.

Method	**Returns**	**DefaultDataDescriptor behavior**
hasChildren(*node*, [*model*])	A Boolean value indicating whether the node is a branch with children.	For XML, returns `true` if the node has at least one child element. For other objects, returns `true` if the node has a nonempty `children` field.
getChildren(*node*, [*collection*])	A node's children.	For XML, returns an XMLListCollection with the child elements. For other Objects, returns the contents of the node's `children` field.
isBranch(*node*, [*collection*])	Whether a node is a branch.	For XML, returns `true` if the node has at least one child, or if it has an `isBranch` attribute. For other Objects, returns `true` if the node has an `isBranch` field.
getData(*node*, [*collection*])	The node data.	Returns the node.
addChildAt(*node*, *child*, *index*, [*model*])	A Boolean value indicating whether the operation succeeded.	For all cases, inserts the node as a child object before the node currently in the index location.
removeChildAt (*node*, *index*, [*model*])	A Boolean value indicating whether the operation succeeded.	For all cases, removes the child of the node in the index location.
getType(*node*) (IMenuDataDescriptor only)	A String with the menu node type. Meaningful values are `check`, `radio`, and `separator`.	For XML, returns the value of the `type` attribute of the node. For other Objects, returns the contents of the node's `type` field.
isEnabled(*node*) (IMenuDataDescriptor only)	A Boolean value indicating whether a menu node is enabled.	For XML, returns the value of the `enabled` attribute of the node. For other Objects, returns the contents of the node's `enabled` field.
setEnabled(*node*, *value*) (IMenuDataDescriptor only)		For XML, sets the value of the `enabled` attribute of the node to `true` or `false`. For other Objects, sets the contents of the node's `enabled` field.
isToggled(*node*) (IMenuDataDescriptor only)	A Boolean value indicating whether a menu node is selected	Returns the value of the node's `toggled` attribute.
setToggled(*node*, *value*) (IMenuDataDescriptor only)		For XML, sets the value of the `selected` attribute of the node to `true` or `false`. For other Objects, sets the contents of the node's `enabled` field.
getGroupName(*node*) (IMenuDataDescriptor only)	The name of the radio button group to which the node belongs.	For XML, returns the value of the `groupName` attribute of the node. For other Objects, returns the contents of the node's `groupName` field.

The following example Object follows the default data provider structure for a Tree control, and is correctly handled by the DefaultDataDescriptor class:

```
[Bindable]
public var fileSystemStructure:Object =
    {label:"mx", children: [
        {label:"Containers", children: [
            {label:"Accordian", children:[]},
            {label:"DividedBox", children: [
                {label:"BoxDivider.as", data:"BoxDivider.as"},
                {label:"BoxUniter.as", data:"BoxUniter.as"}]},
            {label: "Grid", children:[]}]},
        {label: "Controls", children: [
            {label: "Alert", data: "Alert.as"},
            {label: "Styles", children: [
                {label: "AlertForm.as", data:"AlertForm.as"}]},
            {label: "Tree", data: "Tree.as"},
            {label: "Button", data: "Button.as"}]},
        {label: "Core", children:[]}
    ]};
```

For objects, the root is the Object instance, so there must always be a single root (as with XML). You could also use an Array containing nested Arrays as the data provider. In this case the provider has no root; each element in the top level array appears at the top level of the control.

The DefaultDataDescriptor can properly handle well-formed XML nodes. The `isBranch()` method, however, returns `true` only if the parameter node has child nodes or if the node has an `isBranch` attribute with the value `true`. Therefore, if your XML object uses any technique other than a `trueisBranch` attribute to indicate empty branches, you must create a custom data descriptor.

The DefaultDataDescriptor handles collections properly. For example, if a node's `children` property is an ICollectionView instance, the `getChildren()` method returns the children as an ICollectionView object.

Using the <fx:Model> tag with Tree and menu-based controls

The `<fx:Model>` tag lets you define a data provider structure in MXML. The Flex compiler converts the contents of the tag into a hierarchical graph of ActionScript Objects. The `<fx:Model>` tag has two advantages over defining an Object data provider in ActionScript:

- You can define the structure by using an easily read, XML-like format.
- You can bind structure entries to ActionScript variables, so that you can use `<fx:Model>` to create an object-based data provider that gets its data from multiple dynamic sources.

To use an `<fx:Model>` tag with a control that uses a data descriptor, the object generated by the compiler must conform to the data descriptor requirements, as discussed in "Data descriptors and hierarchical data structure" on page 927. Also, as with an XML object, the tag must have a single root element.

In most situations, you should consider using an <fx:XML> or <fx:XMLList> tag, as described in "XML-based data objects" on page 936, instead of using an `<fx:Model>` tag. The XML-based tags support data binding to elements, and the DefaultDataDescriptor class supports all well-structured XML. Therefore you can use a more natural structure, where node names can represent their function, and you do not have to artificially name nodes "children."

To use an `<fx:Model>` tag as the data provider for a control that uses the DefaultDataDescriptor class, all child nodes must be named "children." This requirement differs from the structure that you use with an Object, where the array that contains the child objects is named "children".

The following example shows the use of an `<fx:Model>` tag with data binding as a data provider for a menu, and shows how you can change the menu structure dynamically:

```
<?xml version="1.0"?>
<!-- dpcontrols\ModelWithMenu.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns="*">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            import mx.controls.Menu;
            public var productMenu:Menu;
            public function initMenu(): void {
                productMenu = Menu.createMenu(null, Products.Department);
                productMenu.setStyle("disabledColor", 0xCC3366);
                productMenu.show(10,10);
            }
        ]]>
    </fx:Script>
    <fx:Declarations>
        <fx:Model id="Products">
            <Root>
                <Department label="Toys">
                    <children label="Teddy Bears"/>
                    <children label="Action Figures"/>
                    <children label="Building Blocks"/>
                </Department>
                <Department label="Kitchen">
                    <children label="Electronics">
                        <children label="Crock Pot"/>
                        <children label="Panini Grill"/>
                    </children>
                    <children label="Cookware">
                        <children label="Grill Pan"/>
                        <children label="Iron Skillet" enabled="false"/>
                    </children>
                </Department>
                <!-- The items in this entry are bound to the form data -->
                <Department label="{menuName.text}">
                    <children label="{item1.text}"/>
                    <children label="{item2.text}"/>
                    <children label="{item3.text}"/>
                </Department>
            </Root>
        </fx:Model>
    </fx:Declarations>
    <s:Button label="Show Products" click="initMenu()"/>
    <!-- If you change the contents of the form, the next time you
        display the Menu, it will show the updated data in the last
        main menu item. -->
    <s:Form>
        <s:FormItem label="Third Submenu title">
            <s:TextInput id="menuName" text="Clothing"/>
        </s:FormItem>
        <s:FormItem label="Item 1">
            <s:TextInput id="item1" text="Sweaters"/>
        </s:FormItem>
        <s:FormItem label="Item 2">
            <s:TextInput id="item2" text="Shoes"/>
        </s:FormItem>
        <s:FormItem label="Item 3">
            <s:TextInput id="item3" text="Jackets"/>
        </s:FormItem>
    </s:Form>
</s:Application>
```

Creating a custom data descriptor

If your hierarchical data does not fit the formats supported by the DefaultDataDescriptor class—for example, if your data is in an object that does not use a children field—you can write a custom data descriptor and specify it in your Tree control's `dataDescriptor` property. The custom data descriptor must implement all methods of the `ITreeDataDescriptor` interface.

The following example shows how you can create a custom data descriptor—in this case, for use with a Tree control. This data descriptor correctly handles a data provider that consists of nested ArrayCollection objects.

The following code shows the MyCustomTreeDataDescriptor class, which implements only the ITreeDataDescriptor interface, so it supports Tree controls but not menu-based controls. The custom class supports tree nodes whose children field is either an ArrayCollection or an Object. When getting a node's children, if the children object is an ArrayCollection, it returns the object; otherwise, it wraps the children object in an ArrayCollection before returning it. When adding a node, it uses a different method to add the node, depending on the children field type.

```
package myComponents
// myComponents/MyCustomTreeDataDescriptor.as
{
import mx.collections.ArrayCollection;
import mx.collections.CursorBookmark;
import mx.collections.ICollectionView;
import mx.collections.IViewCursor;
import mx.events.CollectionEvent;
import mx.events.CollectionEventKind;
import mx.controls.treeClasses.*;
public class MyCustomTreeDataDescriptor implements ITreeDataDescriptor
{
    // The getChildren method requires the node to be an Object
    // with a children field.
    // If the field contains an ArrayCollection, it returns the field
    // Otherwise, it wraps the field in an ArrayCollection.
    public function getChildren(node:Object,
        model:Object=null):ICollectionView
    {
        try
        {
            if (node is Object) {
                if(node.children is ArrayCollection){
                    return node.children;
                }else{
                    return new ArrayCollection(node.children);
                }
            }
        }
        catch (e:Error) {
            trace("[Descriptor] exception checking for getChildren");
        }
        return null;
    }
    // The isBranch method simply returns true if the node is an
    // Object with a children field.
    // It does not support empty branches, but does support null children
    // fields.

            }
        }
        return false;
    }
}
}
```

The following example uses the MyCustomTreeDataDescriptor to handle hierarchical nested ArrayCollections and objects. When you click the button, it adds a node to the tree by calling the data descriptor's `addChildAt()` method. Notice that you would not normally use the `addChildAt()` method directly. Instead, you would use the methods of a Tree or menu-based control, which in turn use the data descriptor methods to modify the data provider.

```

</s:Application>
```

XML-based data objects

The data for a tree is often retrieved from a server in the form of XML, but it can also be well-formed XML defined within the `<mx:Tree>` tag. The DefaultDataDescriptor class can handle well-formed XML data structures.

You can use an <fx:XML> or <fx:XMLList> tag to define an XML or XMLList object in MXML. Unlike the XML and XMLList classes in ActionScript, these tags let you use MXML binding expressions in the XML text to extract node contents from variable data. For example, you can bind a node's name attribute to a text input value, as in the following example:

```
<fx:XMLList id="myXMLList">
    <child name="{textInput1.text}"/>
    <child name="{textInput2.text}"/>
</fx:XMLList>
```

You can use an XML object directly as a data provider to a hierarchical data control. However, if the object changes dynamically, you should do the following:

1 Convert the XML or XMLList object to an XMLListCollection object.

2 Make all updates to the data by modifying the XMLListCollection object.

Doing this ensures that the component represents the dynamic data. The XMLListCollection class supports the use of all IList and ICollectionView interface methods, and adds many of the most commonly used XMLList class methods. For more information on using XMLListCollections, see “XMLListCollection objects” on page 937.

The following code example defines two Tree controls. The first uses an XML object directly, and the second uses an XMLListCollection object as the data source:

```
<?xml version="1.0"?>
<!-- dpcontrols\UseXMLDP.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    width="650">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Declarations>
        <fx:XML id="capitals">
            <root>
                <Capitals label="U.S. State Capitals">
                    <capital label="AL" value="Montgomery"/>
                    <capital label="AK" value="Juneau"/>
                    <capital label="AR" value="Little Rock"/>
                    <capital label="AZ" value="Phoenix"/>
                </Capitals>
                <Capitals label="Canadian Province Capitals">
                    <capital label="AB" value="Edmonton"/>
                    <capital label="BC" value="Victoria"/>
                    <capital label="MB" value="Winnipeg"/>
                    <capital label="NB" value="Fredericton"/>
                </Capitals>
            </root>
        </fx:XML>
        <!-- Create an XMLListCollection representing the Tree nodes.
```

```
             capitals.Capitals is an XMLList with both Capitals elements. -->
        <mx:XMLListCollection id="capitalColl" source="{capitals.Capitals}"/>
    </fx:Declarations>
    <s:Label text="These two Tree controls appear identical, although their data sources are
different."/>
    <s:HGroup>
        <!-- When you use an XML-based data provider with a tree
             you must specify the label field, even if it
             is "label". The XML object includes the root,
             so you must set showRoot="false". Remember that
             the Tree will not, by default, reflect dynamic changes
             to the XML object. -->
        <mx:Tree id="Tree1" dataProvider="{capitals}" labelField="@label"
            showRoot="false" width="300"/>

        <!-- The XMLListCollection does not include the XML root. -->
        <mx:Tree id="Tree2" dataProvider="{capitalColl}" labelField="@label"
            width="300"/>
    </s:HGroup>
</s:Application>
```

This example shows two important features of using a hierarchical data provider with a Tree control:

- ECMAScript for XML (E4X) objects must have a single root node, which might not be appropriate for displaying in the Tree. Also, trees can have multiple elements at their highest level. To prevent the tree from displaying the root node, set the `showRoot` property to `false`. (The default `showRoot` value for the Tree control is `true`.) XMLList collections, however, do not have a single root, and you typically do not need to use the `showRoot` property.
- When you use an XML, XMLList, or XMLListCollection object as the tree data provider, you must specify the `labelField` property, even if it is “label”, if the field is an XML attribute. You must do this because you must use the @ sign to signify an attribute.

XMLListCollection objects

XMLListCollection objects provide collection functionality to an XMLList object and make available some of the XML manipulation methods of the native XMLList class, such as the `attributes()`, `children()`, and `elements()` methods. For details of the supported methods, see XMLListCollectionin the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

The following simple example uses an XMLListCollection object as the data provider for a List control. It uses XMLListCollection methods to dynamically add items to and remove them from the data provider and its representation in the List control. The example uses a Tree control to represent a selection of shopping items and a List collection to represent a shopping list.

Users add items to the List control by selecting an item in a Tree control (which uses a static XML object as its data provider) and clicking a button. When the user clicks the button, the event listener uses the XMListCollection `addItem()` method to add the selected XML node to the XMLListCollection. Because the data provider is a collection, the List control is updated to show the new data.

Users remove items in a similar manner, by selecting an item in the list and clicking the Remove button. The event listener uses the XMLListCollection `removeItemAt()` method to remove the item from the data provider and its representation in the List control.

```
<?xml version="1.0"?>
<!-- dpcontrols\XMLListCollectionWithList.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    width="550">

    <fx:Script>
        <![CDATA[
            import mx.collections.XMLListCollection;
            import mx.collections.ArrayCollection;

            /* An XML object with categorized produce. */
            [Bindable]
            public var myData:XML=

            labelField="@name"/>
    </s:HGroup>
</s:Application>
```

Remote data in data provider components

You use Flex data access components: HTTPService, WebService, and RemoteObject, to supply data to Flex data provider components. For more information, see Accessing server-side data.

To use a remote data source to provide data, you represent the result of the remote service with the appropriate object, as follows:

- A RemoteObject component automatically returns an ArrayCollection for any data that is represented on the server as a java.util.List object, and you can use the returned object directly.
- For HTTPService and WebService results, cast the result data to a collection class if the data changes or if you use the same result in multiple places (the latter case is more efficient). As a general rule, use an ArrayCollection for serialized (list-based) objects and an XMLListCollection for XML data.

The following code snippet shows this use, casting a list returned by a web service to an Array in an ArrayCollection:

```
<mx:WebService id="employeeWS" wsdl="http://server.com/service.wsdl"
    showBusyCursor="true"
    fault="alert(event.fault.faultstring)">
    <mx:operation name="getList">
        <mx:request>
            <deptId>{dept.selectedItem.data}</deptId>
        </mx:request>
    </mx:operation>
    ...
</mx:WebService>

<mx:ArrayCollection id="ac"
    source="mx.utils.ArrayUtil.toArray(employeeWS.getList.lastResult)"/>
<mx:DataGrid dataProvider="{ac}" width="100%">
```

For more information on using data access component, see Accessing server-side data.

Handling data pages with Spark components

You can use a data collection with a remote data source. Often, you want to access the data as it arrives from the server rather than waiting for all of the remote data to load. Multiple data items in a collection can be grouped into pages. The application can then handle each page as it arrives, rather than waiting for the entire collection.

A collection that supported data pages dispatches an ItemPendingError error when a request for data item is pending. The application can then handle the error as necessary.

The MX List and MX DataGrid controls have built in support for handling ItemPendingError errors. However, the Spark DataGroup and other Spark controls, such as List, do not.

To support data paging with Spark controls, use the AsyncListView as the data provider of the control. The AsyncListView class implements the IList interface, so it can be used as the data provider of a Spark control. AsyncListView handles ItemPendingError errors thrown when items requested by a call to the `getItemAt()` method are not available.

The following example uses the AsyncListView class with a Spark List control:

```
<fx:Declarations>
    // Define an ArrayCollection to hold the data from a DataService.
    <mx:ArrayCollection id="products"/>
    <mx:DataService id="ds" destination="inventory"/>
</fx:Declarations>
// Define a Button control to populate the ArrayCollection.
<s:Button label="Get Data" click="ds.fill(products);"/>

// Wrap the ArrayCollection in an AsyncListView class to handle ItemPendingError events.
<s:List>
    <mx:AsyncListView list="{products}"/>
</s:List>
```

In this example, the AsyncListView class handles any ItemPendingError errors generated when a data item is not yet available.

The AsyncListView class defines two properties, `createPendingItemFunction` and `createFailedItemFunction`, that you can use to specify callback functions executed for an ItemPendingError error. The callback function specified by `createPendingItemFunction` creates a placeholder item in the collection when a request is pending. The callback function specified by `createFailedItemFunction` creates a placeholder item in the collection when a request fails.

The following example creates these callback functions:

```
<fx:Script>
    <![CDATA[
        import mx.collections.errors.ItemPendingError;

        private function createPendingItem(index:int, ipe:ItemPendingError):Object {
            return "[" + index + " ...]";
        }

        private function createFailedItem(index:int, info:Object):Object {
            return "[" + index + " failed]";
        }
    ]]>
</fx:Script>

<fx:Declarations>
    <mx:ArrayCollection id="products"/>
    <mx:DataService id="ds" destination="inventory"/>
</fx:Declarations>

<s:Button label="Get Data" click="ds.fill(products);"/>

<s:List>
    <mx:AsyncListView list="{products}"
        createPendingItemFunction="{createPendingItem}"
        createFailedItemFunction="{createFailedItem}"/>
</s:List>
```

Data providers and the uid property

Flex data provider controls use a unique identifier (UID) to track data items. Flex can automatically create and manage UIDs. However, there are circumstances when you must supply your own `uid` property by implementing the IUID interface, and there are circumstances when supplying your own `uid` property improves processing efficiency.

Because the Object and Array classes are dynamic, you normally do not do anything special for data objects whose items belong to these classes. However, you should consider implementing the IUID if your data object items belong to custom classes that you define.

***Note:** When Flex creates a UID for an object, such as an item in an ArrayCollection, it adds the UID as an `mx_internal_uid` property of the item. Flex creates `mx_internal_uid` properties for any objects that are dynamic and do not have bindable properties. To avoid having Flex create `mx_internal_uid` properties, the object class should do any of the following things: have at least one property with a `[Bindable]` metadata tag; implement the IUID interface; or have a `uid` property with a value.*

If Flex must consider two or more different objects to be identical, the objects must implement the IUID interface so that you can assign the same `uid` value to multiple objects. A typical case where you must implement the IUID interface is an application that uses paged collections. As the cursor moves through the collection, a particular item might be pulled down from the server and released from memory repeatedly. Every time the item is pulled into memory, a new object is created to represent the item. If you need to compare items for equality, Flex should consider all objects that represent the same item to be the same “thing.”

More common than the case where you must implement the IUID interface is the case where you can improve processing efficiency by doing so. As a general rule, you do not implement the IUID interface if the data provider elements are members of dynamic classes. Flex can automatically create a `uid` property for these classes. There is still some inefficiency, however, so you might consider implementing the IUID interface if processing efficiency is particularly important.

In all other cases, Flex uses the Dictionary mechanism to manage the `uid`, which might not be as efficient as supplying your own UID.

The IUID interface contains a single property, `uid`, which is a unique identifier for the class member, and no methods. Flex provides a UIDUtil class that uses a pseudo-random-number generator to create an identifier that conforms to the standard GUID format. Although this identifier is not guaranteed to be universally unique, it should be unique among all members of your class. To implement a class that uses the UIDUtil class, such as a Person class that has fields for a first name, last name, and ID, you can use the following pattern:

```
package {
    import mx.core.IUID;
    import mx.utils.UIDUtil;

    [Bindable]
    public class Person implements IUID {
        public var id:String;
        public var firstName:String;
        public var lastName:String;
        private var _uid:String;

        public function Person() {
            _uid = UIDUtil.createUID();
        }

        public function get uid():String {
            return _uid;
        }

        public function set uid(value:String):void {
            // Do nothing, the constructor created the uid.
        }
    }
}
```

You do not need to use the UIDUtil class in a case where the objects contain a uniquely-identifying field such as an employee ID. In this case, you can use the person's ID as the `uid` property, because the `uid` property values uniquely identify the object only in the data provider. The following example implements this approach:

```
package
{
    import mx.core.IUID;

    [Bindable]
    public class Person implements IUID {
        public var employee_id:String;
        public var firstName:String;
        public var lastName:String;

        public function get uid(): String {
            return employee_id;
        }

        public function set uid(value: String): void {
            employee_id=value;
        }
    }
}
```

***Note:** Object cloning does not manage or have a relationship with UIDs, so if you clone something that has an internal UID you must also change that internal UID. UIDs are stored on mx_internal_uid only for dynamic Objects. Instances of data classes that implement IUID store their UIDs in a uid property, so that is the property that must be changed after cloning.*

MX data-driven controls

Several MX controls take input from a data provider, an object that contains data. For example, a Tree control reads data from a data provider to define the structure of the tree and any associated data assigned to each tree node.

Several of the controls that use a data provider let you visualize complex data, and there are different ways to populate these controls by using a data provider. The following topics also provide information on data providers and controls that use data providers:

- "Data providers and collections" on page 898 contains details on data providers and how to use collections as data providers.
- "Menu-based controls" on page 985 contains information on using Menu, MenuBar, and PopUpMenuButton controls.
- "AdvancedDataGrid control" on page 1397 contains information on using the AdvancedDataGrid control, which expands on the functionality of the standard DataGrid control to add data visualization features to your Adobe Flex application.
- "OLAPDataGrid control" on page 1454 contains information on using the OLAPDataGrid control, which lets you aggregate large amounts of data for easy display and interpretation.

MX List control

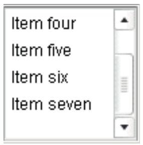
The List control displays a vertical list of items. Its functionality is very similar to that of the `SELECT` form element in HTML. It often contains a vertical scroll bar that lets users access the items in the list. An optional horizontal scroll bar lets users view items when the full width of the list items is unlikely to fit. The user can select one or more items from the list.

Flex also includes the Spark List control. When possible, Adobe recommends that you use the Spark List control. For more information, see "Spark List control" on page 525.

***Note:** The HorizontalList, TileList, DataGrid, Menu, and Tree controls are derived from the MX List control or its immediate parent, the MX ListBase class. As a result, much of the information for the List control applies to these controls.*

For complete reference information, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

The following image shows a List control:



List control sizing

If you specify `horizontalScrollPolicy="on"`, the default width of a List control does not change; it is still large enough to display the widest visible label. If you set `horizontalScrollPolicy="on"`, and specify a List control pixel width, you can use the `measureWidthOfItems()` method to ensure that the scroll bar rightmost position corresponds to the right edge of the content, as the following example shows. Notice that the additional 5 pixels ensures that the rightmost character of the text displays properly.

```
<mx:List id="li2"
    width="200" horizontalScrollPolicy="on"
    maxHorizontalScrollPosition="{li2.measureWidthOfItems() - li2.width +5}">
```

The preceding line ensures that the rightmost position of the scroll bar puts the end of the longest measured list item near the right edge of the List control. Using this technique, however, can reduce application efficiency, so you might consider using explicit sizes instead.

Lists, and all subclasses of the ListBase class, determine their sizes when a style changes or the data provider changes.

If you set a `width` property that is less than the width of the longest label and specify the `horizontalScrollPolicy="off"`, labels that exceed the control width are clipped.

Creating a List control

You use the `<mx:List>` tag to define a List control. Specify an `id` value if you intend to refer to a component elsewhere in your MXML, either in another tag or in an ActionScript block.

The List control uses a list-based data provider. For more information, see “Data providers and collections” on page 898.

You specify the data for the List control by using the `dataProvider` property of the control. However, because `dataProvider` is the List control’s default property, you do not have to specify a `dataProvider` child tag of the `<mx:List>` tag. In the simplest case for creating a static List control, you need only put `<fx:String>` tags in the control body, because Flex also automatically interprets the multiple tags as an Array of Strings, as the following example shows:

```
<?xml version="1.0"?>
<!-- dpcontrols/ListDataProvider.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <mx:List>
        <mx:dataProvider>
            <fx:String>AK</fx:String>
            <fx:String>AL</fx:String>
            <fx:String>AR</fx:String>
        </mx:dataProvider>
    </mx:List>
</s:Application>
```

Because the data in this example is inline static data, it is not necessary to explicitly wrap it in an ArrayList or ArrayCollection object. However, when working with data that could change, it is always best to specify a list or collection explicitly; for more information, see “Data providers and collections” on page 898.

The index of items in the List control is zero-based, which means that values are 0, 1, 2, ... , *n* - 1, where *n* is the total number of items. The value of the item is its label text.

You typically use events to handle user interaction with a List control. The following example code adds a handler for a `change` event to the List control. Flex broadcasts a `mx.ListEvent.CHANGE` event when the value of the control changes due to user interaction.

```
<?xml version="1.0"?>
<!-- dpcontrols/ListChangeEvent.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            import flash.events.Event;
            public function changeEvt(event:Event):void {
                forChange.text=event.currentTarget.selectedItem.label + " " +
                event.currentTarget.selectedIndex;
            }
        ]]>
    </fx:Script>
    <mx:List width="35" change="changeEvt(event)">
        <fx:Object label="AL" data="Montgomery"/>
        <fx:Object label="AK" data="Juneau"/>
        <fx:Object label="AR" data="Little Rock"/>
    </mx:List>
    <mx:TextArea id="forChange" width="150"/>
</s:Application>
```

In this example, you use two properties of the List control, `selectedItem` and `selectedIndex`, in the event handler. Every `change` event updates the TextArea control with the label of the selected item and the item's index in the control.

The `target` property of the object passed to the event handler contains a reference to the List control. You can reference any control property by using the event's `currentTarget` property. The `currentTarget.selectedItem` field contains a copy of the selected item. If you populate the List control with an Array of Strings, the `currentTarget.selectedItem` field contains a String. If you populate it with an Array of Objects, the `currentTarget.selectedItem` field contains the Object that corresponds to the selected item, so, in this case, `currentTarget.selectedItem.label` refers to the selected item's label field.

Using a label function

You can pass a label function to the List control to provide logic that determines the text that appears in the control. The label function must have the following signature:

```
labelFunction(item:Object):String
```

The *`item`* parameter passed in by the Label control contains the list item object. The function must return the string to display in the List control.

***Note:** Most subclasses of ListBase also take a `labelFunction` property with the signature described above. For the DataGrid and DataGridColumn controls, the method signature is `labelFunction(item:Object, dataField:DataGridColumn):String`, where `item` contains the DataGrid item object, and `dataField` specifies the DataGrid column.*

The following example uses a function to combine the values of the `label` and `data` fields for each item for display in the List control:

```
<?xml version="1.0"?>
<!-- dpcontrols/ListLabelFunction.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx" >

    <fx:Script>
        <![CDATA[
            public function myLabelFunc(item:Object):String {
                return item.data + ", " + item.label;
            }
        ]]>
    </fx:Script>
    <fx:Declarations>
        <mx:ArrayList id="myDP">
            <mx:source>
                <fx:Object label="AL" data="Montgomery"/>
                <fx:Object label="AK" data="Juneau"/>
                <fx:Object label="AR" data="Little Rock"/>
            </mx:source>
        </mx:ArrayList>
    </fx:Declarations>
    <mx:List dataProvider="{myDP}" labelFunction="myLabelFunc"/>
</s:Application>
```

***Note:** This example uses an ArrayList object as the data provider. You should always use a list or collection as the data provider when the data can change at run time. For more information, see "Data providers and collections" on page 898.*

Displaying DataTips

DataTips are similar to ToolTips, but display text when the mouse pointer hovers over a row in a List control. Text in a List control that is longer than the control width is clipped on the right side (or requires scrolling, if the control has scroll bars). DataTips can solve that problem by displaying all of the text, including the clipped text, when the mouse pointer hovers over a cell. If you enable data tips, they only appear for fields where the data is clipped. To display DataTips, set the `showDataTips` property of a List control to `true`.

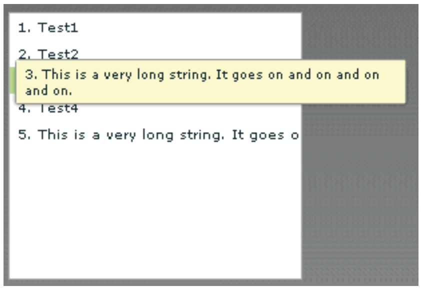
***Note:** To use DataTips with a DataGrid control, you must set the `showDataTips` property on the individual DataGridColumns of the DataGrid.*

The default behavior of the `showDataTips` property is to display the label text. However, you can use the `dataTipField` and `dataTipFunction` properties to determine what is displayed in the DataTip. The `dataTipField` property behaves like the `labelField` property; it specifies the name of the field in the data provider to use as the DataTip for cells in the column. The `dataTipFunction` property behaves like the `labelFunction` property; it specifies the DataTip string to display for list items.

The following example sets the `showDataTips` property for a List control:

```
<mx:List id="myList" dataProvider="{myDP}" width="220" height="200" showDataTips="true"/>
```

This example creates the following List control:



1. Test1
2. Test2
3. This is a very long string. It goes on and on and on and on.
4. Test4
5. This is a very long string. It goes o

Displaying ScrollTips

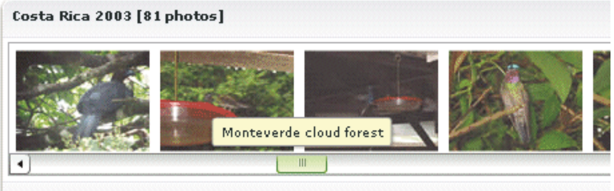
You use ScrollTips to give users context about where they are in a list as they scroll through the list. The tips appear only when you scroll; they don't appear if you only hover the mouse over the scroll bar. ScrollTips are useful when live scrolling is disabled (the `liveScrolling` property is false) so scrolling does not occur until you release the scroll thumb. The default value of the `showScrollTips` property is `false`.

The default behavior of the `showScrollTips` property is to display the index number of the top visible item. You can use the `scrollTipFunction` property to determine what is displayed in the ScrollTip. The `scrollTipFunction` property behaves like the `labelFunction` property; it specifies the ScrollTip string to display for list items. You should avoid going to the server to fill in a ScrollTip.

The following example sets the `showScrollTips` and `scrollTipFunction` properties of a HorizontalList control, which shares many of the same properties and methods as the standard List control; for more information about the HorizontalList control, see "MX HorizontalList control" on page 951. The `scrollTipFunction` property specifies a function that gets the value of the `description` property of the current list item.

```
<mx:HorizontalList id="list" dataProvider="{album.photo}" width="100%"
    itemRenderer="Thumbnail" columnWidth="108" height="100"
    selectionColor="#FFCC00" liveScrolling="false" showScrollTips="true"
    scrollTipFunction="scrollTipFunc"
    change="currentPhoto=album.photo[list.selectedIndex]"/>
```

This code produces the following HorizontalList control:



Vertically aligning text in List control rows

You can use the `verticalAlign` style to vertically align text at the top, middle, or bottom of a List row. The default value is `top`. You can also specify a value of `middle` or `bottom`.

The following example sets the `verticalAlign` property for a List control to `bottom`:

```
<mx:List id="myList" dataProvider="{myDP}"
    width="220" height="200"
    verticalAlign="bottom"/>
```

Setting variable row height and wrapping List text

You can use the `variableRowHeight` property to make the height of List control rows variable based on their content. The default value is `false`. If you set the `variableRowHeight` property to `true`, the `rowHeight` property is ignored and the `rowCount` property is read-only.

The following example sets the `variableRowHeight` property for a List control to `true`:

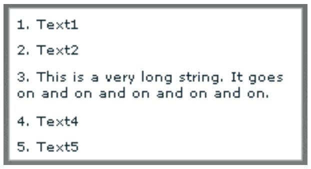
```
<mx:List id="myList" dataProvider="{myDP}"
    width="220" height="200"
    variableRowHeight="true"/>
```

You can use the `wordWrap` property in combination with the `variableRowHeight` property to wrap text to multiple lines when it exceeds the width of a List row.

The following example sets the `wordWrap` and `variableRowHeight` properties to `true`:

```
<mx:List id="myList" dataProvider="{myDP}"
    width="220" height="200"
    variableRowHeight="true" wordWrap="true"/>
```

This code produces the following List control:



1. Text1
2. Text2
3. This is a very long string. It goes on and on and on and on and on.
4. Text4
5. Text5

Alternating row colors in a List control

You can use the `alternatingItemColors` style property to specify an Array that defines the color of each row in the List control. The Array must contain two or more colors. After using all the entries in the Array, the List control repeats the color scheme.

The following example defines an Array with two entries, #66FFFF for light blue and #33CCCC for a blue-gray. Therefore, the rows of the List control alternate between these two colors. If you specify a three-color array, the rows alternate among the three colors, and so on.

```
<mx:List alternatingItemColors="[#66FFFF, #33CCCC]".../>
```

Using a custom item renderer

An item renderer is the object that displays a List control’s data items. The simplest way to use a custom item renderer is to specify an MXML component as the value of the `itemRenderer` property. When you use an MXML component as a item renderer, it can contain multiple levels of containers and controls. You can also use an ActionScript class as a custom item renderer. For detailed information on custom item renderers, see “MX item renderers and item editors” on page 1006

The following example sets the `itemRenderer` property to an MXML component named FancyCellRenderer. It also sets the `variableRowHeight` property to `true` because the MXML component exceeds the default row height:

```
<mx:List id="myList1" dataProvider="{myDP}"
    width="220" height="200"
    itemRenderer="FancyItemRenderer"
    variableRowHeight="true"/>
```

Specifying an icon to the List control

You can specify an icon to display with each List item, as the following example shows:

```
<?xml version="1.0"?>
<!-- dpcontrols/ListIcon.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Script>
        <![CDATA[
            [Embed(source="assets/radioIcon.jpg")]
            public var iconSymbol1:Class;
            [Embed(source="assets/topIcon.jpg")]
            public var iconSymbol2:Class;
        ]]>
    </fx:Script>
   <mx:List iconField="myIcon">
      <mx:dataProvider>
         <fx:Array>
            <fx:Object label="AL" data="Montgomery" myIcon="iconSymbol1"/>
            <fx:Object label="AK" data="Juneau" myIcon="iconSymbol2"/>
            <fx:Object label="AR" data="Little Rock" myIcon="iconSymbol1"/>
         </fx:Array>
      </mx:dataProvider>
   </mx:List>
</s:Application>
```

In this example, you use the `iconField` property to specify the field of each item containing the icon. You use the `Embed` metadata to import the icons, and then reference them in the List control definition.

You can also use the `iconFunction` property to specify a function that determines the icon, similar to the way that you can use the `labelFunction` property to specify a function that determines the label text. The icon function must have the following signature:

```
iconFunction(item:Object):Class
```

The *`item`* parameter passed in by the List control contains the list item object. The function must return the icon class to display in the List control.

The following example shows a List control that uses the `iconFunction` property to determine the icon to display for each item in the list:

```
<?xml version="1.0"?>
<!-- dpcontrols/ListIconFunction.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Script>
        <![CDATA[
            // Embed icons.
            [Embed(source="assets/radioIcon.jpg")]
            public var pavementSymbol:Class;
            [Embed(source="assets/topIcon.jpg")]
            public var normalSymbol:Class;

            // Define data provider.
            private var myDP: Array;
            private function initList():void {
                myDP = [
                    {Artist:'Pavement', Album:'Slanted and Enchanted', Price:11.99},
                    {Artist:'Pavarotti', Album:'Twilight', Price:11.99},
                    {Artist:'Other', Album:'Other', Price:5.99}];

                list1.dataProvider = myDP;
            }

            // Determine icon based on artist. Pavement gets a special icon.
            private function myiconfunction(item:Object):Class {
                var type:String = item.Artist;
                if (type == "Pavement") {
                    return pavementSymbol;
                }
                return normalSymbol;
            }
        ]]>
    </fx:Script>

    <mx:VBox >
        <mx:List id="list1"
            initialize="initList();"
            labelField="Artist"
            iconFunction="myiconfunction" />
    </mx:VBox>
</s:Application>
```

List control user interaction

The user clicks individual list items to select them, and holds down the Control and Shift keys while clicking to select multiple items. (You must set the `allowMultipleSelection` property to `true` to allow multiple selection.)

All mouse or keyboard selections broadcast a `change` event. For mouse interactions, the List control broadcasts this event when the mouse button is released.

If you set the `allowDragSelection` property to `true`, the control scrolls up or down when the user presses the mouse button over the one or more rows, holds the mouse button down, drags the mouse outside the control, and then moves the mouse up and down.

A List control shows the number of records that fit in the display. Paging down through the data displayed by a 10-line List control shows records 0-10, 9-18, 18-27, and so on, with one line overlapping from one page to the next.

The List control has the following keyboard navigation features:

Key	Action
Up Arrow	Moves selection up one item.
Down Arrow	Moves selection down one item.
Page Up	Moves selection up one page.
Page Down	Moves selection down one page.
Home	Moves selection to the top of the list.
End	Moves selection to the bottom of the list.
Alphanumeric keys	Jumps to the next item with a label that begins with the character typed.
Control	Toggle key. Allows for multiple (noncontiguous) selection and deselection. Works with key presses, click selection, and drag selection.
Shift	Contiguous selection key. Allows for contiguous selections. Works with key presses, click selection, and drag selection.

MX HorizontalList control

The HorizontalList control displays a horizontal list of items. The HorizontalList control is particularly useful in combination with a custom item renderer for displaying a list of images and other data. For more information about custom item renderers, see "MX item renderers and item editors" on page 1006.

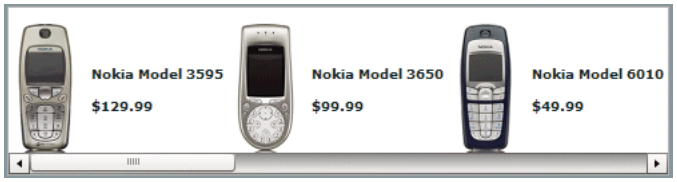
For complete reference information, see HorizontalList in the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

About HorizontaList controls

The contents of a HorizontalList control can look very similar to the contents of an HBox container in which a Repeater object repeats components. However, performance of a HorizontalList control can be better than the combination of an HBox container and a Repeater object because the HorizontalList control only instantiates the objects that fit in its display area. Scrolling in a HorizontalList can be slower than it is when using a Repeater object. For more information about the Repeater object, see "Dynamically repeating controls and containers" on page 867.

The HorizontalList control always displays items from left to right. The control usually contains a horizontal scroll bar, which lets users access all items in the list. An optional vertical scroll bar lets users view items when the full height of the list items is unlikely to fit. The user can select one or more items from the list, depending on the value of the `allowMultipleSelection` property.

The following image shows a HorizontalList control:



For complete reference information, see HorizontalList in the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Creating a HorizontalList control

You use the `<mx:HorizontalList>` tag to define a HorizontalList control. Specify an `id` value if you intend to refer to a component elsewhere in your MXML, either in another tag or in an ActionScript block.

The HorizontalList control shares many properties and methods with the List control; see “MX List control” on page 943 for information on how to use several of these shared properties. The HorizontalList control uses a list-based data provider. For more information, see “Data providers and collections” on page 898.

You specify the data for a HorizontalList control by using the `dataProvider` property of the `<mx:HorizontalList>` tag, as the following example shows:

```
<?xml version="1.0"?>
<!-- dpcontrols/HListDataProvider.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    width="450">

    <fx:Script>
        <![CDATA[
            import mx.collections.*;
            import mx.controls.Image;
            private var catalog:ArrayList;
            private static var cat:Array = [
                "../assets/Nokia_6820.gif", "../assets/Nokia_3595.gif",
                "../assets/Nokia_3650.gif", "../assets/Nokia_6010.gif"
            ];
            /* Initialize the HorizontalList control by setting its dataProvider
                property to an ArrayList containing the items parameter. */
            private function initCatalog(items:Array):void {
                catalog = new ArrayList(items);
                myList.dataProvider = catalog;
            }
        ]]>
    </fx:Script>
    <!-- A four-column HorizontalList. The itemRenderer is a Flex Image control.
       When the control is created, pass the cat array to the initialization routine. -->
    <mx:HorizontalList id="myList"
        columnWidth="100"
        rowHeight="100"
        columnCount="4"
        itemRenderer="mx.controls.Image"
        creationComplete="initCatalog(cat);"/>
</s:Application>
```

In this example, you use the `creationComplete` event to populate the data provider with an ArrayList of image files, and the `itemRenderer` property to specify the Image control as the item renderer. (Note that you use the full package name of the control in the assignment because the code does not import the mx.controls package.) The HorizontalList control then displays the four images specified by the data provider.

HorizontalList control user interaction

The user clicks individual list items to select them, and holds down the Control and Shift keys while clicking to select multiple items.

All mouse or keyboard selections broadcast a `change` event. For mouse interactions, the HorizontalList control broadcasts this event when the mouse button is released. When the user drags the mouse over the items and then outside the control, the control scrolls up or down.

A HorizontalList control shows the number of records that fit in the display. Paging through a four list shows records 0-4, 5-8, and so on, with no overlap from one page to the next.

Keyboard navigation

The HorizontalList control has the following keyboard navigation features:

Key	Action
Page Up	Moves selection to the left one page.
Left Arrow	Moves selection to the left one item.
Down Arrow	Moves selection right one item.
Page Down	Moves selection to the right one page.
Home	Moves selection to the beginning of the list.
End	Moves selection to the end of the list.
Control	Toggle key. Allows for multiple (noncontiguous) selection and deselection when the `allowMultipleSelection` property is set to `true`. Works with key presses, click selection, and drag selection.
Shift	Contiguous selection key. Allows for contiguous selections when `allowMultipleSelection` is set to `true`. Works with key presses, click selection, and drag selection.

MX TileList control

The TileList control displays a tiled list of items. The items are tiled in vertical columns or horizontal rows. The TileList control is particularly useful in combination with a custom item renderer for displaying a list of images and other data. The default item renderer for the TileList control is TileListItemRenderer, which, by default, displays text of the data provider's label field and any icon. For more information about custom item renderers, see "MX item renderers and item editors" on page 1006.

Flex also includes the Spark Tile layout. When possible, Adobe recommends that you use the Spark Tile layout with the Spark List control. For more information, see "Spark List control" on page 525.

For complete reference information, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

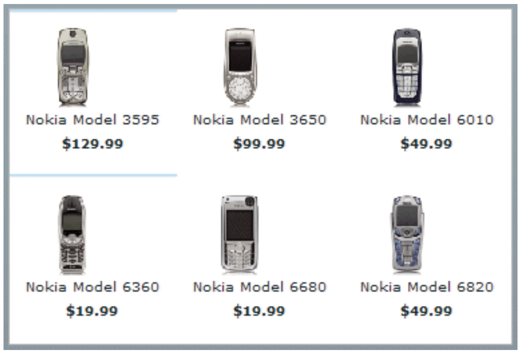
About the TileList control

The contents of a TileList control can look very similar to the contents of a Tile container in which a Repeater object repeats components. However, performance of a TileList control can be better than the combination of a Tile container and a Repeater object because the TileList control only instantiates the objects that fit in its display area. Scrolling in a TileList can be slower than it is when using a Repeater object. For more information about the Repeater object, see "Dynamically repeating controls and containers" on page 867.

The TileList control displays a number of items laid out in equally sized tiles. It often contains a scroll bar on one of its axes to access all items in the list depending on the direction orientation of the list. The user can select one or more items from the list depending on the value of the `allowMultipleSelection` property.

The TileList control lays out its children in one or more vertical columns or horizontal rows, starting new rows or columns as necessary. The direction property determines the primary direction of the layout. The valid values for the direction property are and horizontal (default) and vertical for a layout. In a horizontal layout the tiles are filled in row by row with each row filling the available space in the control. If there are more tiles than fit in the display area, the horizontal control has a vertical scroll. In a vertical layout, the tiles are filled in column by column in the available vertical space, and the control may have a horizontal scroll bar.

The following image shows a TileList control:



Creating a TileList control

You use the <mx:TileList> tag to define a TileList control. Specify an id value if you intend to refer to a component elsewhere in your MXML, either in another tag or in an ActionScript block.

The TileList control shares many properties and methods with the List control; see “MX List control” on page 943 for information on how to use several of these shared properties. The TileList control uses a list-based data provider. For more information, see “Data providers and collections” on page 898.

You specify the data for a TileList control by using the dataProvider property of the <mx:TileList> tag, as the following example shows:

```
<?xml version="1.0"?>
<!-- dpcontrols/TileListDataProvider.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    initialize="initData();" >

    <fx:Script>
        <![CDATA[
            import mx.controls.Button;
            import mx.collections.*;

            private var listArray:Array=[
                {label: "item0", data: 0},{label: "item1", data: 1},
                {label: "item2", data: 2},{label: "item3", data: 3},
                {label: "item4", data: 4},{label: "item5", data: 5},
                {label: "item6", data: 6},{label: "item7", data: 7},
                {label: "item8", data: 8}];

            [Bindable]
            public var TileListdp:ArrayList;

            private function initData():void {
                TileListdp = new ArrayList(listArray);
            }
        ]]>
    </fx:Script>
   <mx:TileList dataProvider="{TileListdp}"
      itemRenderer="mx.controls.Button"/>
</s:Application>
```

In this example, you populate the data provider with an ArrayList that contains an Array of strings defining labels and data values. You then use the `itemRenderer` property to specify a Button control as the item renderer. The Button controls display the data provider label values. The TileList control displays nine Button controls with the specified labels.

TileList control user interaction

The user clicks individual list items to select them, and holds down the Control and Shift keys while clicking to select multiple items.

All mouse or keyboard selections broadcast a `change` event. For mouse interactions, the TileList control broadcasts this event when the mouse button is released. When the user drags the mouse over the items and then outside the control, the control scrolls up or down.

Keyboard navigation

The TileList control has the following keyboard navigation features:

Key	Action
Up Arrow	Moves selection up one item. If the control direction is `vertical`, and the current item is at the top of a column, moves to the last item in the previous column; motion stops at the first item in the first column.
Down Arrow	Moves selection down one item. If the control direction is `vertical`, and the current item is at the bottom of a column, moves to the first item in the next column; motion stops at the last item in the last column.
Right Arrow	Moves selection to the right one item. If the control direction is `horizontal`, and the current item is at the end of a row, moves to the first item in the next row; motion stops at the last item in the last column.
Left Arrow	Moves selection to the left one item. If the control direction is `horizontal`, and the current item is at the beginning of a row, moves to the last item in the previous row; motion stops at the first item in the first row.
Page Up	Moves selection up one page. For a single-page control, moves the selection to the beginning of the list.
Page Down	Moves selection down one page. For a single-page control, moves the selection to the end of the list.
Home	Moves selection to the beginning of the list.
End	Moves selection to the end of the list.
Control	Toggle key. Allows for multiple (noncontiguous) selection and deselection when `allowMultipleSelection` is set to `true`. Works with key presses, click selection, and drag selection.
Shift	Contiguous selection key. Allows for contiguous selections when `allowMultipleSelection` is set to `true`. Works with key presses, click selection, and drag selection.

MX ComboBox control

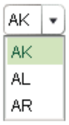
The ComboBox control is a drop-down list from which the user can select a single value. Its functionality is very similar to that of the SELECT form element in HTML.

Flex also includes the Spark ComboBox control. When possible, Adobe recommends that you use the Spark ComboBox control. For more information, see “Spark ComboBox control” on page 536.

For complete reference information, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

About the ComboBox control

The following image shows a ComboBox control:



In its editable state, the user can type text directly into the top of the list, or select one of the preset values from the list. In its noneditable state, as the user types a letter, the drop-down list opens and scrolls to the value that most closely matches the one being entered; matching is only performed on the first letter that the user types.

If the drop-down list hits the lower boundary of the application, it opens upward. If a list item is too long to fit in the horizontal display area, it is truncated to fit. If there are too many items to display in the drop-down list, a vertical scroll bar appears.

Creating a ComboBox control

You use the `<mx:ComboBox>` tag to define a ComboBox control in MXML. Specify an `id` value if you intend to refer to a component elsewhere in your MXML, either in another tag or in an ActionScript block.

The ComboBox control uses a list-based data provider. For more information, see "Data providers and collections" on page 898.

You specify the data for the ComboBox control by using the `dataProvider` property of the `<mx:ComboBox>` tag. The data provider should be a list or collection; the standard list implementation is the ArrayList class. The standard collection implementations are the ArrayCollection and XMLListCollection classes, for working with Array-based and XML-based data, respectively. You can also use a raw data object, such as an Array object, as a data provider; however, it is always better to specify a list or collection explicitly for data that could change. For more information on data providers and collections see "Data providers and collections" on page 898.

In a simple case for creating a ComboBox control, you specify the property by using an `dataProvider` child tag, and use an `<mx:ArrayList>` tag to define the entries as an ArrayList whose source is an Array of Strings, as the following example shows:

```
<?xml version="1.0"?>
<!-- dpcontrols/ComboBoxSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

   <mx:ComboBox>
      <mx:ArrayList>
         <fx:String>AK</fx:String>
         <fx:String>AL</fx:String>
         <fx:String>AR</fx:String>
      </mx:ArrayList>
   </mx:ComboBox>
</s:Application>
```

This example shows how you can take advantages of MXML defaults. You do not have to use an `dataProvider` tag, because `dataProvider` is the default property of the ComboBox control. Similarly, you do not have to use an `<mx:source>` tag inside the `<mx:ArrayList>` tag because `source` is the default property of the ArrayList class. Finally, you do not have to specify an `<fx:Array>` tag for the source array.

The data provider can also contain objects with multiple fields, as in the following example:

```
<?xml version="1.0"?>
<!-- dpcontrols/ComboBoxMultiple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

   <mx:ComboBox>
      <mx:ArrayList>
         <fx:Object label="AL" data="Montgomery"/>
         <fx:Object label="AK" data="Juneau"/>
         <fx:Object label="AR" data="Little Rock"/>
      </mx:ArrayList>
   </mx:ComboBox>
</s:Application>
```

If the data source is an array of strings, as in the first example, the ComboBox displays strings as the items in the drop-down list. If the data source consists of objects, the ComboBox, by default, uses the contents of the label field. You can, however, override this behavior, as described in "Specifying ComboBox labels" on page 959.

The index of items in the ComboBox control is zero-based, which means that values are 0, 1, 2, ... , *n* - 1, where *n* is the total number of items. The value of the item is its label text.

Using events with ComboBox controls

You typically use events to handle user interaction with a ComboBox control.

The ComboBox control broadcasts a `change` event (flash.events.Event class with a `type` property value of `flash.events.Event.CHANGE`) when the value of the control's `selectedIndex` or `selectedItem` property changes due to the following user actions:

- If the user closes the drop-down list by using a mouse click, Enter key, or Control+Up key, and the selected item is different from the previously selected item.
- If the drop-down list is currently closed, and the user presses the Up, Down, Page Up, or Page Down key to select a new item.
- If the ComboBox control is editable, and the user types into the control, Flex broadcasts a `change` event each time the text field of the control changes.

The ComboBox control broadcasts an mx.events.DropdownEvent with a type `mx.events.DropdownEvent.OPEN` (open`)` and `mx.events.DropdownEvent.CLOSE` (close) when the ComboBox control opens and closes. For detailed information on these and other ComboBox events, see ComboBox in the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

The following example displays information from ComboBox events:

```
<?xml version="1.0"?>
<!-- dpcontrols/ComboBoxEvent.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            import flash.events.Event;
            import mx.events.DropdownEvent;
            // Display the type of event for open and close events.
            private function dropEvt(event:DropdownEvent):void {
                forChange.text+=event.type + "\n";
            }
            // Display a selected item's label field and index for change events.
            private function changeEvt(event:Event):void {
                forChange.text+=event.currentTarget.selectedItem.label + " " +
                event.currentTarget.selectedIndex + "\n";
            }
        ]]>
    </fx:Script>
    <mx:ComboBox open="dropEvt(event)" close="dropEvt(event)"
        change="changeEvt(event)" >
        <mx:ArrayList>
            <fx:Object label="AL" data="Montgomery"/>
            <fx:Object label="AK" data="Juneau"/>
            <fx:Object label="AR" data="Little Rock"/>
        </mx:ArrayList>
    </mx:ComboBox>
    <mx:TextArea id="forChange" width="150" height="150"/>
</s:Application>
```

If you populate the ComboBox control with an Array of Strings, the `currentTarget.selectedItem` field contains a String. If you populate it with an Array of Objects, the `currentTarget.selectedItem` field contains the Object that corresponds to the selected item, so, in this case, `currentTarget.selectedItem.label` refers to the selected item object's label field.

In this example, you use two properties of the ComboBox control, `selectedItem` and `selectedIndex`, in the event handlers. Every `change` event updates the TextArea control with the label of the selected item and the item's index in the control, and every `open` or `close` event appends the event type.

Specifying ComboBox labels

If the ComboBox data source is an array of strings, the control displays the string for each item. If the data source is contains Objects, by default, the ComboBox control expects each object to contain a property named `label` that defines the text that appears in the ComboBox control for the item. If each Object does not contain a `label` property, you can use the `labelField` property of the ComboBox control to specify the property name, as the following example shows:

```
    <mx:ComboBox open="dropEvt(event)" close="dropEvt(event)"
            change="changeEvt(event)" labelField="state">
        <mx:ArrayList>
            <fx:Object state="AL" capital="Montgomery"/>
            <fx:Object state="AK" capital="Juneau"/>
            <fx:Object state="AR" capital="Little Rock"/>
        </mx:ArrayList>
    </mx:ComboBox>
```

To make the event handler in the section “Using events with ComboBox controls” on page 958display the state ID and capital, you would modify the `change` event handler to use a property named `state`, as the following example shows:

```
        private function changeEvt(event) {
            forChange.text=event.currentTarget.selectedItem.state + " " +
            event.currentTarget.selectedItem.capital + " " +
            event.currentTarget.selectedIndex;
        }
```

You can also specify the ComboBox labels by using a label function, as described in “Using a label function” on page 945.

Populating a ComboBox control by using variables and models

Flex lets you populate the data provider of a ComboBox control from an ActionScript variable definition or from a Flex data model. Each element of the data provider must contain a string label, and can contain one or more fields with additional data. The following example populates two ComboBox controls; one from an ArrayList variable that it populates directly from an Array, the other from an ArrayList that it populates from an array of items in an `<fx:Model>` tag.

```
<?xml version="1.0"?>
<!-- dpcontrols/ComboBoxVariables.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    initialize="initData();">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import mx.collections.*
            private var COLOR_ARRAY:Array=
                [{label:"Red", data:"#FF0000"},
                {label:"Green", data:"#00FF00"},
                {label:"Blue", data:"#0000FF"}];
            // Declare an ArrayList variable for the colors.
            // Make it Bindable so it can be used in bind
            // expressions ({colorAL}).
            [Bindable]
            public var colorAL:ArrayList;
            // Initialize colorAL ArrayList variable from the Array.
            // Use an initialize event handler to initialize data variables
            // that do not rely on components, so that the initial values are
            // available when the controls that use them are constructed.
            //See the mx:ArrayList tag, below, for a second way to
            //initialize an ArrayList.
            private function initData():void {
                colorAL=new ArrayList(COLOR_ARRAY);
            }
        ]]>
    </fx:Script>
    <fx:Declarations>
        <!-- This example shows two different ways to
            structure a Model. -->
        <fx:Model id="myDP">
            <obj>
                <item label="AL" data="Montgomery"/>
                <item>
                    <label>AK</label>
                    <data>Juneau</data>
                </item>
                <item>
                    <label>AR</label>
                    <data>Little Rock</data>
                </item>
            </obj>
        </fx:Model>

       <!-- Create a stateAL ArrayList that uses as its source an Array of
             the item elements from the myDP model.
             This technique and the declaration and initialization code used for
             the colorAL variable are alternative methods of creating and
             initializing the ArrayList. -->
       <mx:ArrayList id="stateAL" source="{myDP.item}"/>
    </fx:Declarations>
   <mx:ComboBox dataProvider="{colorAL}"/>
   <mx:ComboBox dataProvider="{stateAL}"/>
</s:Application>
```

This example uses a simple model. However, you can populate the model from an external data source or define a custom data model class in ActionScript. For more information on using data models, see "Storing data" on page 889.

You can use remote data providers to supply data to your ComboBox control. For example, when a web service operation returns an Array of strings, you can use the following format to display each string as a row of a ComboBox control:

```
<mx:ArrayCollection id="resultAC"
    source="mx.utils.ArrayUtil.toArray(service.operation.lastResult);"
<mx:ComboBox dataProvider="{resultAC}" />
```

In general, you should use an ArrayCollection for web service operations. An ArrayList is not usually compatible with the results. For more information on using remote data providers, see "Remote data in data provider components" on page 939.

ComboBox control user interaction

A ComboBox control can be noneditable or editable, as specified by the Boolean `editable` property. In a noneditable ComboBox control, a user can make a single selection from a drop-down list. In an editable ComboBox control, the portion button of the control is a text field that the user can enter text directly into or can populate by selecting an item from the drop-down list. When the user makes a selection in the ComboBox control list, the label of the selection is copied to the text field at the top of the ComboBox control.

When a ComboBox control (and not the drop-down box) has focus and is editable, all keystrokes go to the text field and are handled according to the rules of the TextInput control (see “MX TextInput control” on page 825), with the exception of the Control+Down key combination, which opens the drop-down list. When the drop-down list is open, you can use the Up and Down keys to navigate in the list and the Enter key to select an item from the list.

When a ComboBox control has focus and is noneditable, alphanumeric keystrokes move the selection up and down the data provider to the next item with the same first character and display the label in the text field. If the drop-down list is open, the visible selection moves to the selected item.

You can also use the following keys to control a noneditable ComboBox control when the drop-down list is not open:

Key	Description
Control+Down	Opens the drop-down list and gives it focus.
Down	Moves the selection down one item.
End	Moves the selection to the bottom of the collection.
Home	Moves the selection to the top of the collection.
Page Down	Displays the item that would be at the end bottom of the drop-down list. If the current selection is a multiple of the `rowCount` value, displays the item that `rowCount` -1 down the list, or the last item. If the current selection is the last item in the data provider, does nothing.
Page Up	Displays the item that would be at the top of the drop-down. If the current selection is a multiple of the `rowCount` value, displays the item that `rowCount` -1 up the list, or the first item. If the current selection is the first item in the data provider, does nothing.
Up	Moves the selection up one item.

When the drop-down list of a noneditable ComboBox control has focus, alphanumeric keystrokes move the selection up and down the drop-down list to the next item with the same first character. You can also use the following keys to control a drop-down list when it is open:

Key	Description
Control+Up	Closes the drop-down list and returns focus to the ComboBox control.
Down	Moves the selection down one item.
End	Moves the selection to the bottom of the collection.
Enter	Closes the drop-down list and returns focus to the ComboBox control.
Escape	Closes the drop-down list and returns focus to the ComboBox control.
Home	Moves the selection to the top of the collection.
Page Down	Moves to the bottom of the visible list. If the current selection is at the bottom of the list, moves the current selection to the top of the displayed list and displays the next `rowCount`-1 items, if any. If there current selection is the last item in the data provider, does nothing.
Page Up	Moves to the top of the visible list. If the current selection is at the top of the list, moves the current selection to the bottom of the displayed list and displays the previous `rowCount`-1 items, if any. If the current selection is the first item in the data provider, does nothing.
Shift+Tab	Closes the drop-down list and moves the focus to the previous object in the DisplayList.
Tab	Closes the drop-down list and moves the focus to the next object in the DisplayList.
Up	Moves the selection up one item.

MX DataGrid control

The DataGrid control is a list that can display more than one column of data. It is a formatted table of data that lets you set editable table cells, and is the foundation of many data-driven applications.

For information on the following topics, which are often important for creating advanced data grid controls, see:

- How to format the information in each DataGrid cell and control how users enter data in the cells; see “MX item renderers and item editors” on page 1006.
- How to drag objects to and from the data grid; see “Drag and drop” on page 1893.

Flex also includes the Spark DataGrid control. When possible, Adobe recommends that you use the Spark DataGrid control. For more information, see “Spark DataGrid and Grid controls” on page 545.

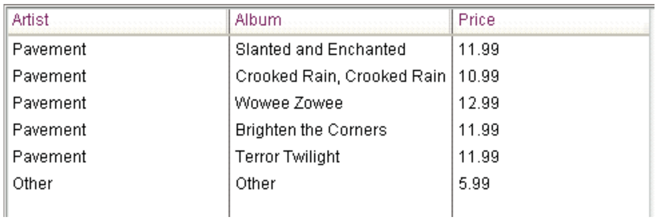
For complete reference information, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

About the MX DataGrid control

The DataGrid control provides the following features:

- Resizable, sortable, and customizable column layouts, including hidable columns
- Optional customizable column and row headers, including optionally wrapping header text
- Columns that the user can resize and reorder at run time
- Selection events
- Ability to use a custom item renderer for any column
- Support for paging through data
- Locked rows and columns that do not scroll

The following image shows a DataGrid control:



Artist	Album	Price
Pavement	Slanted and Enchanted	11.99
Pavement	Crooked Rain, Crooked Rain	10.99
Pavement	Wowee Zowee	12.99
Pavement	Brighten the Corners	11.99
Pavement	Terror Twilight	11.99
Other	Other	5.99

Rows are responsible for rendering items. Each row is laid out vertically below the previous one. Columns are responsible for maintaining the state of each visual column; columns control width, color, and size.

Creating an MX DataGrid control

You use the `<mx:DataGrid>` tag to define a DataGrid control in MXML. Specify an `id` value if you intend to refer to a component elsewhere in your MXML, either in another tag or in an ActionScript block.

The DataGrid control uses a list-based data provider. For more information, see “Data providers and collections” on page 898.

You specify the data for the DataGrid control by using the `dataProvider` property. You can specify data in several different ways. In the simplest case for creating a DataGrid control, you use the `dataProvider` property subtag with `<mx:ArrayList>`, and `<fx:Object>` tags to define the entries as an ArrayList of Objects. Each Object defines a row of the DataGrid control, and properties of the Object define the column entries for the row, as the following example shows:

```
<?xml version="1.0"?>
<!-- dpcontrols/DataGridSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

   <mx:DataGrid>
      <mx:ArrayList>
         <fx:Object>
            <fx:Artist>Pavement</fx:Artist>
            <fx:Price>11.99</fx:Price>
            <fx:Album>Slanted and Enchanted</fx:Album>
         </fx:Object>
         <fx:Object>
            <fx:Artist>Pavement</fx:Artist>
            <fx:Album>Brighten the Corners</fx:Album>
            <fx:Price>11.99</fx:Price>
         </fx:Object>
      </mx:ArrayList>
   </mx:DataGrid>
</s:Application>
```

This example shows how you can take advantages of MXML defaults. You do not have to use an `dataProvider` tag, because `dataProvider` is the default property of the DataGrid control. Similarly, you do not have to use an `<mx:source>` tag inside the `<mx:ArrayList>` tag because `source` is the default property of the ArrayList class. Finally, you do not have to specify an `<fx:Array>` tag for the source array.

You can also define the objects by using properties directly in the Object tags, as the following example shows:

```
<?xml version="1.0"?>
<!-- dpcontrols/DataGridSimpleAttributes.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

   <mx:DataGrid>
      <mx:ArrayList>
         <fx:Object Artist="Pavement"
            Album="Slanted and Enchanted" Price="11.99" />
         <fx:Object Artist="Pavement"
            Album="Brighten the Corners" Price="11.99" />
      </mx:ArrayList>
   </mx:DataGrid>
</s:Application>
```

The column names displayed in the DataGrid control are the property names of the Array Objects. By default, the columns are in alphabetical order by the property names. Different Objects can define their properties in differing orders. If an Array Object omits a property, the DataGrid control displays an empty cell in that row.

Specifying columns

Each column in a DataGrid control is represented by a DataGridColumn object. You use the `columns` property of the DataGrid control and the `<mx:DataGridColumn>` tag to select the DataGrid columns, specify the order in which to display them, and set additional properties. You can also use the DataGridColumn class `visible` property to hide and redisplay columns, as described in the next section.

For complete reference information for the `<mx:DataGridColumn>` tag, see DataGridColumn in the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

You specify an Array element to the `<mx:columns>` child tag of the `<mx:DataGrid>` tag, as the following example shows:

```
<?xml version="1.0"?>
<!-- dpcontrols/DataGridSpecifyColumns.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

   <mx:DataGrid>
      <mx:ArrayList>
         <fx:Object Artist="Pavement" Price="11.99"
            Album="Slanted and Enchanted" />
         <fx:Object Artist="Pavement"
            Album="Brighten the Corners" Price="11.99" />
      </mx:ArrayList>
      <mx:columns>
         <mx:DataGridColumn dataField="Album" />
         <mx:DataGridColumn dataField="Price" />
      </mx:columns>
   </mx:DataGrid>
</s:Application>
```

In this example, you only display the Album and Price columns in the DataGrid control. You can reorder the columns as well, as the following example shows:

```
<mx:columns>
    <mx:DataGridColumn dataField="Price" />
    <mx:DataGridColumn dataField="Album" />
</mx:columns>
```

In this example, you specify that the Price column is the first column in the DataGrid control, and that the Album column is the second.

You can also use the `<mx:DataGridColumn>` tag to set other options. The following example uses the `headerText` property to set the name of the column to a value different than the default name of Album, and uses the `width` property to set the album name column wide enough to display the full album names:

```
<mx:columns>
    <mx:DataGridColumn dataField="Album" width="200" />
    <mx:DataGridColumn dataField="Price" headerText="List Price" />
</mx:columns>
```

Hiding and displaying columns

If you might display a column at some times, but not at others, you can specify the DataGridColumn class `visible` property to hide or show the column. The following example lets you hide or show the album price by clicking a button:

```
<?xml version="1.0"?>
<!-- dpcontrols/DataGridVisibleColumn.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

   <mx:DataGrid id="myDG" width="350">
      <mx:ArrayList>
          <mx:source>
              <fx:Object Artist="Pavement" Price="11.99"
                  Album="Slanted and Enchanted" />
              <fx:Object Artist="Pavement"
                  Album="Brighten the Corners" Price="11.99" />
          </mx:source>
      </mx:ArrayList>
      <mx:columns>
         <mx:DataGridColumn dataField="Artist" />
         <mx:DataGridColumn dataField="Album" />
         <mx:DataGridColumn id="price" dataField="Price" visible="false"/>
      </mx:columns>
   </mx:DataGrid>
   <!-- The column id property specifies the column to show.-->
   <mx:Button label="Toggle Price Column"
      click="price.visible = !price.visible;" />
</s:Application>
```

Passing data to an MX DataGrid control

Flex lets you populate a DataGrid control from an ActionScript variable definition or from a Flex data model. The following example populates a DataGrid control by using a variable:

```
<?xml version="1.0"?>
<!-- dpcontrols/DataGridPassData.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
   initialize="initData();">

    <fx:Script>
        <![CDATA[
            import mx.collections.*;
            private var DGArray:Array = [
                {Artist:'Pavement', Album:'Slanted and Enchanted', Price:11.99},
                {Artist:'Pavement', Album:'Brighten the Corners', Price:11.99}];

            [Bindable]
            public var initDG:ArrayList;
            //Initialize initDG ArrayList variable from the Array.
            //If you use this technique to process an HTTPService,
            //WebService, or RemoteObject result, use an ArrayCollection
            //rather than an ArrayList.
            public function initData():void {
                initDG=new ArrayList(DGArray);
            }
        ]]>
    </fx:Script>
    <mx:DataGrid id="myGrid" width="350" height="200"
        dataProvider="{initDG}" >
        <mx:columns>
            <mx:DataGridColumn dataField="Album" />
            <mx:DataGridColumn dataField="Price" />
        </mx:columns>
    </mx:DataGrid>
</s:Application>
```

In this example, you bind the variable `initDG` to the `<mx:dataProvider>` property. You can still specify a column definition event when using data binding. For a description of using a model as a data provider, see “Populating a ComboBox control by using variables and models” on page 960

Handling events in an MX DataGrid control

The DataGrid control and the DataGridEvent class define several event types that let you respond to user interaction. For example, Flex broadcasts mx.events.ListEvent class event with a `type` property value of `mx.events.ListEvent.ITEM_CLICK` ("itemClick") when a user clicks an item in a DataGrid control. You can handle this event as the following example shows:

```
<?xml version="1.0"?>
<!-- dpcontrols/DataGridEvents.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            import mx.events.ListEvent;
            private function itemClickEvent(event:ListEvent):void {
                clickColumn.text=String(event.columnIndex);
                clickRow.text=String(event.rowIndex);
                eventType.text=event.type;
            }
        ]]>
    </fx:Script>

    <mx:DataGrid id="myGrid" width="350" height="150"
        itemClick="itemClickEvent(event);">
        <mx:ArrayList>
            <fx:Object Artist="Pavement" Price="11.99"
                Album="Slanted and Enchanted" />
            <fx:Object Artist="Pavement" Album="Brighten the Corners"
                Price="11.99" />
        </mx:ArrayList>
    </mx:DataGrid>
    <s:Form>
        <s:FormItem label="Column Index:">
            <s:Label id="clickColumn"/>
        </s:FormItem>
        <s:FormItem label="Row Index:">
            <s:Label id="clickRow"/>
        </s:FormItem>
        <s:FormItem label="Type:">
            <s:Label id="eventType"/>
        </s:FormItem>
    </s:Form>
</s:Application>
```

In this example, you use the event handler to display the column index, row index, and event type in three TextArea controls.

The index of columns in the DataGrid control is zero-based, meaning values are 0, 1, 2, ... , *n* - 1, where *n* is the total number of columns. Row items are also indexed starting at 0. Therefore, if you select the first item in the second row, this example displays 0 in the TextArea for the column index, and 1 in the TextArea for the row index.

To access the selected item in the event handler, you can use the `currentTarget` property of the event object, and the `selectedItem` property of the DataGrid control, as the following code shows:

```
var selectedArtist:String=event.currentTarget.selectedItem.Artist;
```

The `currentTarget` property of the object passed to the event handler contains a reference to the DataGrid control. You can reference any control property by using `currentTarget` followed by a period and the property name. The `currentTarget.selectedItem` field contains the selected item.

Sorting data in an MX DataGrid control

The DataGrid control supports displaying sorted data in two ways:

- By default, the control displays data in the sorted order of its underlying data provider collection. Therefore you can use the collection Sort and SortField classes to control the order of the rows.
- By default, users can sort the display by clicking the column headers. Clicking the column header initially sorts the display in descending order of the entries in the selected column, and clicking the header again reverses the sort order. You can disable sorting an entire DataGrid Control or individual columns.

  For detailed information on using the Sort and SortField classes, see "Sorting and filtering data for viewing" on page 912.

Determining the initial DataGrid sort order

To specify the initial DataGrid sort order, you sort the data provider. While a number of approaches can work, the following technique takes best advantage of the built in features of Flex collections:

- Use an object that implements the ICollectionView interface, such as an ArrayCollection, in the `dataProvider` property of your DataGrid. Specify a Sort object in the data provider object's the `sort` field. Note that you cannot use an ArrayList with a sort field.
- Use the Sort object to control the order of the rows in the `dataProvider` object.

Controlling user sorting of DataGrid displays

The following DataGrid and DataGridColumn properties control how users can sort data:

- The DataGrid `sortableColumns` property is a global switch that enables user sorting of the DataGrid display by clicking column headings. The default this property is `true`.
- The DataGridColumn`sortable` property specifies whether users can sort an individual column. The default this property is `true`.
- The DataGridColumn `sortCompareFunction` property lets you specify a custom comparison function. This property sets the `compare` property of the default SortField class object that the DataGrid uses to sort the grid when users click the headers. It lets you specify the function that compares two objects and determines which would be higher in the sort order, without requiring you to explicitly create a Sort object on your data provider. For detailed information on the comparison function signature and behavior, see sortCompareFunction in the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

  By default, the DataGrid class uses its own sort code to control how the data gets sorted when the user clicks a column. To override this behavior, you create a `headerRelease` event handler to handle the DataGridEvent event that is generated when the user clicks the column header. This event handler must do the following:

  1. Use the event object's `columnIndex` property to determine the clicked column.
  2. Create an MX Sort object with a set of MX SortField objects based on the clicked column and any other rules that you need to control the sorting order. For more information on using Sort objects, see "Sorting and filtering data for viewing" on page 912.
  3. Apply the Sort object to the collection assigned as the data provider.
  4. Call the DataGridEvent class event object's `preventDefault()` method to prevent the DataGrid from doing a default column sort.

     ***Note:** If you specify a* `labelFunction` *property, you must also specify a* `sortCompareFunction` *function. The Computed Columns example in Flex Explorer shows this use.*

The following example shows how to use the headerRelease event handler to do multi-column sorting when a user clicks a DataGrid column header.

Example: Sorting a DataGrid on multiple columns

The following example shows how you can use a collection with a Sort object to determine an initial multi-column sort and to control how the columns sort when you click the headers. The data grid is initially sorted by in-stock status first, artist second, and album name, third. If you click any heading, that column becomes the primary sort criterion, the previous primary criterion becomes the second criterion, and the previous secondary criterion becomes the third criterion.

```
<?xml version="1.0"?>
<!-- dpcontrols/DataGridSort.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    initialize="initDP();"
    width="550" height="400">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            import mx.events.DataGridEvent;
            import mx.collections.*;

            // Declare storage variables and initialize the simple variables.
            // The data provider collection.
            private var myDPColl:ArrayCollection;
            // The Sort object used to sort the collection.
            [Bindable]
            private var sortA:Sort;

            // The sort fields used to determine the sort.
            private var sortByInStock:SortField;
            private var sortByArtist:SortField;
            private var sortByAlbum:SortField;
            private var sortByPrice:SortField;
            // The data source that populates the collection.
            private var myDP:Array = [
                {Artist:'Pavement', Album:'Slanted and Enchanted',
                    Price:11.99, InStock: true},
                {Artist:'Pavement', Album:'Crooked Rain, Crooked Rain',
                    Price:10.99, InStock: false},
                {Artist:'Pavement', Album:'Wowee Zowee',
                    Price:12.99, InStock: true},
                {Artist:'Asphalt', Album:'Brighten the Corners',
                    Price:11.99, InStock: false},
                {Artist:'Asphalt', Album:'Terror Twilight',
                    Price:11.99, InStock: true},
                {Artist:'Asphalt', Album:'Buildings Meet the Sky',
                    Price:14.99, InStock: true},
                {Artist:'Other', Album:'Other',
                    Price:5.99, InStock: true}
            ];
            //Initialize the DataGrid control with sorted data.
            private function initDP():void {
                //Create an ArrayCollection backed by the myDP array of data.
                myDPColl = new ArrayCollection(myDP);
                //Create a Sort object to sort the ArrrayCollection.
                sortA = new Sort();
                //Initialize SortField objects for all valid sort fields:
                // A true second parameter specifies a case-insensitive sort.
                // A true third parameter specifies descending sort order.
                // A true fourth parameter specifies a numeric sort.
                sortByInStock = new SortField("InStock", true, true);
                sortByArtist = new SortField("Artist", true);
                sortByAlbum = new SortField("Album", true);
                sortByPrice = new SortField("Price", true, false, true);
                // Sort the grid using the InStock, Artist, and Album fields.
                sortA.fields=[sortByInStock, sortByArtist, sortByAlbum];
                myDPColl.sort=sortA;
                // Refresh the collection view to show the sort.
                myDPColl.refresh();
                // Initial display of sort fields
                tSort0.text = "First Sort Field: InStock";
                tSort1.text = "Second Sort Field: Artist";
                tSort2.text = "Third Sort Field: Album";
                // Set the ArrayCollection as the DataGrid data provider.
                myGrid.dataProvider=myDPColl;
                // Set the DataGrid row count to the array length,
                // plus one for the header.
                myGrid.rowCount=myDPColl.length +1;
            }

            // Re-sort the DataGrid control when the user clicks a header.
            private function headRelEvt(event:DataGridEvent):void {
                // The new third priority was the old second priority.
                sortA.fields[2] = sortA.fields[1];
                tSort2.text = "Third Sort Field: " + sortA.fields[2].name;
                // The new second priority was the old first priority.
                sortA.fields[1] = sortA.fields[0];
                tSort1.text = "Second Sort Field: " + sortA.fields[1].name;
                // The clicked column determines the new first priority.
                if (event.columnIndex==0) {
                    sortA.fields[0] = sortByArtist;
                } else if (event.columnIndex==1) {
                    sortA.fields[0] = sortByAlbum;
                } else if (event.columnIndex==2) {
                    sortA.fields[0] = sortByPrice;
                } else {
                    sortA.fields[0] = sortByInStock;}
                tSort0.text = "First Sort Field: " + sortA.fields[0].name;
                // Apply the updated sort fields and re-sort.
                myDPColl.sort=sortA;
                // Refresh the collection to show the sort in the grid.
                myDPColl.refresh();
                // Prevent the DataGrid from doing a default column sort.
                event.preventDefault();
            }
        ]]>
    </fx:Script>
    <!-- The Data Grid control.
         By default the grid and its columns can be sorted by clicking.
         The headerRelease event handler overrides the default sort
         behavior. -->
    <mx:DataGrid id="myGrid" width="100%" headerRelease="headRelEvt(event);">
        <mx:columns>
            <mx:DataGridColumn minWidth="120" dataField="Artist" />
            <mx:DataGridColumn minWidth="200" dataField="Album" />
            <mx:DataGridColumn width="75" dataField="Price" />
            <mx:DataGridColumn width="75" dataField="InStock"
               headerText="In Stock"/>
        </mx:columns>
    </mx:DataGrid>
    <mx:VBox>
        <mx:Label id="tSort0" text="First Sort Field: "/>
        <mx:Label id="tSort1" text="Second Sort Field: "/>
        <mx:Label id="tSort2" text="Third Sort Field: "/>
    </mx:VBox>
</s:Application>
```

MX DataGrid control user interaction

The DataGrid control responds to mouse and keyboard activity. The response to a mouse click or key press depends on whether a cell is editable. A cell is editable when the `editable` properties of the DataGrid control and the DataGridColumn containing the cell are both `true`. Clicking within an editable cell directs focus to that cell. Clicking a noneditable cell has no effect on the focus.

Users can modify the DataGrid control appearance in the following ways:

- If the value of the `sortableColumns` property is `true`, the default value, clicking within a column header causes the DataGrid control to be sorted based on the column's cell values.
- If the value of the `draggableColumns` property is `true`, the default value, clicking and holding the mouse button within a column header, dragging horizontally, and releasing the mouse button moves the column to new location.
- If the value of the `resizableColumns` property is `true`, the default value, clicking in the area between columns permits column resizing.

Keyboard navigation

The DataGrid control has the following keyboard navigation features:

Key	Action
Enter Return Shift+Enter	When a cell is in editing state, commits change, and moves editing to the cell on the same column, next row down or up, depending on whether Shift is pressed.
Tab	Moves focus to the next editable cell, traversing the cells in row order. If at the end of the last row, advances to the next element in the parent container that can receive focus.
Shift+Tab	Moves focus to the previous editable cell. If at the beginning of a row, advances to the end of the previous row. If at the beginning of the first row, advances to the previous element in the parent container that can receive focus.
Up Arrow Home Page Up	If editing a cell, shifts the cursor to the beginning of the cell's text. If the cell is not editable, moves selection up one item.

Key	Action
Down Arrow End Page Down	If editing a cell, shifts the cursor to the end of the cell's text. If the cell is not editable, moves selection down one item.
Control	Toggle key. If you set the DataGrid control `allowMultipleSelection` property to `true`, allows for multiple (noncontiguous) selection and deselection. Works with key presses, click selection, and drag selection.
Shift	Contiguous select key. If you set the DataGrid control `allowMultipleSelection` property to `true`, allows for contiguous selections. Works with key presses, click selection, and drag selection.

MX Tree control

The Tree control lets a user view hierarchical data arranged as an expandable tree.

For complete reference information, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*. For information on hierarchical data providers, see "Hierarchical data objects" on page 927.

For information on the following topics, which are often important for using advanced Tree controls, see:

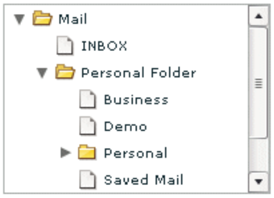
- How to format the information in each Tree node and control how users enter data in the nodes; see "MX item renderers and item editors" on page 1006.
- How to drag objects to and from the Tree control; see "Drag and drop" on page 1893.

About Tree controls

A Tree control is a hierarchical structure of *branch* and *leafnodes*. Each item in a tree is called a node and can be either a leaf or a branch. A branch node can contain leaf or branch nodes, or can be empty (have no children). A leaf node is an end point in the tree.

By default, a leaf is represented by a text label beside a file icon and a branch is represented by a text label beside a folder icon with a disclosure triangle that a user can open to expose children.

The following image shows a Tree control:



Creating a Tree control

You define a Tree control in MXML by using the `<mx:Tree>` tag. The Tree class extends the List class and Tree controls take all of the properties and methods of the List control. For more information about using the List control, see "MX List control" on page 943. Specify an `id` value if you intend to refer to a control elsewhere in your MXML, either in another tag or in an ActionScript block.

The Tree control normally gets its data from a hierarchical data provider, such as an XML structure. If the Tree represents dynamically changing data, you should use a list or collection, such as the standard ArrayCollection, or XMLListCollection object, as the data provider.

The Tree control uses a data descriptor to parse and manipulate the data provider content. By default, the Tree control uses a DefaultDataDescriptor instance, but you can create your own class and specify it in the Tree control's `dataDescriptor` property.

The DefaultDataDescriptor class supports the following types of data:

Collections A collection implementation, such as an XMLListCollection or ArrayCollection object. The DefaultDataDescriptor class includes code to handle collections efficiently. Always use a collection as the data provider if the data in the menu changes dynamically; otherwise the Tree control might display obsolete data.

XML A string containing valid XML text, or any of the following objects containing valid E4X format XML data: `<fx:XML>` or <fx:XMLList> compile-time tag, or an XML or XMLList object.

Other objects An array of items, or an object that contains an array of items, where a node's children are contained in an item named `children`.

The DefaultDataDescriptor class also supports using an `<fx:Model>` tag as a data provider for a menu, but all leaf nodes must have the name `children`; As a general rule, it is a better programming practice to use the `<fx:XML>` or `<fx:XMLList>` tags when you need a Tree data provider that uses binding.

For more information on hierarchical objects and data descriptors, including a detailed description of the formats supported by the DefaultDataDescriptor, see "Data descriptors and hierarchical data structure" on page 927.

The following code contains a single Tree control that defines the tree shown in the image in "MX Tree control" on page 973. This uses an XMLListCollection wrapper around an `<fx:XMLList>` tag. By using an XMLListCollection, you can modify the underlying XML data provider by changing the contents of the `MailBox` XMLListCollection, and the Tree control will represent the changes to the data. This example also does not use the `<mx:dataProvider>` tag because `dataProvider` is the default property of the Tree control.

```
<?xml version="1.0"?>
<!-- dpcontrols/TreeSimple.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

   <mx:Tree id="tree1"
       labelField="@label"
       showRoot="true"
       width="160">
      <mx:XMLListCollection id="MailBox">
         <fx:XMLList>
            <folder label="Mail">
               <folder label="INBOX"/>
               <folder label="Personal Folder">
                  <Pfolder label="Business" />
                  <Pfolder label="Demo" />
                     <Pfolder label="Personal" isBranch="true" />
                     <Pfolder label="Saved Mail" />
                  </folder>
                  <folder label="Sent" />
                  <folder label="Trash" />
            </folder>
         </fx:XMLList>
      </mx:XMLListCollection>
   </mx:Tree>
</s:Application>
```

The tags that represent tree nodes in the XML data can have any name. The Tree control reads the XML and builds the display hierarchy based on the nested relationship of the nodes. For information on valid XML structure, see "Hierarchical data objects" on page 927.

Some data providers have a single top level node, called a *root* node. Other data providers are lists of nodes and do not have a root node. In some cases, you might not want to display the root node as the Tree root. To prevent the tree from displaying the root node, specify the `showRoot` property to `false;` doing this does not affect the data provider contents, only the Tree display. You can only specify a `falseshowRoot` property for data providers that have roots, that is, XML and Object-based data providers.

A branch node can contain multiple child nodes, and, by default, appears as a folder icon with a disclosure triangle that lets users open and close the folder. Leaf nodes appear by default as file icons and cannot contain child nodes.

When a Tree control displays a node of a non-XML data provider, by default, it displays the value of the `label` property of the node as the text label. When you use an E4X XML-based data provider, however, you must specify the label field, even if the label is identified by an attribute named "label". To specify the label field, use the `labelField` property; for example, if the label field is the label attribute, specify `labelField="@label"`.

Handling Tree control events

You typically use events to respond to user interaction with a Tree control. Since the Tree control is derived from the List control, you can use all of the events defined for the List control. The Tree control also dispatches several Event and TreeEvent class events, including `Event.change` and `TreeEvent.itemOpen`. The following example defines event handlers for the `change` and `itemOpen` events:

```
<?xml version="1.0"?>
<!-- dpcontrols/TreeEvents.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

   <fx:Script>
      <![CDATA[
         import flash.events.*;
         import mx.events.*;
         import mx.controls.*;
         private function changeEvt(event:Event):void {
            var theData:String = ""
            if (event.currentTarget.selectedItem.@data) {
               theData = " Data: " + event.currentTarget.selectedItem.@data;
            }
            forChange.text = event.currentTarget.selectedItem.@label + theData;
         }
      private function itemOpenEvt(event:TreeEvent):void {
         forOpen.text = event.item.@label;
      }
   ]]>
   </fx:Script>
   <mx:Tree id="XMLTree1" width="150" height="170"
         labelField="@label" itemOpen="itemOpenEvt(event);"
         change="changeEvt(event);">
      <mx:XMLListCollection id="MailBox">
         <fx:XMLList>
```

```
            <node label="Mail" data="100">
               <node label="Inbox" data="70"/>
               <node label="Personal Folder" data="10">
                  <node label="Business" data="2"/>
                  <node label="Demo" data="3"/>
                  <node label="Personal" data="0" isBranch="true" />
                  <node label="Saved Mail" data="5" />
               </node>
               <node label="Sent" data="15"/>
               <node label="Trash" data="5"/>
            </node>
         </fx:XMLList>
      </mx:XMLListCollection>
   </mx:Tree>
    <s:Form>
        <s:FormItem label="Change Event:">
            <s:Label id="forChange" width="150"/>
        </s:FormItem>
        <s:FormItem label="Open Event:">
            <s:Label id="forOpen" width="150"/>
        </s:FormItem>
    </s:Form>
</s:Application>
```

In this example, you define event listeners for the `change` and `itemOpen` events. The Tree control broadcasts the `change` event when the user selects a tree item, and broadcasts the `itemOpen` event when a user opens a branch node. For each event, the event handler displays the label and the data property, if any, in a TextArea control.

Expanding a tree node

By default, the Tree control displays the root node or nodes of the tree when it first opens. If you want to expand a node of the tree when the tree opens, you can use the `expandItem()` method of the Tree control. The following change to the example in "Handling Tree control events" on page 975 calls the `expandItem()` method as part of the Tree control's `creationComplete` event listener to expand the root node of the tree:

```
<fx:Script>
    <![CDATA[
.
.
.
        private function initTree():void {
            XMLTree1.expandItem(MailBox.getItemAt(0), true);
            forOpen.text=XMLTree1.openItems[0].@label;
        }
        ]]>
    </fx:Script>

<mx:Tree id="tree1" ... creationComplete="initTree();" >
    ...
</mx:Tree>
```

This example must use the Tree control's `creationComplete` event, not the `initialize` event, because the data provider is not fully initialized and available until the `creationComplete` event.

The Tree control `openItems` property is an Array containing all expanded tree nodes. The following line in the example code displays the label of the first (and only) open item in the tree:

```
forOpen.text=XMLTree1.openItems[0].@label;
```

In this example, however, you could also get the `openItems` box to indicate the initial open item by setting the `expandItem()` method to dispatch an `itemOpen` event. You can do this by specifying the fourth, optional parameter of the `expandItem()` method to `true`. The `true` fourth parameter causes the tree to dispatch an `open` event when the item opens. The following example shows the use of the fourth parameter:

```
XMLTree1.expandItem(MailBox.getItemAt(0), true, false, true);
```

You can programmatically walk down a Tree control's nodes and open a node without knowing what depth you are at in the Tree's data provider. One way to do this is by using the `children()` method of a node's XML object to test whether the node has any children; you can use the `expandItem()` method to open the node.

The following example opens nodes in the Tree control based on the values of query string parameters. For example, if you pass *app_url*?0=1&1=2&2=0 to the application, then Flex opens the second item at the top level of the tree, the third item at the next level, and the first item at the third level of the tree (nodes are zero-based).

```
<?xml version="1.0"?>
<!-- dpcontrols/DrillIntoTree.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    creationComplete="initApp();">

    <fx:Script>
      <![CDATA[
        import mx.collections.XMLListCollection;
        import mx.core.FlexGlobals;

        [Bindable]
        private var treeData:XML =
            <root>
                <node label="Monkeys">
                    <node label="South America">
                        <node label="Coastal"/>
                        <node label="Inland"/>
                    </node>
                    <node label="Africa" isBranch="true"/>
                    <node label="Asia" isBranch="true"/>
                </node>
                <node label="Sharks">
                    <node label="South America" isBranch="true"/>
                    <node label="Africa" isBranch="true"/>
                    <node label="Asia" >
                        <node label="Coastal"/>
                        <node label="Inland"/>
                    </node>
                </node>
            </root>;

        private var openSequence:Array = [];
        private function initApp():void {
            /*  Parse URL and place values into openSequence Array.
                This lets you pass any integers on the query string,
                in any order. So:
                http://localhost/flex/flex2/DrillIntoTree.swf?0=1&1=2&2=0
                results in an array of selections like this:
                0:1
                1:2
                2:0
                Non-ints are ignored.
                The Array is then used to drill down into the tree.
            */
           var paramLength:int = 0;
           for (var s:String in FlexGlobals.topLevelApplication.parameters) {
               if (!isNaN(Number(s))) {
                    openSequence[s] = FlexGlobals.topLevelApplication.parameters[s];
                    paramLength += 1;
               }
            }
            openTree();
        }

        private function openTree():void {
            var nodeList:XMLListCollection =
                myTree.dataProvider as XMLListCollection;
            var node:XMLList = nodeList.source;
            for(var i:int=0; i < openSequence.length; i++) {
                var j:int = openSequence[i];
                var n:XML = node[j];
                if( n.children() != null ) {
                    myTree.expandItem(n,true,false);
                    node = n.children();
                } else {
                    break;
                }
            }
            if( n != null ) myTree.selectedItem = n;
        }
      ]]>
    </fx:Script>

    <mx:Tree id="myTree"
        y="50"
        width="221"
        height="257"
        horizontalCenter="0"
        dataProvider="{treeData.node}"
        labelField="@label"/>
</s:Application>
```

Specifying Tree control icons

The Tree control provides four techniques for specifying node icons:

- The `folderOpenIcon`, `folderClosedIcon`, and `defaultLeafIcon` properties
- Data provider node icon fields
- The `setItemItcon()` method
- The `iconFunction` property

Using icon properties

You can use the `folderOpenIcon`, `folderClosedIcon`, and `defaultLeafIcon` properties to control the Tree control icons. For example, the following code specifies a default leaf icon, and icons for the open and closed states of branch nodes:

```
<mx:Tree folderOpenIcon="@Embed(source='open.jpg')"
    folderClosedIcon="@Embed(source='closed.jpg')"
    defaultLeafIcon="@Embed(source='def.jpg')">
```

Using icon fields

You can specify an icon displayed with each Tree leaf when you populate it by using XML, as the following example shows:

```
<?xml version="1.0"?>
<!-- dpcontrols/TreeIconField.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
            [Bindable]
            [Embed(source="assets/radioIcon.jpg")]
            public var iconSymbol1:Class;
            [Bindable]
            [Embed(source="assets/topIcon.jpg")]
            public var iconSymbol2:Class;
        ]]>
    </fx:Script>
   <mx:Tree iconField="@icon"
       labelField="@label"
       showRoot="false"
        width="160">
        <fx:XMLList>
            <node label="New">
                <node label="HTML Document" icon="iconSymbol2"/>
                <node label="Text Document" icon="iconSymbol2"/>
            </node>
            <node label="Close" icon="iconSymbol1"/>
        </fx:XMLList>
    </mx:Tree>
</s:Application>
```

In this example, you use the `iconField` property to specify the field of each item containing the icon. You use the `Embed` metadata to import the icons, then reference them in the XML definition. You cannot use icon fields to specify icons for individual branch nodes; instead you must use the Tree control's `folderOpenIcon`, `folderClosedIcon` properties, each of which specifies an icon to use for all open or closed branches, or use the `setItemIcon()` method to set individual node icons.

Using the setItemIcon() method

You can use the `setItemIcon()` method to specify the icon, or both the open and closed icons for a tree item. This method lets you dynamically specify and change icons for individual branches and nodes. For details on this function see setItemIcon() in *ActionScript 3.0 Reference for the Adobe Flash Platform*. The following example sets the open and closed node icon for the first branch node and the icon for the second branch (which does not have any leaves):

```
<?xml version="1.0"?>
<!-- dpcontrols/TreeItemIcon.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
   <fx:Script>
      <![CDATA[
         [Bindable]
         [Embed(source="assets/radioIcon.jpg")]
         public var iconSymbol1:Class;
         [Bindable]
         [Embed(source="assets/topIcon.jpg")]
         public var iconSymbol2:Class;

         private function setIcons():void {
            myTree.setItemIcon(myTree.dataProvider.getItemAt(0),
               iconSymbol1, iconSymbol2);
            myTree.setItemIcon(myTree.dataProvider.getItemAt(1),
               iconSymbol2, null);
         }
      ]]>
   </fx:Script>
   <mx:Tree id="myTree" labelField="@label"
      showRoot="false"
      width="160" initialize="setIcons();">
      <fx:XMLList>
         <node label="New">
            <node label="HTML Document"/>
            <node label="Text Document"/>
         </node>
         <node label="Close"/>
      </fx:XMLList>
   </mx:Tree>
</s:Application>
```

Using an icon function

You can use the Tree control `iconFunction` property to specify a function that dynamically sets all icons for the tree. For information on using the `iconFunction` property in Flex controls, see “Specifying an icon to the List control” on page 948.

Opening a Tree control to a specific node

By default, a Tree control is collapsed when it initializes, but you can initialize it so that it is expanded with a specific node selected, as the following example shows. In this application, the `initTree()` method is called after the Tree control is created. This method expands the root node of the Tree control and sets its `selectedIndex` property to the index number of a specific node.

```
<?xml version="1.0"?>
<!-- dpcontrols/TreeOpenNode.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Script>
        <![CDATA[
            import flash.events.*;
            import mx.events.*;
            import mx.controls.*;
            private function initTree():void {
                XMLTree1.expandItem(MailBox.getItemAt(0), true);
                XMLTree1.selectedIndex = 2;
            }
        ]]>
    </fx:Script>
    <mx:Tree id="XMLTree1"
        width="150" height="170"
        labelField="@label"
        creationComplete="initTree();">
        <mx:XMLListCollection id="MailBox">
            <fx:XMLList>
                <node label="Mail" data="100">
                    <node label="Inbox" data="70"/>
                    <node label="Personal Folder" data="10">
                        <node label="Business" data="2"/>
                        <node label="Demo" data="3"/>
                        <node label="Saved Mail" data="5" />
                    </node>
                    <node label="Sent" data="15"/>
                    <node label="Trash" data="5"/>
                   </node>
            </fx:XMLList>
        </mx:XMLListCollection>
    </mx:Tree>
</s:Application>
```

Adding and removing leaf nodes at run time

You can add and remove leaf nodes from a Tree control at run time. The following example contains code for making these changes. The application initializes with predefined branches and leaf nodes that represent company departments and employees. You can dynamically add leaf (employee) nodes to the Operations department branch at run time. You can also remove any leaf node, including any you create at run time.

The XML in this example contains two different element names, department and employee. The Tree control's label function, `treeLabel()`, determines what text is displayed for these types of elements. It uses E4X syntax to return either the title of a department or the name of an employee. Those values are then used in the `addEmployee()`and `removeEmployee()`methods.

To add employees to the Operations department, the `addEmployee()` method uses E4X syntax to get the Operations department node based on the value of its title attribute, and stores it in the dept variable, which is of type XMLList. It then appends a child node to the Operations node by calling `dept.appendChild()`.

The `removeEmployee()` method stores the currently selected item in the node variable, which is of type XML. The method calls the `node.localName()` method to determine if the selected item is an employee node. If the item is an employee node, it is deleted.

```
<?xml version="1.0"?>
<!-- dpcontrols/TreeAddRemoveNode.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

</s:Application>
```

Tree user interaction

You can let users edit tree control labels. The controls also support several keyboard navigation and editing keys.

Editing a node label at run time

Set the `editable` property of the Tree control to `true` to make node labels editable at run time. To edit a node label, the user selects the label, and then enters a new label or edits the existing label text.

To support label editing, the Tree control's List superclass uses the following events. These events belong to the ListEvent class:

Event	Description
`itemEditBegin`	Dispatched when the editedItemPosition property has been set and the cell can be edited.
`itemEditEnd`	Dispatched when cell editing session ends for any reason.
`itemFocusIn`	Dispatched when tree node gets the focus: when a user selects the label or tabs to it.
`itemFocusOut`	Dispatched when a label loses focus.
`itemClick`	Dispatched when a user clicks on an item in the control.

These events are commonly used in custom item editors. For more information see "MX item renderers and item editors" on page 1006.

Using the keyboard to edit labels

If you set the Tree `editable` property to `true`, you can use the following keys to edit labels:

Key	**Description**
Down Arrow Page Down End	Moves the caret to the end of the label.
Up Arrow Page Up Home	Moves the caret to the beginning of the label.
Right Arrow	Moves the caret forward one character.
Left Arrow	Moves the caret backward one character.
Enter	Ends editing and moves selection to the next visible node, which can then be edited. At the last node, selects the label.
Shift Enter	Ends editing and moves selection to the previous visible node, which can then be edited. At the first node, selects the label.
Escape	Cancels the edit, restores the text, and changes the row state from editing to selected.
TAB	When in editing mode, accepts the current changes, selects the row below, and goes into editing mode with the label text selected. If at the last element in the tree or not in editing mode, sends focus to the next control.
Shift-TAB	When in editing mode, accepts the current changes, selects the row above, and goes into editing mode. If at the first element in the tree or not in editing mode, sends focus to the previous control.

Tree Navigation keys

When a Tree control is not editable and has focus from clicking or tabbing, you use the following keys to control it:

Key	**Description**
Down Arrow	Moves the selection down one. When the Tree control gets focus, use the Down arrow to move focus to the first node.
Up Arrow	Moves the selection up one item.
Right Arrow	Opens a selected branch node. If a branch is already open, moves to the first child node.
Left Arrow	Closes a selected branch node. If a leaf node or a closed branch node is currently selected, selects the parent node.
Spacebar or * (Asterisk on numeric keypad)	Opens or closes a selected branch node (toggles the state).
+ (Plus sign on numeric keypad)	Opens a selected branch node.
- (Minus sign on numeric keypad)	Closes a selected branch node.
Control + Arrow keys	Moves the focus, but does not select a node. Use the Spacebar to select a node.
End	Moves the selection to the bottom of the list.
Home	Moves the selection to the top of the list.
Page down	Moves the selection down one page.

Key	Description
Page up	Moves the selection up one page.
Control	If the `allowMultipleSelection` property is `true`, allows multiple noncontiguous selections.
Shift	If the `allowMultipleSelection` property is `true`, allows multiple contiguous selections.

Menu-based controls

There are three Adobe® Flex® Framework controls that you can use to create or interact with menus.

About menu-based controls

Flex framework includes three controls that present hierarchical data in a cascading menu format. All menu controls can have icons and labels for each menu item, and dispatch events of the mx.events.MenuEvent class in response to user actions. You can use the following menu-based controls:

Menu control A visual menu that can have cascading submenus. You typically display a menu control in response to some user action, such as clicking a button. You cannot define a Menu control by using an MXML tag; you must define it, display it, and hide it by using ActionScript.

MenuBar control A horizontal bar of menu items. Each item in the menu bar can have a submenu that displays when you click the MenuBar item. The MenuBar control is effectively a static (non-pop-up) menu that displays the top level of the menu as the bar items.

PopUpMenuButton control A subclass of the PopUpButton control that displays a Menu control when you click the secondary button. The primary button label changes when you select an item from the pop-up menu.

Defining menu structure and data

All menu-based controls use data providers with the following characteristics to specify the structure and contents of the menus:

- The data providers are often hierarchical, but you can also have a single-level menu.
- Individual menu items include fields that determine the menu item appearance and behavior. Menu-based controls support fields that define the label text, an icon, the menu item type, and item status. For information on meaningful fields, see "Specifying and using menu entry information" on page 986.

About menu data providers

The `dataProvider` property of a menu-based control specifies an object that defines the structure and contents of the menu. If a menu's contents are dynamic, you change the menu by modifying its data provider.

Menu-based controls typically get their data from hierarchical data providers, such as nested arrays of objects or XML. If the menu represents dynamically changing data, you use an object that implements the ICollectionView interface, such as ArrayCollection or XMLListCollection.

Menu-based controls use a data descriptor to parse and manipulate the data provider contents. By default, menu-based controls use a DefaultDataDescriptor class descriptor, but you can create your own class and specify it in the Menu control's `dataDescriptor` property.

The DefaultDataDescriptor class supports the following types of data:

XML A string that contains valid XML text, or any of the following objects containing valid E4X format XML data: an `<fx:XML>` or `<fx:XMLList>` compile-time tag, or an XML or XMLList object.

Other objects An array of items, or an object that contains an array of items, where a node's children are contained in an item named `children`. You can also use the `<fx:Model>` compile-time tag to create nested objects that support data binding, but you must follow the structure defined in "Using the <fx:Model> tag with Tree and menu-based controls" on page 929.

Collections An object that implements the ICollectionView interface (such as the ArrayCollection or XMLListCollection classes) and whose data source conforms to the structure specified in either of the previous bullets. The DefaultDataDescriptor class includes code to handle collections efficiently. Always use a collection as the data provider if the data in the menu changes dynamically; otherwise, the Menu displays obsolete data.

For more information on hierarchical objects and data descriptors, including a detailed description of the formats supported by the DefaultDataDescriptor, see "Data descriptors and hierarchical data structure" on page 927.

As with all data-driven controls, if the data provider contents can change dynamically, and you want the Menu to update with the changes, ensure that the data source is a collection, such as an ArrayCollection or XMLListCollection object. To modify the menu, change the underlying collection, and the menu will update its appearance accordingly.

Node (menu item) tags in the XML data can have any name. Many examples in this topic use tags such as `<node>` for all menu items, or `<menuItem>` for top-level items and `<subMenuItem>` for submenu items, but it might be more realistic to use tag names that identify the data, such as `<person>`, `<address>`, and so on. The menu-handling code reads through the XML and builds the display hierarchy based on the nested relationship of the nodes. For more information, see "Specifying and using menu entry information" on page 986.

Most menus have multiple items at the top level, not a single root item. XML objects, such as the XML object created by the `<fx:XML>` tag, must have a single root node. To display a menu that uses a data provider that has a root that you do not want to display, set the Menu, PopUpMenuButton, or MenuBar `showRoot` property to `false`.

Specifying and using menu entry information

Information in menu-based control data providers determines how each menu entry appears and is used. To access or change the menu contents, you modify the contents of the data provider.

The menu-based classes use the methods of the IMenuDataDescriptor interface to access and manipulate information in the data provider that defines the menu behavior and contents. Flex provides a DefaultDataDescriptor class that implements this interface. The menu-based controls use the DefaultDataDescriptor class if you do not set the `dataDescriptor` property.

Menu entry types

Each data provider entry can specify an item type and type-specific information about the menu item. Menu-based classes support the following item types (`type` field values):

normal (the default) Selecting an item with the `normal` type triggers a `change` event, or, if the item has children, opens a submenu.

check Selecting an item with the `check` type toggles the menu item's `toggled` property between `true` and `false` values. When the menu item is in the `true` state, it displays a check mark in the menu next to the item's label.

radio Items with the `radio` type operate in groups, much like RadioButton controls; you can select only one radio menu item in each group at a time. The example in this section defines three submenu items as radio buttons within the group "one".

When a radio button is selected, the radio item's toggled property is set to true, and the toggled properties of all other radio items in the group are set to false. The Menu control displays a solid circle next to the radio button that is currently selected. The selection property of the radio group is set to the label of the selected menu item.

separator Items with the separator type provide a simple horizontal line that divides the items in a menu into different visual groups.

Menu attributes

Menu items can specify several attributes that determine how the item is displayed and behaves. The following table lists the attributes you can specify, their data types, their purposes, and how the data provider must represent them if the menu uses the DefaultDataDescriptor class to parse the data provider:

Attribute	Type	Description
enabled	Boolean	Specifies whether the user can select the menu item (true), or not (false). If not specified, Flex treats the item as if the value were true. If you use the default data descriptor, data providers must use an enabled XML attribute or object field to specify this characteristic.
groupName	String	(Required, and meaningful, for radio type only) The identifier that associates radio button items in a radio group. If you use the default data descriptor, data providers must use a groupName XML attribute or object field to specify this characteristic.
icon	Class	Specifies the class identifier of an image asset. This item is not used for the check, radio, or separator types. You can use the checkIcon and radioIcon styles to specify the icons used for radio and check box items that are selected. The menu's iconField or iconFunction property determines the name of the field in the data that specifies the icon, or a function for determining the icons.
label	String	Specifies the text that appears in the control. This item is used for all menu item types except separator. The menu's labelField or labelFunction property determines the name of the field in the data that specifies the label, or a function for determining the labels. (If the data provider is in E4X XML format, you must specify one of these properties to display a label.) If the data provider is an array of strings, Flex uses the string value as the label.
toggled	Boolean	Specifies whether a check or radio item is selected. If not specified, Flex treats the item as if the value were false and the item is not selected. If you use the default data descriptor, data providers must use a toggled XML attribute or object field to specify this characteristic.
type	String	Specifies the type of menu item. Meaningful values are separator, check, or radio. Flex treats all other values, or nodes with no type entry, as normal menu entries. If you use the default data descriptor, data providers must use a type XML attribute or object field to specify this characteristic.

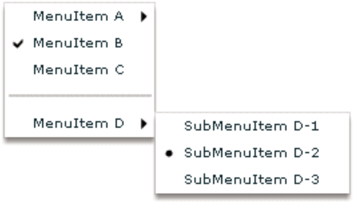
Menu-based controls ignore all other object fields or XML attributes, so you can use them for application-specific data.

Example: An Array menu data provider

The following example displays a Menu that uses an Array data provider and shows how you define the menu characteristics in the data provider. For an application that specifies an identical menu structure in XML, see "Example: Creating a simple Menu control" on page 999.

```
<?xml version="1.0"?>
<!-- menus/ArrayDataProvider.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            import mx.controls.Menu;
            // Method to create an Array-based menu.
            private function createAndShow():void {
                // The third parameter sets the showRoot property to false.
                // You must set this property in the createMenu method,
                // not later.
                var myMenu:Menu = Menu.createMenu(null, menuData, true);
                myMenu.show(10, 10);
            }
            // The Array data provider
            [Bindable]
            public var menuData:Array = [
                {label: "MenuItem A", children: [
                    {label: "SubMenuItem A-1", enabled: false},
                    {label: "SubMenuItem A-2", type: "normal"}
                    ]},
                {label: "MenuItem B", type: "check", toggled: true},
                {label: "MenuItem C", type: "check", toggled: false},
                {type: "separator"},
                {label: "MenuItem D", children: [
                    {label: "SubMenuItem D-1", type: "radio",
                        groupName: "g1"},
                    {label: "SubMenuItem D-2", type: "radio",
                        groupName: "g1", toggled: true},
                    {label: "SubMenuItem D-3", type: "radio",
                        groupName: "g1"}
                    ]}
                ];
        ]]>
    </fx:Script>
    <!-- Button control to create and open the menu. -->
    <mx:Button x="300" y="10"
        label="Open Menu"
        click="createAndShow();"/>
</s:Application>
```

The following image shows the resulting control, with MenuItem D open; notice that check item B and radio item D-2 are selected:



Example: An XML menu data provider with icons

The following example displays a menu control that uses XML as the data provider, and specifies custom icons for the items in the control:

```
<?xml version="1.0"?>
<!-- SimpleMenuControlIcon.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
            // Import the Menu control.
            import mx.controls.Menu;

            [Bindable]
            [Embed(source="assets/topIcon.jpg")]
            public var myTopIcon:Class;

            [Bindable]
            [Embed(source="assets/radioIcon.jpg")]
            public var myRadioIcon:Class;

            [Bindable]
            [Embed(source="assets/checkIcon.gif")]
            public var myCheckIcon:Class;
            // Create and display the Menu control.
            private function createAndShow():void {
                var myMenu:Menu = Menu.createMenu(null, myMenuData, false);
                myMenu.labelField="@label";
                // Specify the check icon.
                myMenu.setStyle('checkIcon', myCheckIcon);
                // Specify the radio button icon.
                myMenu.setStyle('radioIcon', myRadioIcon);
                // Specify the icon for the topmenu items.
                myMenu.iconField="@icon";
                myMenu.show(10, 10);
            }
        ]]>
    </fx:Script>
    <fx:Declarations>
        <!-- Define the menu data. -->
        <fx:XML format="e4x" id="myMenuData">
            <root>
                <menuitem label="MenuItem A" icon="myTopIcon">
                    <menuitem label="SubMenuItem A-1" enabled="false"/>
                    <menuitem label="SubMenuItem A-2"/>
                </menuitem>
                <menuitem label="MenuItem B" type="check" toggled="true"/>
                <menuitem label="MenuItem C" type="check" toggled="false"
```

```
                    icon="myTopIcon"/>
                <menuitem type="separator"/>
                <menuitem label="MenuItem D" icon="myTopIcon">
                    <menuitem label="SubMenuItem D-1" type="radio"
                        groupName="one"/>
                    <menuitem label="SubMenuItem D-2" type="radio"
                        groupName="one" toggled="true"/>
                    <menuitem label="SubMenuItem D-3" type="radio"
                        groupName="one"/>
                </menuitem>
            </root>
        </fx:XML>
    </fx:Declarations>
    <mx:VBox>
        <!-- Define a Button control to open the menu -->
        <mx:Button id="myButton"
            label="Open Menu"
            click="createAndShow();"/>
    </mx:VBox>
</s:Application>
```

Menu-based control events

User interaction with a Menu or menu-based control is event-driven; that is, applications typically handle events generated when the user opens, closes, or selects within a menu, or submenu or rolls over or out of menu items. For detailed information on events and how to use them, see “Events” on page 54.

The Menu and MenuBar controls dispatch an identical set of menu-specific events. Event handling with PopUpMenuButton controls differs from the other two controls, but shares many elements in common with the others.

Menu control events

The Menu control defines the following menu-specific event types, of the MenuEvent class:

change (`MenuEvent.CHANGE`) Dispatched when a user changes current menu selection by using the keyboard or mouse.

itemClick (`MenuEvent.ITEM_CLICK`) Dispatched when a user selects an enabled menu item of type `normal`, `check`, or `radio`. This event is not dispatched when a user selects a menu item of type `separator`, a menu item that opens a submenu, or a disabled menu item.

itemRollOut (`MenuEvent.ITEM_ROLL_OUT`) Dispatched when the mouse pointer rolls off of a Menu item.

itemRollOver (`MenuEvent.ITEM_ROLL_OVER`) Dispatched when the mouse pointer rolls onto a Menu item.

menuHide (`MenuEvent.MENU_HIDE`) Dispatched when the entire menu or a submenu closes.

menuShow (`MenuEvent.MENU_SHOW`) Dispatched when the entire menu or a submenu opens.

The event object passed to the event listener is of type MenuEvent and contains one or more of the following menu-specific properties:

Property	Description
`item`	The item in the data provider for the menu item associated with the event.
`index`	The index of the item in the menu or submenu that contains it.
`label`	The label of the item.
`menu`	A reference to the Menu control where the event occurred.
`menuBar`	The MenuBar control instance that is the parent of the menu, or `undefined` when the menu does not belong to a MenuBar. For more information, see "MenuBar control" on page 1001.

To access properties and fields of an object-based menu item, you specify the menu item field name, as follows:

```
ta1.text = event.item.label
```

To access attributes of an E4X XML-based menu item, you specify the menu item attribute name in E4X syntax, as follows:

```
ta1.text = event.item.@label
```

***Note:** If you set an event listener on a submenu of a menu-based control, and the menu data provider's structure changes (for example, an element is removed), the event listener might no longer exist. To ensure that the event listener is available when the data provider structure changes, either listen on events of the menu-based control, not a submenu, or add the event listener each time an event occurs that changes the data provider's structure.*

The following example shows a menu with a simple event listener. For a more complex example, see "Example: Using Menu control events" on page 994.

```
<?xml version="1.0"?>

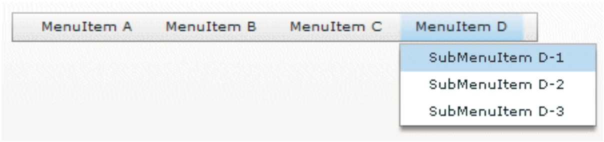
        id="ta1"/>
</s:Application>
```

MenuBar events

The following figure shows a MenuBar control:



For the menu bar, the following events occur:

change (`MenuEvent.CHANGE`) Dispatched when a user changes current menu bar selection by using the keyboard or mouse. This event is also dispatched when the user changes the current menu selection in a pop-up submenu. When the event occurs on the menu bar, the `menu` property of the MenuEvent object is `null`.

itemRollOut (`MenuEvent.ITEM_ROLL_OUT`) Dispatched when the mouse pointer rolls off of a menu bar item.

itemRollOver (`MenuEvent.ITEM_ROLL_OVER`) Dispatched when the mouse pointer rolls onto a menu bar item.

menuHide (`MenuEvent.MENU_HIDE`) Dispatched when a pop-up submenu closes.

menuShow (`MenuEvent.MENU_SHOW`) Dispatched when a pop-up submenu opens, or the user selects a menu bar item with no drop-down menu.

***Note:** The MenuBar control does not dispatch the `itemClick` event when you select an item on the menu bar; it only dispatches the `itemClick` event when you select an item on a pop-up submenu.*

For each pop-up submenu, the MenuBar dispatches the `change`, `itemClick`, `itemRollOut`, `itemRollOver`, `menuShow`, and `menuHide` events in the same way it does for the Menu control. Handle events triggered by the pop-up menus as you would handle events from Menu controls. For more information, see “Menu control events” on page 990.

The following example handles events for the menu bar and for the pop-up submenus.

```
<?xml version="1.0"?>
<!-- menus/MenuBarEventInfo.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    creationComplete="initCollections();">

```

Example: Using Menu control events

The following example lets you experiment with Menu control events. It lets you display two menus, one with an XML data provider and one with an Array data provider. A TextArea control displays information about each event as a user opens the menus, moves the mouse, and selects menu items. It shows some of the differences in how you handle XML and object-based menus, and indicates some of the types of information that are available about each Menu event.

```
<?xml version="1.0"?>
<!-- menus/ExtendedMenuExample.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
        /* Import the Menu control and MenuEvent class. */
        import mx.controls.Menu;
        import mx.events.MenuEvent;

        /* Define a variable for the Menu control. */
        private var myMenu:Menu;
        /* The event listener that creates menu with an XML data
           provider and adds event listeners for the menu. */
        private function createAndShow():void {
            /* Clear the event output display. */
            ta1.text="";

</s:Application>
```

PopUpMenuButton control events

Because the PopUpMenuButton is a subclass of the PopUpButton control, it supports all of that control's events. When the user clicks the main button, the PopUpMenuButton control dispatches a `click` (`MouseEvent.CLICK)` event.

When the user clicks the PopUpMenuButton main button, the control dispatches an `itemClick` (MenuEvent.`ITEM_CLICK)` event that contains information about the selected menu item. Therefore, the same `itemClick` event is dispatched when the user clicks the main button or selects the current item from the pop-up menu. Because the same event is dispatched in both cases, clicking on the main button produces the same behavior as clicking on the last selected menuItem, so the main button plays the role of a frequently used menu item.

The following example shows how the PopUpMenuButton generates events and how an application can handle them:

```
<?xml version="1.0"?>
<!-- menus/PopUpMenuButtonEvents.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009" 
    xmlns:s="library://ns.adobe.com/flex/spark" 
    xmlns:mx="library://ns.adobe.com/flex/mx" 
    height="600" width="600" 
    creationComplete="initData();">
    <fx:Script>
        <![CDATA[
        import mx.events.*;
        import mx.controls.*;

        // Set the Inbox (fourth) item in the menu as the button item.
        private function initData():void {
            Menu(p1.popUp).selectedIndex=3;
        }

        // itemClick event handler, invoked when you select from the menu.
        // Shows the event's label, index properties, and the values of the 
        // label and data fields of the data provider entry specified by 
        // the event's item property.
        public function itemClickHandler(event:MenuEvent):void {
            Alert.show("itemClick event label: " + event.label
                + "  \nindex: " + event.index
                + "  \nitem.label: " + event.item.label
                + "  \nitem.data: " + event.item.data);
        }

        //Click event handler for the main button.
        public function clickHandler(event:MouseEvent):void {
            Alert.show(" Click Event currentTarget.label: "
                + event.currentTarget.label);
        }

        //The menu data provider
        [Bindable]
        public var menuDP:Array = [
            {label: "Inbox", data: "inbox"},
            {label: "Calendar", data: "calendar"},
            {label: "Sent", data: "sent"},
            {label: "Deleted Items", data: "deleted"},
            {label: "Spam", data: "spam"}
        ];
    ]]></fx:Script>
    <mx:PopUpMenuButton  id="p1"
        showRoot="true"
        dataProvider="{menuDP}"
        click="clickHandler(event);"
        itemClick="itemClickHandler(event);"/>
</s:Application>
```

When the user selects an item from the pop-up menu, the following things occur:

- The PopUpMenuButton dispatches an `itemClick` event.
- The application's `itemClickHandler()` event listener function handles the `itemClick` event and displays the information about the event in an Alert control.

When the user clicks the main button, the following things occur:

- The PopUpMenuButton control dispatches a `click` event.
- The PopUpMenuButton control dispatches an `itemClick` event.
- The application's `itemClickHandler()` event listener function handles the `itemClick` event and displays information about the selected Menu item in an Alert control.
- The application's `clickHandler()` event listener function also handles the `MouseEvent.CLICK` event, and displays the Button label in an Alert control.

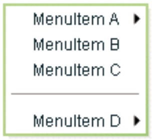
Menu control

The Menu control is a pop-up control that contains a menu of individually selectable choices. You use ActionScript to create a Menu control that pops up in response to a user action, typically as part of an event listener. Because you create a Menu control in response to an event, it does not have an MXML tag; you can create Menu controls in ActionScript only.

For complete reference information, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

About the Menu Control

The following example shows a Menu control:



In this example, the MenuItem A and MenuItem D items open submenus. Submenus open when the user moves the mouse pointer over the parent item or accesses the parent item by using keyboard keys.

The default location of the Menu control is the upper-left corner of your application, at *x*, *y* coordinates 0,0. You can pass `x` and `y` arguments to the `show()` method to control the position relative to the application.

After a Menu opens, it remains visible until the user selects an enabled menu item, the user selects another component in the application, or a script closes the menu.

To create a *static* menu that stays visible all the time, use the MenuBar control or PopUpMenuButton control. For more information on the MenuBar control, see "MenuBar control" on page 1001. For more information on the PopUpMenuButton control, see "PopUpMenuButton control" on page 1003.

Create a Menu control

You cannot create a Menu control by using an MXML tag; you must create it in ActionScript.

1. Create an instance of the Menu control by calling the static ActionScript `Menu.createMenu()` method and passing the method an instance of the data provider that contains the information that populates the control as the second parameter; for example:

   ```
   var myMenu:Menu = Menu.createMenu(null, myMenuData);
   ```

   (The first parameter can optionally specify the parent container of the menu.)

   If you do not display the root node of the data provider, for example, if the data provider is an XML document in E4X format, use a third parameter with the value `false`. This parameter sets the menu's `showRoot` property. The following example creates a menu that does not show the data provider root:

   ```
   var myMenu:Menu = Menu.createMenu(null, myMenuData, false);
   ```

   ***Note:** To hide the root node, you must set the `showRoot` property in the `createMenu` method. Setting the property after you create the menu has no effect.*

2. Display the Menu instance by calling the ActionScript `Menu.show()` method; for example:

   ```
   myMenu.show(10, 10);
   ```

***Note:** Menus displayed by using the `Menu.popUpMenu()` method are not removed automatically; you must call the `PopUpManager.removePopUp()` method on the Menu object. The `show()` method automatically adds the Menu object to the display list, and the `hide()` method automatically removes it from the display list. Clicking outside the menu (or pressing Escape) also hides the Menu object and removes it from the display list.*

Example: Creating a simple Menu control

The following example uses the `<fx:XML>` tag to define the data for the Menu control and a Button control to trigger the event that opens the Menu control:

```
<?xml version="1.0"?>
<!-- menus/SimpleMenuControl.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx" >
    <fx:Script>
        <![CDATA[
            // Import the Menu control.
            import mx.controls.Menu;
            // Create and display the Menu control.
            private function createAndShow():void {
                var myMenu:Menu = Menu.createMenu(null, myMenuData, false);
                myMenu.labelField="@label";
                myMenu.show(10, 10);
            }
        ]]>
    </fx:Script>
    <fx:Declarations>
        <!-- Define the menu data. -->
        <fx:XML format="e4x" id="myMenuData">
            <root>
                <menuitem label="MenuItem A" >
                    <menuitem label="SubMenuItem A-1" enabled="false"/>
                    <menuitem label="SubMenuItem A-2"/>
                </menuitem>
                <menuitem label="MenuItem B" type="check" toggled="true"/>
                <menuitem label="MenuItem C" type="check" toggled="false"/>
                <menuitem type="separator"/>
                <menuitem label="MenuItem D" >
                    <menuitem label="SubMenuItem D-1" type="radio"
                        groupName="one"/>
                    <menuitem label="SubMenuItem D-2" type="radio"
                        groupName="one" toggled="true"/>
                    <menuitem label="SubMenuItem D-3" type="radio"
                        groupName="one"/>
                </menuitem>
            </root>
        </fx:XML>
    </fx:Declarations>
    <mx:VBox>
        <!-- Define a Button control to open the menu -->
        <mx:Button id="myButton"
            label="Open Menu"
            click="createAndShow();"/>
    </mx:VBox>
</s:Application>
```

You can assign any name to node tags in the XML data. In the previous sample, each node is named with the generic `<menuitem>` tag, but you can have used `<node>`, `<subNode>`, `<person>`, `<address>` and so on.

Because this example uses an E4X XML data source, you must specify the label field by using the E4X @ attribute specifier syntax, and you tell the control not to show the data provider root node.

Several attributes or fields, such as the `type` attribute, have meaning to the Menu control. For information on how Flex interprets and uses the data provider data, see "Specifying and using menu entry information" on page 986.

Menu control user interaction

You can use the mouse or the keyboard to interact with a Menu control. Clicking selects a menu item and closes the menu, except with the following types of menu items:

Disabled items or separators Rolling over or clicking menu items has no effect and the menu remains visible.

Submenu anchors Rolling over the items activates the submenu; clicking them has no effect; rolling onto any menu item other than one of the submenu items closes the submenu.

When a Menu control has focus, you can use the following keys to control it:

Key	Description
Down Arrow Up Arrow	Moves the selection down and up the rows of the menu. The selection loops at the top or bottom row.
Right Arrow	Opens a submenu, or moves the selection to the next menu in a menu bar.
Left Arrow	Closes a submenu and returns focus to the parent menu (if a parent menu exists), or moves the selection to the previous menu in a menu bar (if the menu bar exists).
Enter	Opens a submenu, has the effect of clicking and releasing the mouse on a row if a submenu does not exist.
Escape	Closes a menu level.

MenuBar control

A MenuBar control displays the top level of a menu as a horizontal bar of menu items, where each item on the bar can pop up a submenu. The MenuBar control interprets the data provider in the same way as the Menu control, and supports the same events as the Menu control. Unlike the Menu control, a MenuBar control is static; that is, it does not function as a pop-up menu, but is always visible in your application. Because the MenuBar is static, you can define it directly in MXML.

For complete reference information, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*. For more information on the Menu control, see “Menu control events” on page 990.

About the MenuBar control

The following example shows a MenuBar control:

The control shows the labels of the top level of the data provider menu. When a user selects a top-level menu item, the MenuBar control opens a submenu. The submenu stays open until the user selects another top-level menu item, selects a submenu item, or clicks outside the MenuBar area.

Creating a MenuBar control

You define a MenuBar control in MXML by using the `<mx:MenuBar>` tag. Specify an `id` value if you intend to refer to a component elsewhere in your MXML application, either in another tag or in an ActionScript block.

You specify the data for the MenuBar control by using the `dataProvider` property. The MenuBar control uses the same types of data providers as does the Menu control. For more information on data providers for Menu and MenuBar controls, see “Defining menu structure and data” on page 985. For more information on hierarchical data providers, see “Hierarchical data objects” on page 927.

In a simple case for creating a MenuBar control, you might use an `<fx:XML>` or `<fx:XMLList>` tag and standard XML node syntax to define the menu data provider. When you used an XML-based data provider, you must keep the following rules in mind:

- With the `<fx:XML>` tag you must have a single root node, and you set the `showRoot` property of the MenuBar control to `false`. (otherwise, your MenuBar would have only the root as a button). With the `<fx:XMLList>` tag you define a list of XML nodes, and the top level nodes define the bar buttons.
- If your data provider has a label attribute (even if it is called "label"), you must set the MenuBar control's `labelField` property and use the E4X @ notation for the label; for example:

  ```
  labelField="@label"
  ```

The `dataProvider` property is the default property of the `MenuBar` control, so you can define the XML or XMLList object as a direct child of the `<mx:MenuBar> tag`, as the following example shows:

```
<?xml version="1.0"?>
<!-- menus/MenuBarControl.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx" >
    <!-- Define the menu; dataProvider is the default MenuBar property.
      Because this uses an XML data provider, specify the labelField and
      showRoot properties. -->
    <mx:MenuBar id="myMenuBar" labelField="@label">
        <fx:XMLList>
            <menuitem label="MenuItem A">
                <menuitem label="SubMenuItem A-1" enabled="false"/>
                <menuitem label="SubMenuItem A-2"/>
            </menuitem>
            <menuitem label="MenuItem B"/>
            <menuitem label="MenuItem C"/>
            <menuitem label="MenuItem D">
                <menuitem label="SubMenuItem D-1"
                    type="radio" groupName="one"/>
                <menuitem label="SubMenuItem D-2"
                    type="radio" groupName="one"
                    selected="true"/>
                <menuitem label="SubMenuItem D-3"
                    type="radio" groupName="one"/>
            </menuitem>
        </fx:XMLList>
    </mx:MenuBar>
</s:Application>
```

The top-level nodes in the MenuBar control correspond to the buttons on the bar. Therefore, in this example, the MenuBar control displays the four labels shown in the preceding image.

You can assign any name to node tags in the XML data. In the previous example, each node is named with the generic `<menuitem>` tag, but you can use `<node>`, `<subNode>`, `<person>`, `<address>`, and so on. Several attributes or fields, such as the `type` attribute, have meaning to the MenuBar control. For information on how Flex interprets and uses the data provider data, see "Specifying and using menu entry information" on page 986.

MenuBar control user interaction

The user interaction of the MenuBar is the same as for the Menu control, with the following difference: when the MenuBar control has the focus, the left arrow opens the previous menu. If the current menu bar item has a closed pop-up menu, the right arrow opens the current menu; if the pop-up menu is open, the right arrow opens the next menu. (The behavior wraps around the ends of the MenuBar control.)

For more information, see "Menu control user interaction" on page 1001.

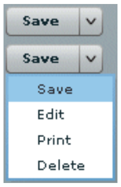
PopUpMenuButton control

The PopUpMenuButton is a PopUpButton control whose secondary button pops up a Menu control. When the user selects an item from the pop-up menu, the main button of the PopUpButton changes to show the icon and label of the selected menu item. Unlike the Menu and MenuBar controls, the PopUpMenuButton supports only a single-level menu.

For complete reference information, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*. For more information on the Menu control, see "Menu control events" on page 990. For more information on PopUpButton controls, see "PopUpButton control" on page 702.

About the PopUpMenuButton control

The following example shows a PopUpMenuButton control before and after clicking the secondary pop-up button:



The PopUpMenuButton works as follows.

- When you click the smaller button, which by default displays a **v** icon, the control displays a pop-up menu below the button.
- When you select an item from the pop-up menu, the main PopUpMenuButton button label changes to show the selected item's label and the PopUpMenuButton control dispatches a `MenuEvent.CHANGE` event.
- When you click the main button, the PopUpMenuButton control dispatches a `MenuEvent.CHANGE` event and a `MouseEvent.ITEM_CLICK` event.

For information on handling PopUpMenuButton events, see "PopUpMenuButton control events" on page 997.

The PopUpMenuButton control lets users change the function of the main button by selecting items from the pop-up menu. The most recently selected item becomes the main button item.

This behavior is useful for buttons when there are a number of user actions, users tend to select the same option frequently, and the application developer cannot assume which option should be the default. Text editors often use such controls in their control bar for options, such as spacing, for which a user is likely to have a preferred setting, but the developer cannot determine it in advance. Microsoft Word, for example, uses such controls for specifying line spacing, borders, and text and highlight color.

You can use the PopUpButton control to create pop-up menu buttons with behaviors that differ from those of the PopUpMenuButton; for example, buttons that do not change the default action of the main button when the user selects a menu item. For more information, see "PopUpButton control" on page 702.

Creating a PopUpMenuButton control

You define a PopUpMenuButton control in MXML by using the `<mx:PopUpMenuButton>` tag. Specify an `id` value if you intend to refer to a component elsewhere in your MXML application, either in another tag or in an ActionScript block.

You specify the data for the PopUpMenuButton control by using the `dataProvider` property. For information on valid data providers, including their structure and contents, see "Defining menu structure and data" on page 985.

By default, the initially selected item is the first item in the pop-up menu dataProvider, and the default main button label is the item's label, as determined by the `labelField` or `labelFunction` property. To set the initial main button label to a specific item's label and functionality, write a listener for the PopUpMenuButton control's `creationComplete` event that sets the `selectedIndex` property of the Menu subcontrol, as follows:

```
Menu(MyPopUpControl.popUp).selectedIndex=2;
```

You must cast the PopUpMenuButton control's `popUp` property to a Menu because the property type is IUIComponent, not Menu.

You can also use the `label` property of the PopUpMenuButton control to set the main button label.

When a popped up menu closes, it loses its selection and related properties.

Note: *You must use the PopUpMenuButton's `creationComplete` event, not the `initialize` event, to set the main button label from the data provider.*

Example: Creating a PopUpMenuButton control

The following example creates a PopUpMenuButton control by using an E4X XML data provider.

```
<?xml version="1.0"?>
<!-- menus/PopUpMenuButtonControl.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
            import mx.controls.Menu

            // The initData function sets the initial value of the button
            // label by setting the Menu subcontrol's selectedIndex property.
            // You must cast the popUp property to a Menu.
            private function initData():void {
                Menu(pb2.popUp).selectedIndex=2;
            }
        ]]>
    </fx:Script>
    <fx:Declarations>
        <fx:XML format="e4x" id="dp2">
            <root>
                <editItem label="Cut"/>
                <editItem label="Copy"/>
                <editItem label="Paste"/>
                <separator type="separator"/>
                <editItem label="Delete"/>
            </root>
        </fx:XML>
    </fx:Declarations>
    <mx:PopUpMenuButton id="pb2"
        dataProvider="{dp2}"
        labelField="@label"
        showRoot="false"
        creationComplete="initData();"/>
</s:Application>
```

Because this example uses an E4X XML data source, you must specify the label field by using the E4X @ attribute specifier syntax, and you must tell the control not to show the data provider root node.

Using the label property

The `label` property of the PopUpMenuButton control specifies the contents of the label on the main button, and overrides any label from the pop-up menu that is determined by the `labelField` or `labelFunction` property. The `label` property is useful for creating a main button label with fixed and a variable parts; for example, a mail "Send to:" button where only the destination text is controlled by the pop-up menu, so the main button could say "Send to: Inbox" or "Send to: Trash" based on the selection from a menu that lists "Menu" and "Trash."

To use a dynamic `label` property, use a PopUpMenuButton control `change` event listener to set the label based on the event's `label` property, as in the following example:

```
<?xml version="1.0"?>
<!-- menus/PopUpMenuButtonLabel.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
            import mx.events.MenuEvent;

            public function itemClickHandler(event:MenuEvent):void {
                event.currentTarget.label= "Send to: " + event.label;
            }
            [Bindable]
            public var menuData:Array = [
                {label: "Inbox", data: "inbox"},
                {label: "Calendar", data: "calendar"},
                {label: "Sent", data: "sent"},
                {label: "Deleted Items", data: "deleted"},
                {label: "Spam", data: "spam"}
            ];
        ]]>
    </fx:Script>
    <mx:PopUpMenuButton id="p1"
        showRoot="true"
        dataProvider="{menuData}"
        label="Send to: Inbox"
        itemClick="itemClickHandler(event);"/>
</s:Application>
```

PopUpMenuButton user interaction

The user interaction of the PopUpMenuButton control main button and secondary button is the same as for the PopUpButton control. The user interaction with the pop-up menu is the same as for the Menu control. For more information on the PopUpButton user interaction, see “User interaction” on page 704. For more information on Menu control user interaction, see “Menu control user interaction” on page 1001.

MX item renderers and item editors

You can customize the appearance and behavior of cells in MX list-based data provider controls that you use in applications built with Adobe® Flex®, including the DataGrid, HorizontalList, List, Menu, MenuBar, TileList, and Tree controls. To control the appearance of cells in list controls, you create custom item renderers and item editors.

For more information about creating more advanced item editors, see “Advanced data display with MX item editors” on page 1048.

For information on using item renderers with Spark components, see “Custom Spark item renderers” on page 470.

About MX item renderers

MX supports several controls that you can use to represent lists of items. These controls let the application user scroll through the item list and select one or more items from the list. All MX list components are derived from the ListBase class, and include the following controls:

- DataGrid

- HorizontalList
- List
- Menu
- MenuBar
- TileList
- Tree

A list control gets its data from a data provider. A *data provider* is a collection that contains a data object such as an Array or XMLList object. For example, a Tree control reads data from a data provider to define the structure of the tree and any associated data that is assigned to each tree node. *Collections* are objects that contain a set of methods that let you access, sort, filter, and modify the data items in a data object. The standard collection types are the ArrayCollection and XMLListCollection classes, for working with Array-based and XMLList-based data, respectively.

Collections provide a level of abstraction between Flex components and the data that you use to populate them. You can populate multiple components from the same collection, switch the collection that a component uses as a data provider at run time, or modify a collection so that changes are reflected by all components that use it as a data provider.

You can think of the data provider as the model, and the Flex components as the view of the model. By separating the model from the view, you can change one without changing the other. Each list control has a default mechanism for controlling the display of data, or view, and lets you override that default. To override the default view, you create a custom *item renderer*.

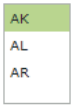
In addition to controlling the display of data using an item renderer, the DataGrid, List, and Tree controls let users edit the data. For example, you could let users update the Quantity column of a DataGrid control if you are using it for a shopping cart. As with the display of data, the list controls have a default mechanism for letting users edit data that you can override by creating a custom *item editor*.

Default item rendering and cell editing in MX

Each MX list-based control has a default item renderer defined for it. The simplest item renderer is the DataGridItemRenderer class, which defines the item renderer for the DataGrid control. This item renderer assumes that each element in a data provider is a text string.

Other item renderers include the ListItemRenderer, MenuItemRenderer, MenuBarItem, TileListItemRenderer, and TreeItemRenderer. By default, these item renderers combine an image with text.

For example, the following image shows a List control that displays three items using its default item renderer:



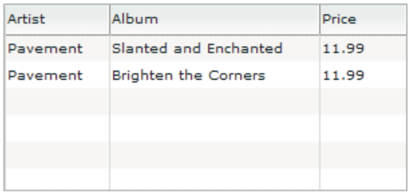
AK
AL
AR

In this example, the List control uses the default item renderer to display each of the three strings that represent postal codes for Alaska, Alabama, and Arkansas. You use the following code to create this List control:

```
<?xml version="1.0"?>
<!-- itemRenderers\list\ListDefaultRenderer.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <mx:List width="50" height ="75">
        <mx:dataProvider>
            <fx:String>AK</fx:String>
            <fx:String>AL</fx:String>
            <fx:String>AR</fx:String>
        </mx:dataProvider>
    </mx:List>
</s:Application>
```

Because the data in this example is inline static data, it is not necessary to explicitly wrap it in an ArrayCollection instance. However, when you work with data that could change, it is always best to specify a collection explicitly; for more information, see “Data providers and collections” on page 898.

In the next example, the data provider for the DataGrid control contains fields for an artist, album name, and price. Each of these fields appears in the DataGrid control using the default item renderer, which displays data as text.



Artist	Album	Price
Pavement	Slanted and Enchanted	11.99
Pavement	Brighten the Corners	11.99

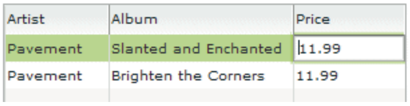
The following code creates the example shown in the previous image:

```
<?xml version="1.0"?>
<!-- itemRenderers\dataGrid\DGDefaultRenderer.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx" >

    <fx:Script>
        <![CDATA[
          import mx.collections.ArrayCollection;

          [Bindable]
          private var initDG:ArrayCollection = new ArrayCollection([
            {Artist:'Pavement', Album:'Slanted and Enchanted', Price:11.99},
            {Artist:'Pavement', Album:'Brighten the Corners', Price:11.99}
          ]);
        ]]>
    </fx:Script>
    <mx:Panel paddingTop="10" paddingBottom="10"
        paddingLeft="10" paddingRight="10">
        <mx:DataGrid id="myGrid" dataProvider="{initDG}"
            width="100%" editable="true">
            <mx:columns>
                <mx:DataGridColumn dataField="Artist" resizable="true"/>
                <mx:DataGridColumn dataField="Album" resizable="true"/>
                <mx:DataGridColumn dataField="Price" resizable="true"/>
            </mx:columns>
        </mx:DataGrid>
    </mx:Panel>
</s:Application>
```

An editable component lets the user modify the data in the list control, and propagates the changes in the data back to the underlying data provider of the control. The DataGrid, List, and Tree controls have a property named `editable` that, if set to `true`, lets you edit the contents of a cell. By default, the list controls use a TextInput control as the item editor. That means when you select a cell in the list control, Flex opens a TextInput control that contains the current contents of the cell and lets you edit it, as the following image shows:



Artist	Album	Price
Pavement	Slanted and Enchanted	11.99
Pavement	Brighten the Corners	11.99

In this image, you use the default item editor to edit the price of the first album in the DataGrid control.

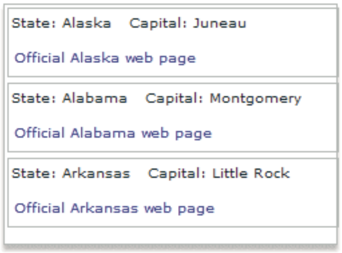
For more information on item editors, see “Advanced data display with MX item editors” on page 1048.

Using custom MX item renderers and item editors

To control the display of a list component, you write a custom item renderer or custom item editor. Your custom item renderers and item editors still use the underlying functionality of the list control, but let you control the display and editing of the data. Custom item renderers and item editors provide you with several advantages:

- You can create a more compelling user interface by replacing the display of text with a more user-intuitive appearance.
- You can combine multiple elements in a single list item, such as a label and an image.
- You can programmatically control the display of the data.

The following List control is a modification of the List control in the section “Default item rendering and cell editing in MX” on page 1007. In this example, you use a custom item renderer to display the state name, capital, and a URL to the state’s official web site in each list item:



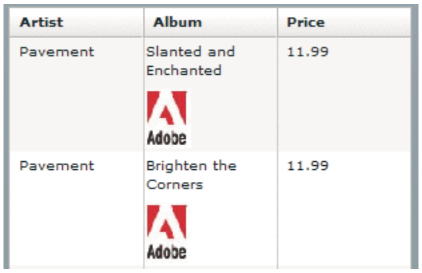
State: Alaska Capital: Juneau
Official Alaska web page

State: Alabama Capital: Montgomery
Official Alabama web page

State: Arkansas Capital: Little Rock
Official Arkansas web page

For the code for this example, see “Example: Using an item renderer with an MX List control” on page 1043.

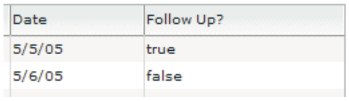
In the next image, you use a default item renderer for the first and third columns of the DataGrid control. You use a custom item renderer for the second column to display the album cover along with the album title in the DataGrid control.



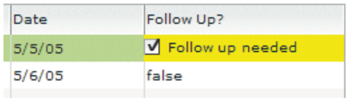
Artist	Album	Price
Pavement	Slanted and Enchanted	11.99
Pavement	Brighten the Corners	11.99

For the code for this example, see “Creating a complex inline item renderer or item editor” on page 1027.

Just as you can define a custom item renderer to control the display of a cell, you can use a custom item editor to edit the contents of the cell. For example, if the custom item renderer displays an image, you could define a custom item editor that uses a ComboBox control that lets users select an image from a list of available images. Or you could use a CheckBox control to let the user set a `true` or `false` value for a cell, as the right side of the following example shows:



Date	Follow Up?
5/5/05	true
5/6/05	false



Date	Follow Up?
5/5/05	☑ Follow up needed
5/6/05	false

For the code for this example, see “Creating a simple item editor component” on page 1035.

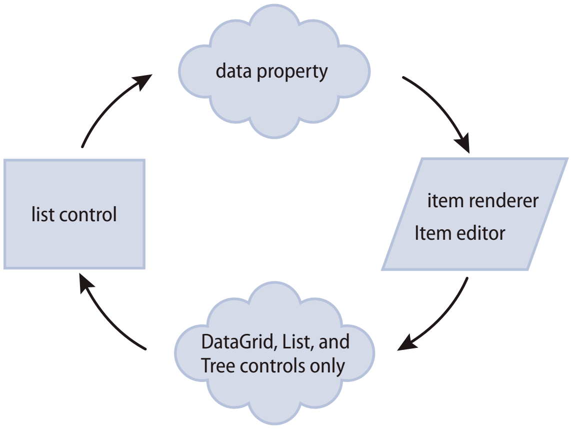
Using an item renderer does not imply that the control also has an item editor. Often, you do not allow your controls to be edited; that is, they are for display only.

You can also use an item editor without a corresponding item renderer. For example, you could display information such as a male/female or true/false as text using the default item renderer. But, you could then use a custom item editor with a ComboBox control that provides the user only a limited set of options to enter into the cell when changing the value.

MX item renderer and item editor architecture

In order for an item renderer or item editor to work with the contents of a list control, the list control must be able to pass information to the item renderer or item editor. An item editor must also be able to pass updated information back to the list control.

The following image shows the relationship of a list control to an item renderer or item editor:



To pass information to an item renderer or item editor, Flex sets the `data` property of the item renderer or item editor to the cell data. In the previous image, you can see the `data` property that is used to pass the data to the item renderer or item editor.

By default, an item editor can pass back a single value to the list control that becomes the new value of the edited cell. To return more than one value, you must write additional code to return the data back to the list control.

Any Flex component that you want to use in an item renderer or item editor, and that requires access to the cell data of the list control, must implement the IDataRenderer interface to support the `data` property. You can use additional components in an item renderer that do not support the `data` property, if those components do not need to access data passed from the list control.

The contents of the `data` property depend on the type of control, as the following table shows:

Control	Contents of the data property
DataGrid	Contains the data provider element for the entire row of the DataGrid control. That means if you use a different item renderer for each cell of the DataGrid control, each cell in a row receives the same information in the `data` property.
Tree List	Contains the data provider element for the node of the List or Tree control.
HorizontalList TileList	Contains the data provider element for the cell.
Menu	Contains the data provider element for the menu item.
MenuBar	Contains the data provider element for the menu bar item.

For more information about item editors, see “Advanced data display with MX item editors” on page 1048.

About MX item renderer and item editor interfaces

The Flex item renderer and item editor architecture is defined by several interfaces. Flex components that you can use as item renderers and item editors implement one or more of these interfaces. If you create your own custom component to use as an item renderer or item editor, your component must implement one or more of these interfaces, depending on how you intend to use it.

The following table describes the interfaces that you use with item renderers and item editors:

Interface	Use
IDataRenderer	Defines the `data` property used to pass information to an item renderer or item editor. All item renderers and item editors must implement this interface. Many Flex components implement this interface, such as the chart renderer classes and many Flex controls.
IDropInListItemRenderer	Defines the `listData` property required by drop-in item renderers and item editors. All drop-in item renderers and item editors must implement this interface. For more information, see "Creating MX drop-in item renderers and item editors" on page 1022. The `listData` property is of type BaseListData, where the BaseListData class has three subclasses: DataGridListData, ListData, TreeListData. The actual data type of the value of the `listData` property depends on the control using the drop-in item renderer or item editor. For a DataGrid control, the value is of type DataGridListData; for a List control, the value is of type ListData; and for a Tree control, the value is of type TreeListData.
IListItemRenderer	Defines the complete set of interfaces that an item renderer or item editor must implement to be used with any Flex control other than a Chart control. A renderer for a Chart control has to implement only the IDataRenderer interface. The set of interfaces includes the following: IDataRenderer, IFlexDisplayObject, ILayoutClient, IStyleable, and IUIComponent. The UIComponent class implements all of these interfaces, except the IDataRenderer interface. Therefore, if you create a custom item renderer or item editor as a subclass of the UIComponent class, you have to implement only the IDataRenderer interface. If you implement a drop-in item renderer or item editor as a subclass of the UIComponent class, you have to implement only the IDataRenderer and IDropInListItemRenderer interfaces.

Application layout with item renderers and item editors

All list controls, with the exception of the TileList and HorizontalList controls, ignore item renderers when calculating the default height and width of their contents. By default, item renderers are sized to the full width of a control, or the width of the column for a DataGrid control. Therefore, if you define a custom item renderer that requires a size other than its default, you should explicitly size the control.

Vertical controls such as the List and Tree controls use the `rowHeight` property to determine the default cell height. You can also set the `variableRowHeight` property to `true` if each row has a different height. Otherwise, Flex sets the height of each cell to 20 pixels.

For the HorizontalList control, Flex can use the value of the `columnWidth` property, if specified. For the TileList control, Flex uses the values of the `columnWidth` and `rowHeight` properties. If you omit these properties, Flex examines the control's data provider to determine the default size of each cell, including an item renderer, if specified. Otherwise, Flex sets the height and width of each cell to 50 pixels.

Creating an MX item renderer and item editor

One of the first decisions that you must make when using custom item renderers and item editors is how to implement them. Flex lets you define item renderers and item editors in three different ways:

Drop-in item renderers and item editors Insert a single component to define an item renderer or item editor. For more information, see "Using an MX drop-in item renderer or item editor" on page 1013.

Inline item renderers and item editors Define one or more components using child tags of the list control to define an item renderer or item editor. For more information, see "Using an MX inline item renderer or item editor" on page 1014.

Item renderer and item editor components Define an item renderer or item editor as a reusable component. For more information, see "Using a component as an MX item renderer or item editor" on page 1015.

The following sections describe each technique.

Using an MX drop-in item renderer or item editor

For simple item renderers and item editors, such as using a NumericStepper control to edit a field of a DataGrid control, you can use a drop-in item editor. A *drop-in item renderer* or *drop-in item editor* is a Flex component that you specify as the value of the `itemRenderer` or `itemEditor` property of a list control.

In the following example, you specify the NumericStepper control as the item editor for a column of the DataGrid control:

```
<?xml version="1.0"?>
<!-- itemRenderers\dropin\DropInNumStepper.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;

            [Bindable]
            private var myDP:ArrayCollection = new ArrayCollection([
                {label1:"Order #2314", quant:3, Sent:true},
                {label1:"Order #2315", quant:3, Sent:false}
            ]);
        ]]>
    </fx:Script>
    <mx:DataGrid id="myDG" dataProvider="{myDP}"
        variableRowHeight="true"
        editable="true" >
        <mx:columns>
            <mx:DataGridColumn dataField="label1" headerText="Order #"/>
            <mx:DataGridColumn dataField="quant"
                headerText="Qty"
                itemEditor="mx.controls.NumericStepper"
                editorDataField="value"
            />
        </mx:columns >
    </mx:DataGrid>
</s:Application>
```

In this example, when the user selects a cell of the column to edit it, Flex displays the NumericStepper control in that cell. Flex automatically uses the `data` property to populate the NumericStepper control with the current value of the column.

You use the `editorDataField` property to specify the property of the item editor that returns the new data for the cell. By default, the list control uses the `text` field of the TextInput control to supply the new value; therefore, the default value of the `editorDataField` property is `"text"`. In this example, you specify that the `value` field of the NumericStepper supplies the new value for the cell.

You can use only a subset of the Flex components as drop-in item renderers and item editors—those components that implement the IDropInListItemRenderer interface. For more information on using drop-in item renderers and item editors, and for a list of controls that support drop-in item renderers and item editors, see "Creating MX drop-in item renderers and item editors" on page 1022.

Using an MX inline item renderer or item editor

In the section "Using an MX drop-in item renderer or item editor" on page 1013, the example shows how easy it is to use drop-in item renderers and item editors. The only drawback to using them is that you cannot configure them. You can specify the drop-in item renderers and item editors only as the values of a list control property.

To create more flexible item renderers and item editors, you develop your item renderer or item editor as an inline component. In the next example, you modify the previous example to use a NumericStepper control as an inline item editor. With an inline item editor, you can configure the NumericStepper control just as if you used it as a stand-alone control.

```
<?xml version="1.0"?>
<!-- itemRenderers\inline\InlineNumStepper.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;

            [Bindable]
            private var myDP:ArrayCollection = new ArrayCollection([
                {label1:"Order #2314", quant:3, Sent:true},
                {label1:"Order #2315", quant:3, Sent:false}
            ]);
        ]]>
    </fx:Script>
    <mx:DataGrid id="myDG" dataProvider="{myDP}"
        variableRowHeight="true"
        editable="true" >
        <mx:columns>
            <mx:DataGridColumn dataField="label1" headerText="Order #"/>
            <mx:DataGridColumn dataField="quant" editorDataField="value" headerText="Qty">
                <mx:itemEditor>
                    <fx:Component>
                        <mx:NumericStepper stepSize="1" maximum="50"/>
                    </fx:Component>
                </mx:itemEditor>
            </mx:DataGridColumn>
        </mx:columns>
    </mx:DataGrid>
</s:Application>
```

In this example, you define the NumericStepper control as the item editor for the column, and specify a maximum value of 50 and a step size of 1 for the NumericStepper control.

For more information on creating inline item renderers and item editors, see “Creating MX inline item renderers and editors” on page 1025.

Using a component as an MX item renderer or item editor

One disadvantage of using drop-in and inline item renderers and editors is that you define the item renderer or editor in the application file; therefore, it is not reusable in another location in the application, or in another application. You can create a reusable item renderer or item editor as a Flex component, and then use that component anywhere in an application that requires the item renderer.

For example, the following code uses a NumericStepper control to define a custom item editor as an MXML component:

```
<?xml version="1.0"?>
<!-- itemRenderers\component\myComponents\NSEditor.mxml -->
<mx:NumericStepper xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    stepSize="1"
    maximum="50"/>
```

The custom MXML component defines the item editor as a NumericStepper control. In this example, the custom item editor is named NSEditor and is implemented as an MXML component in the NSEditor.mxml file. You place the file NSEditor.mxml in the myComponents directory beneath your main application directory.

You can then use this component anywhere in an application, as the following example shows:

```
<?xml version="1.0"?>
<!-- itemRenderers\component\MainNSEditor.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;

            [Bindable]
            private var myDP:ArrayCollection = new ArrayCollection([
                {label1:"Order #2314", quant:3, Sent:true},
                {label1:"Order #2315", quant:3, Sent:false}
            ]);
        ]]>
    </fx:Script>
    <mx:DataGrid id="myDG" dataProvider="{myDP}"
            variableRowHeight="true"
            editable="true" >
        <mx:columns>
            <mx:DataGridColumn dataField="label1"
                headerText="Order #"/>
            <mx:DataGridColumn dataField="quant"
                itemEditor="myComponents.NSEditor"
                editorDataField="value"/>
        </mx:columns >
    </mx:DataGrid>
</s:Application>
```

When the user selects a cell in the quant column of the DataGrid control, Flex displays a NumericStepper control with the current cell value.

You might have several locations in your application where users can modify a numeric value. You defined this item editor as a custom component; therefore, you can reuse it anywhere in your application.

For more information on creating item renderers and item editors as components, see “Creating MX item renderers and item editor components” on page 1033.

Using editable controls in an MX item renderer

Item renderers do not impose restrictions on the types of Flex components that you can use in them. For example, you can use controls, such as the Label, LinkButton, Button, and Text controls, to display data, but these controls do not let the user modify the contents of the control.

Or you can use controls such as the CheckBox, ComboBox, and TextInput controls that both display data and let users interact with the control to modify or change it. For example, you could use a CheckBox control to display a selected (`true` value) or unselected (`false` value) cell in a DataGrid control.

When the user selects the cell of the DataGrid control that contains the CheckBox control, the user can interact with the control to change its state. To the user, it appears that the DataGrid control is editable.

However, an item renderer by default is not connected to the editing mechanism of the list control; it does not propagate changes to the list control's data provider, nor does it dispatch an event when the user modifies the cell. Although the list control appears to the user to be editable, it really is not.

In another example, the user changes the value of the CheckBox control, and then sorts the DataGrid column. But the DataGrid sorts the cell by the value in the data provider, not the value in the CheckBox control, so the user perceives that the sort works incorrectly.

You can manage this situation in several ways, including the following:

- In your item renderer, do not use controls that let users modify them (CheckBox, ComboBox, and others).
- Create custom versions of these controls to prohibit user interaction with them.
- Use the `rendererIsEditor` property of the list control to specify that the item renderer is also an item editor. For more information, see "Example: Using an item renderer as an item editor" on page 1066.
- Write your own code for the item renderer and hosting control to pass data back from the item renderer when you do let users interact with it.

Setting the itemRenderer or itemEditor property in ActionScript

The `itemRenderer` and `itemEditor` properties are of type IFactory. When you set these properties in MXML, the MXML compiler automatically casts the property value to the type ClassFactory, a class that implements the IFactory interface.

When you set these properties in ActionScript, you must explicitly cast the property value to ClassFactory, as the following example shows:

```
<?xml version="1.0"?>
<!-- itemRenderers\list\AppListStateRendererEditorAS.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
            import mx.core.ClassFactory;

            // Cast the value of the itemRenderer property
            // to ClassFactory.
            public function initCellEditor():void {
                myList.itemRenderer=new ClassFactory(RendererState);
            }
        ]]>
    </fx:Script>
    <mx:List id="myList" variableRowHeight="true"
            height="180" width="250"
            initialize="initCellEditor();">
        <mx:dataProvider>
            <fx:Object label="Alaska"
                data="Juneau"
                webPage="http://www.state.ak.us/"/>
            <fx:Object label="Alabama"
                data="Montgomery"
                webPage="http://www.alabama.gov/" />
            <fx:Object label="Arkansas"
                data="Little Rock"
                webPage="http://www.state.ar.us/"/>
        </mx:dataProvider>
    </mx:List>
</s:Application>
```

Shown below is the code for the RenderState.mxml item renderer:

```
<?xml version="1.0"?>
<!-- itemRenderers\list\RendererState.mxml -->
<mx:VBox xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
            // Import Event and URLRequest classes.
            import flash.events.Event;
            import flash.net.URLRequest;

            private var u:URLRequest;

            // Event handler to open URL using navigateToURL().
            private function handleClick(eventObj:Event):void {
                u = new URLRequest(data.webPage);
                navigateToURL(u);
            }
        ]]>
    </fx:Script>

    <mx:HBox >
        <!-- Use Label controls to display state and capital names. -->
        <mx:Label id="State" text="State: {data.label}"/>
        <mx:Label id="Statecapital" text="Capital: {data.data}" />
    </mx:HBox>
    <!-- Define the Link control to open a URL. -->
    <mx:LinkButton id="webPage" label="Official {data.label} web page"
        click="handleClick(event);" color="blue"  />
</mx:VBox>
```

About the MX item renderer and item editor life cycle

Flex creates instances of item renderers and item editors as needed by your application for display and measurement purposes. Therefore, the number of instances of an item renderer or item editor in your application is not necessarily directly related to the number of visible item renderers. Also, if the list control is scrolled or resized, a single item renderer instance may be reused to represent more than one data item. Thus, you should not make assumptions about how many instances of your item renderer and item editor are active at any time.

Because Flex can reuse an item renderer, ensure that you fully define its state. For example, you use a CheckBox control in an item renderer to display a `true` (checked) or `false` (unchecked) value based on the current value of the `data` property. A common mistake is to assume that the CheckBox control in the item renderer is always in its default state of unchecked. Developers then write an item renderer to inspect the `data` property for a value of `true` and set the CheckBox control to checked if found.

However, you must take into account that the CheckBox may already be checked. So, you must inspect the `data` property for a value of `false`, and explicitly uncheck the control if it is checked.

Accessing the listData property

If a component implements the IDropInListItemRenderer interface, you can use its `listData` property to obtain information about the data passed to the component when you use the component in an item renderer or item editor. The `listData` property is of type BaseListData, where the BaseListData class defines the following properties:

Property	Description
owner	A reference to the list control that uses the item renderer or item editor.
rowIndex	The index of the row of the DataGrid, List, or Tree control relative to the currently visible rows of the control, where the first row is at an index of 1.
label	The text representation of the item data based on the List class's itemToLabel() method.

The BaseListData class has three subclasses: DataGridListData, ListData, TreeListData that define additional properties. For example, the DataGridListData class adds the columnIndex and dataField properties that you can access from an item renderer or item editor.

The data type of the value of the listData property depends on the control that uses the item renderer or item editor. For a DataGrid control, the value is of type DataGridListData; for a List control, the value is of type ListData; and for a Tree control, the value is of type TreeListData.

The TextArea control is one of the Flex controls that implements the IDropInListItemRenderer interface The item renderer in the following example uses the listData property of the TextArea control to display the row and column of each item renderer in the DataGrid control:

```
<?xml version="1.0"?>
<!-- itemRenderers\dataGrid\myComponents\RendererDGListData.mxml -->
<mx:TextArea xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    preinitialize="initTA();">
    <fx:Script>
        <![CDATA[

            import mx.controls.dataGridClasses.DataGridListData;
            import flash.events.Event;

            public function initTA():void {
                addEventListener("dataChange", handleDataChanged);
            }
            public function handleDataChanged(event:Event):void {
                // Cast listData to DataGridListData.
                var myListData:DataGridListData =
                    DataGridListData(listData);

                // Access information about the data passed
                // to the cell renderer.
                text="row index: " + String(myListData.rowIndex) +
                    " column index: " + String(myListData.columnIndex);
            }
        ]]>
    </fx:Script>
</mx:TextArea>
```

Because you use this item renderer in a DataGrid control, the data type of the value of the listData property is DataGridListData. You use the dataChange event in this example to set the contents of the TextArea control every time the data property changes.

The DataGrid control in the following example uses this item renderer to display the column and row index of each cell of the DataGrid control:

```
<?xml version="1.0"?>
<!-- itemRenderers\dataGrid\MainDGListDataRenderer.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;

            [Bindable]
            public var initDG:ArrayCollection = new ArrayCollection([
                { Company: 'Acme', Contact: 'Bob Jones',
                    Phone: '413-555-1212', Date: '5/5/05'},
                { Company: 'Allied', Contact: 'Jane Smith',
                    Phone: '617-555-3434', Date: '5/6/05'}
            ]);
        ]]>
    </fx:Script>
    <mx:Panel paddingTop="10" paddingBottom="10"
        paddingLeft="10" paddingRight="10" >
        <mx:DataGrid id="myGrid" dataProvider="{initDG}"
                variableRowHeight="true">
            <mx:columns>
                <mx:DataGridColumn dataField="Company"
                    itemRenderer="myComponents.RendererDGListData"/>
                <mx:DataGridColumn dataField="Contact"
                    itemRenderer="myComponents.RendererDGListData"/>
                <mx:DataGridColumn dataField="Phone"
                    itemRenderer="myComponents.RendererDGListData"/>
                <mx:DataGridColumn dataField="Date"
                    itemRenderer="myComponents.RendererDGListData"/>
            </mx:columns>
        </mx:DataGrid>
    </mx:Panel>
</s:Application>
```

Handling data binding warnings from the compiler

Many of the following examples, and those in “Advanced data display with MX item editors” on page 1048, define the application data as an ArrayCollection of Objects. However, you might get compiler warning for these examples because the Object class does not support data binding. That does not matter with these examples because the data is static.

If your data is dynamic, and you want it to support data binding, you can instead define your own data class that supports binding. For example, you could create the following subclass of Object that supports data binding, and use it instead:

```
package
{
    [Bindable]
    public class MyBindableObj extends Object
    {
        public function MyBindableObj()  {
            super();
        }

        public var Artist:String = new String();

        public var Album:String = new String();

        public var Price:Number = new Number();

        public var Cover:String = new String();
    }
}
```

By inserting the `[Bindable]` metadata tag before the class definition, you specify that all public properties support data binding. For more information on data binding, see “Data binding” on page 299.

Creating MX drop-in item renderers and item editors

Several MX controls are designed to work as item renderers and item editors. This lets you specify these controls as values of the `itemRenderer` or `itemEditor` property. When you specify one of these controls as a property value, it is called a drop-in item renderer or drop-in item editor.

To use a component as a drop-in item renderer or drop-in item editor, a component must implement the IDropInListItemRenderer interface. The following controls implement the IDropInListItemRenderer interface, making them usable directly as a drop-in item renderer or drop-in item editor:

- Button
- CheckBox
- DateField
- Image
- Label
- NumericStepper
- Text
- TextArea
- TextInput

You can define your own components for use as drop-in item renderers or drop-in item editors. The only requirement is that they, too, implement the IDropInListItemRenderer interface.

Using MX drop-in item renderers and item editors

When you use a control as a drop-in item renderer, Flex sets the control’s default property to the current value of the cell. When you use a control as an item editor, the initial value of the cell becomes the current value of the control. Any edits made to the cell are copied back to the data provider of the list control.

The following table lists the MX components that you can use as drop-in item renderers and item editors, and the default property of the component:

Control	Default property	Notes
Button	`selected`	Cannot specify a label for the Button control.
CheckBox	`selected`	If used as a drop-in item renderer in a Tree control, the Tree displays only check boxes with no text.
DateField	`selectedDate`	Requires that the data provider of the list control has a field of type Date.
Image	`source`	Set an explicit row height by using the `rowHeight` property, or set the `variableRowHeight` property to `true` to size the row correctly.
Label	`text`	
NumericStepper	`value`	
Text	`text`	
TextArea	`text`	
TextInput	`text`	

In the following example, you use the NumericStepper, DateField, and CheckBox controls as the drop-in item renderers and item editors for a DataGrid control:

```
<?xml version="1.0"?>
<!-- itemRenderers\inline\CBInlineCellEditor.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;

            [Bindable]
            private var myDP:ArrayCollection = new ArrayCollection([
                {label1:"Order #2314", contact:"John Doe",
                    quant:3, solddate:new Date(2005, 0, 1), Sent:true},
                {label1:"Order #2315", contact:"Jane Doe",
                    quant:3, solddate:new Date(2005, 0, 5), Sent:false}
            ]);
        ]]>
    </fx:Script>
    <mx:DataGrid id="myDG"
            dataProvider="{myDP}"
            variableRowHeight="true"
            width="500" height="250"
            editable="true">
        <mx:columns>
            <mx:DataGridColumn dataField="label1"
                headerText="Order #"
                editable="false"/>
            <mx:DataGridColumn dataField="quant"
                headerText="Quantity"
                itemEditor="mx.controls.NumericStepper"
                editorDataField="value"/>
            <mx:DataGridColumn dataField="solddate"
                headerText="Date"
                itemRenderer="mx.controls.DateField"
                rendererIsEditor="true"
                editorDataField="selectedDate"/>
            <mx:DataGridColumn dataField="Sent"
                itemRenderer="mx.controls.CheckBox"
                rendererIsEditor="true"
                editorDataField="selected"/>
        </mx:columns >
    </mx:DataGrid>
</s:Application>
```

To determine the field of the data provider used to populate the drop-in item renderer, Flex uses the value of the `dataField` property for the `<mx:DataGridColumn>` tag. In this example, you do the following:

- You set the `dataField` property of the second column to `quant`, and define the NumericStepper control as the item editor. Therefore, the column displays the cell value as text, and opens the NumericStepper control when you select the cell to edit it. The NumericStepper control displays the current value of the cell, and any changes you make to it are copied back to the data provider of the DataGrid control.
- You set the `dataField` property of the third column to `solddate`, and define the DateField control as the item renderer and item editor by setting the `rendererIsEditor` property to `true`. The data provider defines the data as an object of type Date, which is required to use the DateField control as the item renderer or item editor. Therefore, the column displays the date value using the DateField control, and also uses the DateField control to edit the cell value.
- You set the `dataField` property of the fourth column to `Sent`, and define the CheckBox control as the item renderer and item editor. Typically, you use `itemEditor` property to specify a different class as the item editor, and specify to use the same control as both the item renderer and item editor by setting the `rendererIsEditor` property to `true`. The CheckBox control displays a check mark in the cell if the Sent field for the row is set to `true`, and an empty check box if the field is set to `false`.

  For more information on using an item renderer as an item editor, see "Creating an editable cell in MX" on page 1049.

***Note:** When you use a CheckBox control as a drop-in item renderer, the control appears flush against the left cell border. To center a CheckBox control, or any drop-in item renderer, create a custom item renderer that wraps the control in a container, such as the HBox container. However, the addition of the container can affect application performance when you are rendering large amounts of data. For more information, see "Creating MX item renderers and item editor components" on page 1033.*

When you use the Image control as a drop-in item renderer, you usually have to set the row height to accommodate the image, as the following example shows:

```
<?xml version="1.0"?>
<!-- itemRenderers\DGDropInImageRenderer.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx" >

    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;

            [Bindable]
            private var initDG:ArrayCollection = new ArrayCollection([
                {Artist:'Pavement', Album:'Slanted and Enchanted',
                    Price:11.99, Cover:'../assets/slanted.jpg'},
                {Artist:'Pavement', Album:'Brighten the Corners',
                    Price:11.99, Cover:'../assets/brighten.jpg'}
            ]);
        ]]>
    </fx:Script>
    <mx:DataGrid id="myGrid" dataProvider="{initDG}" rowHeight="50">
        <mx:columns>
            <mx:DataGridColumn dataField="Artist"/>
            <mx:DataGridColumn dataField="Album"/>
            <mx:DataGridColumn dataField="Cover"
                itemRenderer="mx.controls.Image"/>
            <mx:DataGridColumn dataField="Price"/>
        </mx:columns>
    </mx:DataGrid>
</s:Application>
```

In this example, you use the Image control to display the album cover in a cell of the DataGrid control.

Requirements of a drop-in item renderer in a List control

When you use the `itemRenderer` property of the List control to specify a drop-in item renderer, the data in the data provider must be of the type expected by the item renderer control. For example, if you use an Image control as a drop-in item renderer, the data provider for the List control must have String data in the field.

Creating MX inline item renderers and editors

You define inline item renderers and item editors in the MXML definition of a component. Inline item renderers and item editors give you complete control over item rendering and cell editing.

Creating a simple inline item renderer or item editor

A simple inline item renderer contains a single control that supports the `data` property. Flex automatically copies the current cell data to the item renderer, as the following example shows:

```
<?xml version="1.0"?>
<!-- itemRenderers\InlineImageRenderer.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx" >

    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;

            [Bindable]
            private var initDG:ArrayCollection = new ArrayCollection([
                {Artist:'Pavement', Album:'Slanted and Enchanted',
                    Price:11.99, Cover: '../assets/slanted.jpg'},
                {Artist:'Pavement', Album:'Brighten the Corners',
                    Price:11.99, Cover: '../assets/brighten.jpg'}
            ]);
        ]]>
    </fx:Script>
    <mx:DataGrid id="myGrid" dataProvider="{initDG}" rowHeight="50">
        <mx:columns>
            <mx:DataGridColumn dataField="Artist"/>
            <mx:DataGridColumn dataField="Album"/>
            <mx:DataGridColumn dataField="Cover">
                <mx:itemRenderer>
                    <fx:Component>
                        <mx:Image height="45"/>
                    </fx:Component>
                </mx:itemRenderer>
            </mx:DataGridColumn>
            <mx:DataGridColumn dataField="Price"/>
        </mx:columns>
    </mx:DataGrid>
</s:Application>
```

In this example, you use an Image control to display the album cover.

A simple inline item editor contains a single control that supports the `data` property. Flex automatically copies the current cell data to the item renderer or item editor, and copies the new cell data back to the list control based on the value of the `editorDataField` property, as the following example item editor shows:

```
<?xml version="1.0"?>
<!-- itemRenderers\inline\InlineNumStepper.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;

            [Bindable]
            private var myDP:ArrayCollection = new ArrayCollection([
                {label1:"Order #2314", quant:3, Sent:true},
                {label1:"Order #2315", quant:3, Sent:false}
            ]);
        ]]>
    </fx:Script>
    <mx:DataGrid id="myDG" dataProvider="{myDP}"
        variableRowHeight="true"
        editable="true" >
        <mx:columns>
            <mx:DataGridColumn dataField="label1" headerText="Order #"/>
            <mx:DataGridColumn dataField="quant" editorDataField="value" headerText="Qty">
                <mx:itemEditor>
                    <fx:Component>
                        <mx:NumericStepper stepSize="1" maximum="50"/>
                    </fx:Component>
                </mx:itemEditor>
            </mx:DataGridColumn>
        </mx:columns>
    </mx:DataGrid>
</s:Application>
```

In this example, you return the new cell value by using the value property of the NumericStepper control.

Creating a complex inline item renderer or item editor

A complex item renderer or item editor defines multiple controls. For example, the section "Default item rendering and cell editing in MX" on page 1007 showed a DataGrid control that displayed information about albums by using three text fields. You could add a visual element to your DataGrid control to make it more compelling. To do that, you modify the data provider so that it contains a reference to a JPEG image of the album cover.

Rather than displaying the album name and album image in separate cells of the DataGrid control, you can use an inline item renderer to make them appear in a single cell, as the following example shows:

```
<?xml version="1.0"?>
<!-- itemRenderers\InlineDGRenderer.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Script>
        <![CDATA[

            import mx.collections.ArrayCollection;

            // Variable in the Application scope.
            public var localVar:String="Application localVar";

            // Data includes URL to album cover.
            [Bindable]
            private var initDG:ArrayCollection = new ArrayCollection([
                {Artist:'Pavement', Album:'Slanted and Enchanted',
                    Price:11.99, Cover:'../assets/slanted.jpg'},
                {Artist:'Pavement', Album:'Brighten the Corners',
                    Price:11.99, Cover:'../assets/brighten.jpg'}
            ]);
        ]]>
    </fx:Script>
    <mx:DataGrid id="myGrid" dataProvider="{initDG}"
            variableRowHeight="true">
        <mx:columns>
                <mx:DataGridColumn dataField="Artist"/>
                <mx:DataGridColumn dataField="Album">
                    <mx:itemRenderer>
                        <fx:Component>
                            <mx:VBox>
                                <mx:Text id="albumName"
                                    width="100%" text="{data.Album}"/>
                                <mx:Image id="albumImage"
                                    height="45" source="{data.Cover}"/>
                            </mx:VBox>
                        </fx:Component>
                    </mx:itemRenderer>
                </mx:DataGridColumn>
                <mx:DataGridColumn dataField="Price"/>
        </mx:columns>
    </mx:DataGrid>
</s:Application>
```

In the preceding example, you define three columns in the DataGrid control, and assign your item renderer to the second column. For an image that shows the output of this application, see “Using custom MX item renderers and item editors” on page 1009.

Notice that the Text and Image controls in the item renderer both use the `data` property to initialize their values. This is necessary because you defined multiple controls in the item renderer, and Flex cannot automatically determine which data element in the data provider is associated with each control of the item renderer.

Even if the top-level container of an inline item renderer has a single child control, you must use the `data` property to initialize the child control, as the following example shows:

```
<mx:DataGridColumn dataField="Cover">
    <mx:itemRenderer>
        <fx:Component>
            <mx:VBox horizontalAlign="center">
                <mx:Image height="45" source="{data.Cover}"/>
            </mx:VBox>
        </fx:Component>
    </mx:itemRenderer>
</mx:DataGridColumn>
```

In the preceding example, you make the Image control a child of a VBox container so that you can align the image in the cell. Because the Image control is now a child of the VBox container, you must initialize it by using the `data` property.

You can define multiple controls in a complex inline item editor, which lets you edit multiple values of the data provider for the list control. Alternatively, you can define a complex inline item editor so it returns a value other than a String. For more information, see “Advanced data display with MX item editors” on page 1048.

Items allowed in an inline component

The only restriction on what you can and cannot do in an inline item renderer or editor is that you cannot create an empty `<fx:Component></fx:Component>` tag. For example, you can combine effect and style definitions in an inline item renderer or editor along with your rendering and editing logic.

You can include the following items in an inline item renderer or editor:

- Binding tags
- Effect tags
- Metadata tags
- Model tags
- Scripts tags
- Service tags
- State tags
- Styles tags
- XML tags
- `id` attributes, except for the top-most component

Using the Component tag

You use the `<fx:Component>` tag to define an inline item renderer or item editor in an MXML file.

Defining the scope in an Component tag

The `<fx:Component>` tag defines a new scope in an MXML file, where the local scope of the item renderer or item editor is defined by the MXML code block delimited by the `<fx:Component>` and `</fx:Component>` tags. To access elements outside of the local scope of the item renderer or item editor, you prefix the element name with the `outerDocument` keyword.

For example, you define one variable named localVar in the scope of the main application, and another variable with the same name in the scope of the item renderer. From within the item renderer, you access the application’s localVar by prefixing it with `outerDocument` keyword, as the following example shows:

```
<?xml version="1.0"?>
<!-- itemRenderers\InlineDGImageScope.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;

            // Variable in the Application scope.
            [Bindable]
            public var localVar:String="Application localVar";

            // Data includes URL to album cover.
            [Bindable]
            private var initDG:ArrayCollection = new ArrayCollection([
                { Artist:'Pavement', Album:'Slanted and Enchanted',
                    Price:11.99, Cover:'../assets/slanted.jpg'},
                { Artist:'Pavement', Album:'Brighten the Corners',
                    Price:11.99, Cover:'../assets/brighten.jpg'}
            ]);
        ]]>
    </fx:Script>
    <mx:DataGrid id="myGrid" dataProvider="{initDG}" width="100%"
            variableRowHeight="true">
        <mx:columns>
            <mx:DataGridColumn dataField="Artist"/>
            <mx:DataGridColumn dataField="Album"/>
            <mx:DataGridColumn dataField="Cover">
                <mx:itemRenderer>
                  <fx:Component>
                    <mx:VBox>
                        <fx:Script>
                          <![CDATA[
                            // Variable in the renderer scope.
                            [Bindable]
                            public var localVar:String="Renderer localVar";
                          ]]>
                         </fx:Script>
                         <mx:Text id="albumName"
                            width="100%"
                            selectable="false"
                            text="{data.Album}"/>
                         <mx:Image id="albumImage"
                            height="45"
                            source="{data.Cover}"/>
                         <mx:TextArea
                            text="{'Renderer localVar= ' + localVar}"/>
                         <mx:TextArea
                            text="{'Application localVar= ' + outerDocument.localVar}"/>
                    </mx:VBox>
                  </fx:Component>
                </mx:itemRenderer>
            </mx:DataGridColumn>
            <mx:DataGridColumn dataField="Price"/>
        </mx:columns>
    </mx:DataGrid>
</s:Application>
```

One use of the `outerDocument` keyword is to initialize the data provider of a control in the inline item editor. For example, you can use a web service, or other mechanism, to pass data into the application, such as the list of U.S. states. You can then initialize all ComboBox controls that are used as item editors from a single property of the application that contains the list of U.S. states.

Specifying a class name to the inline component

You can optionally specify the `className` property of the `<fx:Component>` tag to explicitly name the class generated by Flex for the inline component. By naming the class, you define a way to reference the elements in the inline component.

Creating a reusable inline item renderer or item editor

Rather than defining an inline item renderer or item editor in the definition of a component, you can define a reusable inline item renderer or item editor for use in multiple locations in your application.

For example, you use the `<fx:Component>` tag to define an inline item editor that consists of a ComboBox control for selecting the state portion of an address. You then use that inline item editor in two different DataGrid controls, as the following example shows:

```
<?xml version="1.0"?>
<!-- itemRenderers\inline\InlineDGEditorCBReUse.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    width="700" >

    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;

            [Bindable]
            public var initDG:ArrayCollection = new ArrayCollection([
                {Company: 'Acme', Contact: 'Bob Jones',
                    Phone: '413-555-1212', City: 'Boston', State: 'MA'},
                {Company: 'Allied', Contact: 'Jane Smith',
                    Phone: '617-555-3434', City: 'SanFrancisco', State: 'CA'}
            ]);
            [Bindable]
            public var initDG2:ArrayCollection = new ArrayCollection([
                {Company: 'MyCo', Contact: 'Stan Stanley',
                    Phone: '413-555-5555', City: 'Boston', State: 'MA'},
                {Company: 'YourCo', Contact: 'Dave Davis',
                    Phone: '617-555-1212', City: 'SanFrancisco', State: 'CA'}
            ]);
        ]]>
    </fx:Script>
    <fx:Declarations>
        <fx:Component id="inlineEditor">
            <mx:ComboBox >
                <mx:dataProvider>
                    <fx:String>AL</fx:String>
                    <fx:String>AK</fx:String>
                    <fx:String>AR</fx:String>
                    <fx:String>CA</fx:String>
                    <fx:String>MA</fx:String>
                </mx:dataProvider>
            </mx:ComboBox>
        </fx:Component>
    </fx:Declarations>
    <mx:DataGrid id="myGrid"
        variableRowHeight="true"
        dataProvider="{initDG}"
        editable="true" >
        <mx:columns>
            <mx:DataGridColumn dataField="Company" editable="false"/>
            <mx:DataGridColumn dataField="Contact"/>
            <mx:DataGridColumn dataField="Phone"/>
            <mx:DataGridColumn dataField="City"/>
            <mx:DataGridColumn dataField="State"
                width="150"
                editorDataField="selectedItem"
                itemEditor="{inlineEditor}"/>
        </mx:columns>
    </mx:DataGrid>

    <mx:DataGrid id="myGrid2"
        variableRowHeight="true"
        dataProvider="{initDG2}"
        editable="true">
        <mx:columns>
            <mx:DataGridColumn dataField="Company" editable="false"/>
            <mx:DataGridColumn dataField="Contact"/>
            <mx:DataGridColumn dataField="Phone"/>
            <mx:DataGridColumn dataField="City"/>
            <mx:DataGridColumn dataField="State"
                width="150"
                editorDataField="selectedItem"
                itemEditor="{inlineEditor}"/>
        </mx:columns>
    </mx:DataGrid>
</s:Application>
```

In this example, you specify the `id` property of the inline item editor defined by the `<fx:Component>` tag. You then use data binding to specify the editor as the value of the `itemEditor` property for the two DataGrid controls.

The inline item editor or item renderer defined in the `<fx:Component>` tag appears only where you use it in the DataGrid control; otherwise, Flex ignores it when laying out your application.

Creating MX item renderers and item editor components

Defining a custom item renderer or item editor by using an MXML component gives you greater flexibility and functionality than using a drop-in item renderer or item editor. Many of the rules for defining item renderers and item editors as custom components are the same as for using inline item renderers and editors. For more information, see "Creating MX inline item renderers and editors" on page 1025.

For more information on working with custom components, see *"Custom Flex components" on page 2356*.

Creating an item renderer component

The section "Default item rendering and cell editing in MX" on page 1007 shows a DataGrid control that displays information about albums by using three text fields. You could add a visual element to your DataGrid control to make it more compelling. To do that, you modify the data provider so that it contains a URL for a JPEG image of the album cover.

The default item renderer for a DataGrid control displays data as text. To get the DataGrid control to display the image of the album cover, you use the custom item renderer defined in the RendererDGImage.mxml file, as the following example shows:

```
<?xml version="1.0"?>
<!-- itemRenderers\myComponents\RendererDGImage.mxml -->
<mx:HBox xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    horizontalAlign="center" >
    <mx:Image id="albumImage" height="175" source="{data.Cover}"/>
</mx:HBox>
```

The item renderer contains an Image control in an HBox container. The HBox container specifies to center the image in the container; otherwise, the image appears flush left in the cell. The Image control specifies the height of the image as 75 pixels. By default, an image has a height of 0 pixels; therefore, if you omit the height, the image does not appear.

You use data binding to associate fields of a `data` property with the controls in an item renderer or item editor. In this example, the `data` property that is passed to the item renderer contains the element of the data provider for the entire row of the DataGrid control. You then bind the Cover field of the `data` property to the Image control.

The following example illustrates using a custom item renderer with the DataGrid control:

```
<?xml version="1.0"?>
<!-- itemRenderers\MainDGImageRenderer.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;

            [Bindable]
            private var initDG:ArrayCollection = new ArrayCollection([
                {Artist:'Pavement', Album:'Slanted and Enchanted',
                    Price:11.99, Cover: '../assets/slanted.jpg'},
                {Artist:'Pavement', Album:'Brighten the Corners',
                    Price:11.99, Cover: '../assets/brighten.jpg'}
            ]);
        ]]>
    </fx:Script>
    <mx:DataGrid id="myGrid"
        dataProvider="{initDG}"
        variableRowHeight="true">
        <mx:columns>
            <mx:DataGridColumn dataField="Artist"/>
            <mx:DataGridColumn dataField="Album"/>
            <mx:DataGridColumn dataField="Cover"
                itemRenderer="myComponents.RendererDGImage"/>
            <mx:DataGridColumn dataField="Price"/>
        </mx:columns>
    </mx:DataGrid>
</s:Application>
```

The DataGrid control contains a column for the album cover that uses the `itemRenderer` property to specify the name of the MXML file that contains the item renderer for that column. Now, when you run this example, the DataGrid control uses your custom item renderer for the Cover column to display an image of the album cover.

Rather than having the album name and album image in separate cells of the DataGrid control, you can use an item renderer to make them appear in a single cell, as the following example shows:

```
<?xml version="1.0"?>
<!-- itemRenderers\myComponents\RendererDGTitleImage.mxml -->
<mx:VBox xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    horizontalAlign="center" height="75">
    <mx:Text id="albumName"
        width="100%"
        selectable="false"
        text="{data.Album}"/>
    <mx:Image id="albumImage"
        source="{data.Cover}"/>
</mx:VBox>
```

You save this item renderer to the RendererDGTitleImage.mxml file. The DataGrid control in the main application references the item renderer, as the following example shows:

```
<?xml version="1.0"?>
<!-- itemRenderers\MainDGTitleRenderer.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;

            [Bindable]
            private var initDG:ArrayCollection = new ArrayCollection([
                {Artist:'Pavement', Album:'Slanted and Enchanted',
                    Price:11.99, Cover: '../assets/slanted.jpg'},
                {Artist:'Pavement', Album:'Brighten the Corners',
                    Price:11.99, Cover: '../assets/brighten.jpg'}
            ]);
        ]]>
    </fx:Script>
    <mx:DataGrid id="myGrid"
        dataProvider="{initDG}"
        variableRowHeight="true">
        <mx:columns>
            <mx:DataGridColumn dataField="Artist" />
            <mx:DataGridColumn dataField="Album"
                itemRenderer="myComponents.RendererDGTitleImage" />
            <mx:DataGridColumn dataField="Price"  />
        </mx:columns>
    </mx:DataGrid>
</s:Application>
```

In the preceding example, you define three columns in the DataGrid control, and assign your item renderer to the second column. For an image that shows the output of this application, see "Using custom MX item renderers and item editors" on page 1009.

Creating a simple item editor component

A simple item editor component defines a single control that you use to edit a cell, and returns a single value to the list control. For an example of a simple item editor component, see "Using a component as an MX item renderer or item editor" on page 1015.

A complex item editor can contain multiple components, or can return something other than a single value to the list control. For more information, see “Advanced data display with MX item editors” on page 1048.

Overriding the data property

All components that you use in a custom item renderer or item editor that require access to the data passed to the renderer must implement the mx.core.IDataRenderer interface to define the `data` property. All Flex containers and many Flex components support this property.

Classes implement the mx.core.IDataRenderer interface by defining the `data` property as a setter and getter method, with the following signature:

```
override public function set data(value:Object):void
public function get data():Object
```

In the setter method, *value* is the `data` property passed to the item renderer.

If you define a custom component and you want to support the `data` property, your component must implement the mx.core.IDataRenderer interface. If your component is a subclass of a class that already implements the mx.core.IDataRenderer interface, you do not have to reimplement the interface.

To add programmatic logic to the controls in your item renderer or item editor that already implement the `data` property, you can override the setter or getter method for the `data` property. Typically, you override the setter method so that you can perform some operation based on the value that is passed to it.

For example, the following DataGrid control uses `true` and `false` for the values of the SalePrice field of the data provider. Although you could display these values in your DataGrid control, you can create a more compelling DataGrid control by displaying images instead, as the following item renderer shows:

```
<?xml version="1.0"?>
<!-- itemRenderers\component\myComponents\RendererDGImageSelect.mxml -->
<mx:HBox xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    horizontalAlign="center">
    <fx:Script>
        <![CDATA[
            import mx.events.FlexEvent;
            [Embed(source="saleIcon.jpg")]
            [Bindable]
            public var sale:Class;

            [Embed(source="noSaleIcon.jpg")]
            [Bindable]
            public var noSale:Class;
            override public function set data(value:Object):void {
                if(value != null)  {
                    super.data = value;
                    if (value.SalePrice == true) onSale.source=new sale();
                    else onSale.source=new noSale();
                }
                // Dispatch the dataChange event.
                dispatchEvent(new FlexEvent(FlexEvent.DATA_CHANGE));
            }
        ]]>
    </fx:Script>
    <mx:Image id="onSale" height="20"/>
</mx:HBox>
```

In this example, you override the setter method for the HBox container. In the override, use super.data to set the data property for the base class, and then set the source property of the Image control based on the value of the SalePrice field. If the field is true, which indicates that the item is on sale, you display one icon. If the item is not on sale, you display a different icon.

The override also dispatches the dataChange event to indicate that the data property has changed. You typically dispatch this event from the setter method.

About using the creationComplete and dataChange events

Flex dispatches the creationComplete event once for a component after the component is created and initialized. Many custom components define an event listener for the creationComplete event to handle any postprocessing tasks that must be performed after the component is completely created and initialized.

However, although for an item renderer or item editor, Flex might reuse an instance of the item renderer or item editor, a reused instance of an item renderer or item editor does not redispatch the creationComplete event. Instead, you can use the dataChange event with an item renderer or item editor. Flex dispatches the dataChange event every time the data property changes. The example in the section "Accessing the listData property" on page 1019 uses the dataChange event to update the TextArea in an item renderer for a DataGrid control.

Creating an MX item renderer in ActionScript

Although you commonly create item renderers and editors in MXML, you can also create them in ActionScript, as the following example item renderer shows:

```
package myComponents {
    // myComponents/CellField.as
    import mx.controls.*;
    import mx.controls.dataGridClasses.DataGridListData;
    import mx.core.*;
    public class CellField extends TextInput
    {
        // Get the initial background color.
        public var tempBGColor:Number;

        // Define the constructor and set properties.
        public function CellField() {
            super();
            height=60;
            width=80;
            tempBGColor = getStyle("contentBackgroundColor");
            editable=false;
        }
        // Override the set method for the data property.
        override public function set data(value:Object):void {
            super.data = value;
            // Since the item renderer can be recycled,
            // set the initial background color.
            setStyle("contentBackgroundColor", tempBGColor);

            if (value != null)
            {
                text = value[DataGridListData(listData).dataField];
                if(Number(text) > 100)
                {
                    setStyle("contentBackgroundColor", 0xFF0000);
                }
                else
                {
                    setStyle("contentBackgroundColor", 0xFFFFFF);
                }
            }
            else
            {
                // If value is null, clear text.
                text= "";
            }
            super.invalidateDisplayList();
        }
    }
}
```

In the preceding example, you create a subclass of the TextInput control as your item renderer. The class must be public to be used as an item renderer or editor. This item renderer displays a red background if the value of the DataGrid cell is greater than 100.

You can use this item renderer in a DataGrid control, as the following example shows:

```
<?xml version="1.0" encoding="iso-8859-1"?>
<!-- itemRenderers\asRenderer\MainASItemRenderer.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    width="600" height="600">
    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;

            [Bindable]
            private var initDG:ArrayCollection = new ArrayCollection([
                {Monday: 12, Tuesday: 22, Wednesday: 452, Thursday: 90},
                {Monday: 258, Tuesday: 22, Wednesday: 45, Thursday: 46},
                {Monday: 4, Tuesday: 123, Wednesday: 50, Thursday: 95},
                {Monday: 12, Tuesday: 52, Wednesday: 111, Thursday: 20},
                {Monday: 22, Tuesday: 78, Wednesday: 4, Thursday: 51}
            ]);
        ]]>
    </fx:Script>
    <mx:Text text="All cells over 100 are red" />

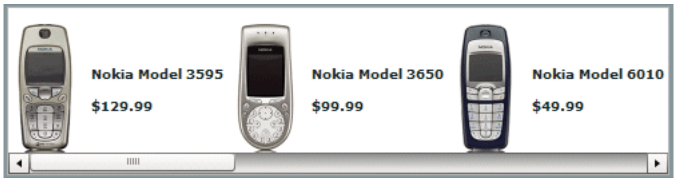
    <mx:DataGrid id="myDataGrid"
        dataProvider="{initDG}"
        variableRowHeight="true">
        <mx:columns>
            <mx:DataGridColumn dataField="Monday"
                itemRenderer="myComponents.CellField" />
            <mx:DataGridColumn dataField="Tuesday"
                itemRenderer="myComponents.CellField" />
            <mx:DataGridColumn dataField="Wednesday"
                itemRenderer="myComponents.CellField" />
            <mx:DataGridColumn dataField="Thursday"
                itemRenderer="myComponents.CellField" />
        </mx:columns>
    </mx:DataGrid>
</s:Application>
```

Working with MX item renderers

Example: Using an item renderer with the MX TileList and HorizontalList controls

The TileList and HorizontalList controls display a tiled list of items. The TileList control displays items in vertical columns. The HorizontalList control displays items in horizontal rows. The TileList and HorizontalList controls are particularly useful in combination with a custom item renderer for displaying a list of images and other data.

The following image shows a HorizontalList control that is used to display a product catalog:



Each item in the HorizontalList control contains an image, a descriptive text string, and a price. The following code shows the application that displays the catalog. The item renderer for the HorizontalList control is an MXML component named Thumbnail.

```
<?xml version="1.0"?>
<!-- itemRenderers\MainTlistThumbnailRenderer.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Declarations>
        <fx:Model id="catalog" source="catalog.xml"/>
    </fx:Declarations>
    <mx:HorizontalList id="myList"
        columnWidth="125"
        rowHeight="125"
        columnCount="4"
        dataProvider="{catalog.product}"
        itemRenderer="myComponents.Thumbnail"/>
</s:Application>
```

The file catalog.xml defines the data provider for the HorizontalList control:

```
<?xml version="1.0"?>
<catalog>
    <product id="1">
        <name>Nokia Model 3595</name>
        <price>129.99</price>
        <image>../assets/products/Nokia_3595.gif</image>
        <thumbnail>../assets/products/Nokia_3595_sm.gif</thumbnail>
    </product>
    <product id="2">
        <name>Nokia Model 3650</name>
        <price>99.99</price>
        <image>../assets/products/Nokia_3650.gif</image>
        <thumbnail>../assets/products/Nokia_3650_sm.gif</thumbnail>
    </product>
    <product id="3">
        <name>Nokia Model 6010</name>
        <price>49.99</price>
        <image>../assets/products/Nokia_6010.gif</image>
        <thumbnail>../assets/products/Nokia_6010_sm.gif</thumbnail>
    </product>
    <product id="4">
        <name>Nokia Model 6360</name>
        <price>19.99</price>
        <image>../assets/products/Nokia_6360.gif</image>
        <thumbnail>../assets/products/Nokia_6360_sm.gif</thumbnail>
    </product>
    <product id="5">
        <name>Nokia Model 6680</name>
        <price>19.99</price>
        <image>../assets/products/Nokia_6680.gif</image>
        <thumbnail>../assets/products/Nokia_6680_sm.gif</thumbnail>
    </product>
    <product id="6">
        <name>Nokia Model 6820</name>
        <price>49.99</price>
        <image>../assets/products/Nokia_6820.gif</image>
        <thumbnail>../assets/products/Nokia_6820_sm.gif</thumbnail>
    </product>
</catalog>
```

The following example shows the Thumbnail.mxml MXML component. In this example, you define the item renderer to contain three controls: an Image control and two Label controls. These controls examine the `data` property that is passed to the item renderer to determine the content to display.

```
<?xml version="1.0" ?>
<!-- itemRenderers\myComponents\Thumbnail.mxml -->
<mx:VBox xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    horizontalAlign="center"
    verticalGap="0" borderStyle="none" backgroundColor="white" >
    <mx:Image id="image" width="60" height="60" source="{data.image}"/>
    <mx:Label text="{data.name}" width="120" textAlign="center"/>
    <mx:Label text="${data.price}" fontWeight="bold"/>
</mx:VBox>
```

For more information on the TileList and HorizontalList controls, see “MX data-driven controls” on page 943.

Example: Using an item renderer with an MX DataGrid control

The DataGrid control works with the DataGridColumn class to configure the grid. For a DataGrid control, you can specify two types of renderers: one for the cells of each column, and one for the header cell at the top of each column. To specify an item renderer for a column of a DataGrid control, you use the `DataGridColumn.itemRenderer` property. To specify an item renderer for a column header cell, you use the `DataGridColumn.headerRenderer` property.

For example, to highlight a column in the DataGrid control, you can use using an icon in the column header cell to indicate a sale price, as the following item renderer shows:

```
<?xml version="1.0"?>
<!-- itemRenderers\dataGrid\myComponents\RendererDGHeader.mxml -->
<mx:HBox xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
            [Embed(source="saleIcon.jpg")]
            [Bindable]
            public var sale:Class;
        ]]>
    </fx:Script>
    <mx:Label text="Sale Price!"/>
    <mx:Image height="20" source="{sale}"/>
</mx:HBox>
```

This item renderer uses a Label control to insert the text “Sale Price!” and an Image control to insert an icon in the column header.

The following example shows the main application:

```
<?xml version="1.0"?>
<!-- itemRenderers\dataGrid\MainDGHeaderRenderer.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Script>
        <![CDATA[
          import mx.collections.ArrayCollection;

          [Bindable]
          private var initDG:ArrayCollection = new ArrayCollection([
            {Artist:'Pavement', Album:'Slanted and Enchanted',
                Price:11.99, SalePrice: true },
            {Artist:'Pavement', Album:'Brighten the Corners',
                Price:11.99, SalePrice: false }
          ]);
        ]]>
    </fx:Script>
    <mx:DataGrid id="myGrid"
        dataProvider="{initDG}"
        variableRowHeight="true">
        <mx:columns>
            <mx:DataGridColumn dataField="Artist"/>
            <mx:DataGridColumn dataField="Album"/>
            <mx:DataGridColumn dataField="Price"/>
            <mx:DataGridColumn width="150" dataField="SalePrice"
                headerRenderer="myComponents.RendererDGHeader"/>
        </mx:columns>
    </mx:DataGrid>
</s:Application>
```

In this example, the DataGrid control displays the String `true` or `false` in the column to indicate that the price is a sale price. You can also define an item renderer for that column to display a more compelling icon rather than text. For an example that uses an item renderer with a DataGrid control, see "Using custom MX item renderers and item editors" on page 1009.

Example: Using an item renderer with an MX List control

When you use a custom item renderer with a List control, you specify it using the `List.itemRenderer` property, as the following example shows:

```
<?xml version="1.0"?>
<!-- itemRenderers\list\MainListStateRenderer.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    height="700" width="700">
    <mx:List id="myList"
        height="180" width="250"
        variableRowHeight="true"
        itemRenderer="myComponents.RendererState">
        <mx:dataProvider>
            <fx:Object label="Alaska"
                data="Juneau"
                webPage="http://www.state.ak.us/"/>
            <fx:Object label="Alabama"
                data="Montgomery"
                webPage="http://www.alabama.gov/" />
            <fx:Object label="Arkansas"
                data="Little Rock"
                webPage="http://www.state.ar.us/"/>
        </mx:dataProvider>
    </mx:List>
</s:Application>
```

The previous example sets the `rowHeight` property to 75 pixels because the item renderer displays content that exceeds the default row height of the List control. To see an image that shows this application, see "Using custom MX item renderers and item editors" on page 1009.

The following item renderer, RendererState.mxml, displays the parts of each List item, and creates a LinkButton control which lets you open the state's web site:

```
<?xml version="1.0"?>
<!-- itemRenderers\list\myComponents\RendererState.mxml -->
<mx:VBox xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
            // Import Event and URLRequest classes.
            import flash.events.Event;
            import flash.net.URLRequest;

            private var u:URLRequest;

            // Event handler to open URL using
            // the navigateToURL() method.
            private function handleClick(eventObj:Event):void {
                u = new URLRequest(data.webPage);
                navigateToURL(u);
            }
        ]]>
    </fx:Script>

    <mx:HBox >
        <!-- Use Label controls to display state and capital names. -->
        <mx:Label id="State" text="State: {data.label}"/>
        <mx:Label id="Statecapital" text="Capital: {data.data}" />
    </mx:HBox>
    <!-- Define the Link control to open a URL. -->
    <mx:LinkButton id="webPage" label="Official {data.label} web page"
        click="handleClick(event);" color="blue"  />
</mx:VBox>
```

Example: Using an item renderer with an MX Tree control

For the Tree control, you use the `itemRenderer` property to specify a single renderer for all nodes of the tree. If you define a custom item renderer, you are responsible for handling the display of the entire node, including the text and icon.

One option is to define an item renderer as a subclass of the default item renderer class, the TreeItemRenderer class. You can then modify the item renderer as required by your application without implementing the entire renderer, as the following example shows:

```
package myComponents
{
    // itemRenderers/tree/myComponents/MyTreeItemRenderer.as
    import mx.controls.treeClasses.*;
    import mx.collections.*;
    public class MyTreeItemRenderer extends TreeItemRenderer
    {
        // Define the constructor.
        public function MyTreeItemRenderer() {
            super();
        }

        // Override the set method for the data property
        // to set the font color and style of each node.
        override public function set data(value:Object):void {
            super.data = value;
            if(TreeListData(super.listData).hasChildren)
            {
                setStyle("color", 0xff0000);
                setStyle("fontWeight", 'bold');
            }
            else
            {
                setStyle("color", 0x000000);
                setStyle("fontWeight", 'normal');
            }
        }

        // Override the updateDisplayList() method
        // to set the text for each tree node.
        override protected function updateDisplayList(unscaledWidth:Number,
            unscaledHeight:Number):void {

            super.updateDisplayList(unscaledWidth, unscaledHeight);
            if(super.data)
            {
                if(TreeListData(super.listData).hasChildren)
                {
                    var tmp:XMLList =
                        new XMLList(TreeListData(super.listData).item);
                    var myStr:int = tmp[0].children().length();
                    super.label.text =  TreeListData(super.listData).label +
                        "(" + myStr + ")";
                }
            }
        }
    }
}
```

For each node that has a child node, this item renderer displays the node text in red and includes the count of the number of child nodes in parentheses. The following example uses this item renderer in an application:

```
<?xml version="1.0" encoding="iso-8859-1"?>
<!-- itemRenderers\tree\MainTreeItemRenderer.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    initialize="initCollections();">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[

            import mx.collections.*;

            public var xmlBalanced:XMLList =
                <>
                    <node label="Containers">
                        <node label="DividedBoxClasses">
                            <node label="BoxDivider" data="BoxDivider.as"/>
                        </node>
                        <node label="GridClasses">
                            <node label="GridRow" data="GridRow.as"/>
                            <node label="GridItem" data="GridItem.as"/>
                            <node label="Other File" data="Other.as"/>
                        </node>
                    </node>
                    <node label="Data">
                        <node label="Messages">
                            <node label="DataMessage"
                                data="DataMessage.as"/>
                            <node label="SequenceMessage"
                                data="SequenceMessage.as"/>
                        </node>
                        <node label="Events">
                            <node label="ConflictEvents"
                                data="ConflictEvent.as"/>
                            <node label="CommitFaultEvent"
                                data="CommitFaultEvent.as"/>
                        </node>
                    </node>
                </>;

            [Bindable]
            public var xlcBalanced:XMLListCollection;

            private function initCollections():void {
                xlcBalanced = new XMLListCollection(xmlBalanced);
            }
        ]]>
    </fx:Script>
    <mx:Text width="400"
        text="The nodes with children are in bold red text, with the number of children in
parenthesis.)"/>
    <mx:Tree id="compBalanced"
        width="400" height="500"
        dataProvider="{xlcBalanced}"
        labelField="@label"
        itemRenderer="myComponents.MyTreeItemRenderer"/>
</s:Application>
```

Advanced data display with MX item editors

Item editors let you modify the value of a cell of a list-based control. The DataGrid, List, and Tree controls support item editors.

For an introduction to item renderers and item editors, see “MX item renderers and item editors” on page 1006.

About the MX cell editing process

The following sequence of steps occurs when a cell in a list-based control is edited:

1 User releases the mouse button while over a cell, tabs to a cell, or in another way attempts to edit a cell.

2 Flex dispatches the `itemEditBeginning` event. You can use this event to disable editing of a specific cell or cells. For more information, see “Example: Preventing a cell from being edited” on page 1062.

3 Flex dispatches the `itemEditBegin` event to open the item editor. You can use this event to modify the data passed to the item editor. For more information, see “Example: Modifying data passed to or received from an item editor” on page 1063.

4 The user edits the cell.

5 The user ends the editing session. Typically the cell editing session ends when the user removes focus from the cell.

6 Flex dispatches the `itemEditEnd` event to close the item editor and update the list-based control with the new cell data. You can use this event to modify the data returned to the cell, validate the new data, or return data in a format other than the format returned by the item editor. For more information, see “Example: Modifying data passed to or received from an item editor” on page 1063.

7 The new data value appears in the cell.

Creating an editable cell in MX

The DataGrid, List, and Tree controls include an `editable` property that you set to `true` to let users edit the contents of the control. By default, the value of the `editable` property is `false`, which means that you cannot edit the cells. For a DataGrid control, setting the `editable` property to `true` enables editing for all columns of the grid. You can disable editing for any column by setting the `DatagridColumn.editable` property to `false`.

Your list-based controls can use the default item editor (TextInput control), a custom item editor, or a custom item renderer as an editor. The `rendererIsEditor` property of the list-based controls determines whether you can use an item renderer as an item editor, as the following table shows:

rendererIsEditor property	itemRenderer property	itemEditor property
`false` (default)	Specifies the item renderer.	Specifies the item editor. Selecting the cell opens the item editor as defined by the `itemEditor` property. If the `itemEditor` property is undefined, use the default item editor (TextInput control).
`true`	Specifies the item renderer to display the cell contents. You can use the item renderer as an item editor.	Ignored.

As this table shows, the state of the `rendererIsEditor` property defines whether to use a custom item renderer as the item editor, or a custom item editor. If you set the `rendererIsEditor` property to `true`, Flex uses the item renderer as an item editor, and ignores the `itemEditor` property.

For an example, see "Example: Using an item renderer as an item editor" on page 1066.

Returning data from an MX item editor

By default, Flex expects an item editor to return a single value to the list-based control. You use the `editorDataField` property of the list-based control to specify the property of the item editor that contains the new data. Flex converts the value to the appropriate data type for the cell.

The default item editor is a TextInput control. Therefore, the default value of the `editorDataField` property is `"text"`, which corresponds to the `text` property of the TextInput control. If you specify a custom item editor, you also set the `editorDataField` property to the appropriate property of the item editor, as the following example shows:

```
<?xml version="1.0"?>
<!-- itemRenderers\dropin\DropInNumStepper.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;

            [Bindable]
            private var myDP:ArrayCollection = new ArrayCollection([
                {label1:"Order #2314", quant:3, Sent:true},
                {label1:"Order #2315", quant:3, Sent:false}
            ]);
        ]]>
    </fx:Script>
    <mx:DataGrid id="myDG" dataProvider="{myDP}"
        variableRowHeight="true"
        editable="true" >
        <mx:columns>
            <mx:DataGridColumn dataField="label1" headerText="Order #"/>
            <mx:DataGridColumn dataField="quant"
                headerText="Qty"
                itemEditor="mx.controls.NumericStepper"
                editorDataField="value"
            />
        </mx:columns >
    </mx:DataGrid>
</s:Application>
```

In the preceding example, you use a NumericStepper control as the item editor, and therefore set the `editorDataField` property to `"value"`, the property of the NumericStepper control that contains the new cell data.

Defining a property to return data

An item editor can contain more than a single component. For example, the following item editor contains a parent VBox container with a child CheckBox control used to edit the cell:

```
<?xml version="1.0"?>
<!-- itemRenderers\dataGrid\myComponents\EditorDGCheckBox.mxml -->
<mx:VBox xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    backgroundColor="yellow">
    <fx:Script>
        <![CDATA[
            // Define a property for returning the new value to the cell.
            public var cbSelected:Boolean;
        ]]>
    </fx:Script>

    <mx:CheckBox id="followUpCB" label="Follow up needed"
        height="100%" width="100%"
        selected="{data.FollowUp}"
        click="cbSelected=followUpCB.selected"
        updateComplete="cbSelected=followUpCB.selected;"/>
</mx:VBox>
```

In the preceding example, when the user selects the cell, Flex displays the CheckBox control in a yellow background, as defined by the parent VBox container. The user then selects or deselects the CheckBox control to set the new value for the cell.

To return a value to the list-based control, the VBox container defines a new property named `cbSelected`. This is necessary because you can only set the `editorDataField` property to a property of the top-level component of the item editor. That means you cannot set `editorDataField` to the `selected` property of the CheckBox control when it is a child of the VBox container.

You use the `updateComplete` event to set the value of the `cbSelected` property in case the user selects the cell to open the CheckBox control, but does not change the state of the CheckBox control.

In the following example, you use this item editor in a DataGrid control that displays a list of customer contacts. The list includes the company name, contact name, and phone number, and a column that indicates whether you must follow up with that contact.

```
<?xml version="1.0"?>
<!-- itemRenderers\dataGrid\MainDGCheckBoxEditor.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    width="650">

    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;

            [Bindable]
            private var initDG:ArrayCollection = new ArrayCollection([
                {Company: 'Acme', Contact: 'Bob Jones',
                    Phone: '413-555-1212', Date: '5/5/05' , FollowUp: true },
                {Company: 'Allied', Contact: 'Jane Smith',
                    Phone: '617-555-3434', Date: '5/6/05' , FollowUp: false}
            ]);
        ]]>
    </fx:Script>
    <mx:DataGrid id="myGrid"
        dataProvider="{initDG}"
        editable="true" >
        <mx:columns>
            <mx:DataGridColumn dataField="Company" editable="false"/>
            <mx:DataGridColumn dataField="Contact"/>
            <mx:DataGridColumn dataField="Phone"/>
            <mx:DataGridColumn dataField="Date"/>
            <mx:DataGridColumn dataField="FollowUp"
                width="150"
                headerText="Follow Up?"
                itemEditor="myComponents.EditorDGCheckBox"
                editorDataField="cbSelected"/>
        </mx:columns>
    </mx:DataGrid>
</s:Application>
```

Notice that the `editorDataField` property is set to `cbSelected`, the new property of the VBox container.

You also use this same mechanism with an inline item renderer that contains multiple controls. For example, you can modify the previous DataGrid example to use an inline item editor, rather than an item editor component, as the following code shows:

```
<?xml version="1.0"?>
<!-- itemRenderers\inline\InlineDGCheckBoxEditor.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    width="650">

    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;

            [Bindable]
            private var initDG:ArrayCollection = new ArrayCollection([
                {Company: 'Acme', Contact: 'Bob Jones',
                    Phone: '413-555-1212', Date: '5/5/05' , FollowUp: true },
                {Company: 'Allied', Contact: 'Jane Smith',
                    Phone: '617-555-3434', Date: '5/6/05' , FollowUp: false}
            ]);
        ]]>
    </fx:Script>
    <mx:DataGrid id="myGrid"
        dataProvider="{initDG}"
        editable="true">
        <mx:columns>
            <mx:DataGridColumn dataField="Company" editable="false"/>
            <mx:DataGridColumn dataField="Contact"/>
            <mx:DataGridColumn dataField="Phone"/>
            <mx:DataGridColumn dataField="Date"/>
            <mx:DataGridColumn dataField="FollowUp"
                width="150"
                headerText="Follow Up?"
                editorDataField="cbSelected">

                <mx:itemEditor>
                    <fx:Component>
                        <mx:VBox backgroundColor="yellow">
                            <fx:Script>
                                <![CDATA[
                                    // Define a property for returning
                                    // the new value to the cell.
                                    [Bindable]
                                    public var cbSelected:Boolean;
                                ]]>
                            </fx:Script>

                            <mx:CheckBox id="followUpCB"
                                label="Follow up needed"
                                height="100%" width="100%"
                                selected="{data.FollowUp}"
                                click="cbSelected=followUpCB.selected"/>
                        </mx:VBox>
                    </fx:Component>
                </mx:itemEditor>
            </mx:DataGridColumn>
        </mx:columns>
    </mx:DataGrid>
</s:Application>
```

Sizing and positioning an MX item editor

When an item editor appears, it appears as a pop-up control above the selected cell of the list-based control. The list-based control also hides the current value of the cell.

The CheckBox control in the previous example, “Defining a property to return data” on page 1050, sizes itself to 100% for both `width` and `height`, and the VBox container sets its `backgroundColor` style property to yellow. By sizing the item editor to the size of the cell, and by setting the background color of the container, you completely cover the underlying cell.

The following table describes the properties of the list-based controls that you can use to size the item editor:

Property	Description
`editorHeightOffset`	Specifies the height of the item editor, in pixels, relative to the size of the cell for a DataGridColumn control, or the text field of a Tree control.
`editorWidthOffset`	Specifies the width of the item editor, in pixels, relative to the size of the cell for a DataGridColum control, or the text field of a Tree control.
`editorXOffset`	Specifies the *x* location of the upper-left corner of the item editor, in pixels, relative to the upper-left corner of the cell for a DataGridColumn control, or from the upper-left corner of the text field of a Tree control.
`editorYOffset`	Specifies the *y* location of the upper-left corner of the item editor, in pixels, relative to the upper-left corner of the cell for a DataGridColumn control, or from the upper-left corner of the text field of a Tree control.

The following code modifies the definition of the DataGridColumn control from the previous section to use the `editorXOffset` and `editorYOffset` properties to move the item editor down and to the right by 15 pixels so that it has a more prominent appearance in the DataGrid control:

```

                                label="Follow up needed"
                                height="100%" width="100%"
                                selected="{data.FollowUp}"
                                click="cbSelected=followUpCB.selected"/>
                        </mx:VBox>
                    </fx:Component>
                </mx:itemEditor>
            </mx:DataGridColumn>
        </mx:columns>
    </mx:DataGrid>
</s:Application>
```

Creating an MX item editor that responds to the Enter key

When you use the default item editor in a list-based control, you can edit the cell value, and then press the Enter key to move focus to the next cell in the control. When you create a simple item editor that contains only a single component, and that component implements the IFocusable interface, the item editor also responds to the Enter key. The following components implement the IFocusable interface: Accordion, Button, ButtonBar, ComboBase, DateChooser, DateField, ListBase, MenuBar, NumericStepper, TabNavigator, TextArea, and TextInput.

In the following example, you define a complex item renderer with a VBox container as the top-level component and a CheckBox control as its child component:

```
<?xml version="1.0"?>
<!-- itemRenderers\dataGrid\myComponents\EditorDGCheckBox.mxml -->
<mx:VBox xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    backgroundColor="yellow">
    <fx:Script>
        <![CDATA[
            // Define a property for returning the new value to the cell.
            public var cbSelected:Boolean;
        ]]>
    </fx:Script>

    <mx:CheckBox id="followUpCB" label="Follow up needed"
        height="100%" width="100%"
        selected="{data.FollowUp}"
        click="cbSelected=followUpCB.selected"
        updateComplete="cbSelected=followUpCB.selected;"/>
</mx:VBox>
```

When this item editor opens, the CheckBox control can obtain focus for editing, but pressing the Enter key does not move focus to the next cell because the parent VBox container does not implement the IFocusManagerComponent interface. You can modify this example to implement the IFocusManagerComponent interface, as the following code shows:

```
<?xml version="1.0"?>
<!-- itemRenderers\dataGrid\myComponents\EditorDGCheckBoxFocusable.mxml -->
<mx:VBox xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    backgroundColor="yellow"
    implements="mx.managers.IFocusManagerComponent" >
    <fx:Script>
        <![CDATA[
            // Define a property for returning the new value to the cell.
            public var cbSelected:Boolean;

            // Implement the drawFocus() method for the VBox.
            override public function drawFocus(isFocused:Boolean):void {
                // This method can be empty, or you can use it
                // to make a visual change to the component.
            }
        ]]>
    </fx:Script>

    <mx:CheckBox id="followUpCB"
        label="Follow up needed"
        height="100%" width="100%"
        selected="{data.FollowUp}"
        click="cbSelected=followUpCB.selected"
        updateComplete="cbSelected=followUpCB.selected;"/>
</mx:VBox>
```

While the IFocusManagerComponent interface defines several properties and methods, the UIComponent class defines or inherits implementations for all of them except for the `drawFocus()` method. Therefore, you only have to implement that one method so that your item editor responds to the Enter key.

Using MX cell editing events

A list component dispatches the following events as part of the cell editing process: the `itemEditBeginning`, `itemEditBegin`, and the `itemEditEnd` events. The list-based controls define default event listeners for all three of these events.

You can write your own event listeners for one or more of these events to customize the editing process. When you write your own event listener, it executes before the default event listener, which is defined by the component, and then the default listener executes. For example, you can modify the data passed to or returned from an item editor. You can modify the data in the event listener for the `itemEditBegin` event. When it completes, the default event listener runs to continue the editing process.

However, you can replace the default event listener for the component with your own event listener. To prevent the default event listener from executing, you call the `preventDefault()` method from anywhere in your event listener.

Use the following events when you create an item editor:

1 `itemEditBeginning`

Dispatched when the user releases the mouse button while over a cell, tabs to a cell, or in any way attempts to edit a cell.

The list-based controls have a default listener for the `itemEditBeginning` event that sets the `editedItemPosition` property of the list-based control to the cell that has focus.

You typically write your own event listener for this event to prevent editing of a specific cell or cells. To prevent editing, call the `preventDefault()` method from within your event listener, which stops the default event listener from executing, and prevents any editing from occurring on the cell. For more information, see "Example: Preventing a cell from being edited" on page 1062.

2 `itemEditBegin`

Dispatched before an item editor opens.

The list components have a default listener for the `itemEditBegin` event that calls the `createItemEditor()` method to perform the following actions:

- Creates an item editor object, and copies the `data` property from the cell to the editor. By default, the item editor object is an instance of the TextInput control. You use the `itemEditor` property of the list-based control to specify a custom item editor class.
- Sets the `itemEditorInstance` property of the list-based control to reference the item editor object.

You can write an event listener for this event to modify the data passed to the item editor. For example, you might modify the data, its format, or other information used by the item editor. For more information, see "Example: Modifying data passed to or received from an item editor" on page 1063.

You can also create an event listener to determine which item editor you use to edit the cell. For example, you might have two different item editors. Within the event listener, you can examine the data to be edited, open the appropriate item editor by setting the `itemEditor` property to the appropriate editor, and then call the `createItemEditor()` method. In this case, first you call `preventDefault()` to stop Flex from calling the `createItemEditor()` method as part of the default event listener.

You can call the `createItemEditor()` method only from within the event listener for the `itemEditBegin` event. To create an editor at other times, set the `editedItemPosition` property to generate the `itemEditBegin` event.

3 `itemEditEnd`

Dispatched when the cell editing session ends, typically when focus is removed from the cell.

The list components have a default listener for this event that copies the data from the item editor to the data provider of the list-based control. The default event listener performs the following actions:

- Uses the `editorDataField` property of the list-based control to determine the property of the item editor that contains the new data. The default item editor is the TextInput control, so the default value of the `editorDataField` property is `"text"` to specify that the `text` property of the TextInput control contains the new cell data.
- Depending on the reason for ending the editing session, the default event listener calls the `destroyItemEditor()` method to close the item editor. For more information, see "Determining the reason for an itemEditEnd event" on page 1060.

You typically write an event listener for this event to perform the following actions:

- Modify the data returned from the item editor.

  In your event listener, you can modify the data returned by the editor to the list-based control. For example, you can reformat the data before returning it to the list-based control.

- Examine the data entered into the item editor:

  In your event listener, you can examine the data entered into the item editor. If the data is incorrect, you can call the `preventDefault()` method to stop Flex from passing the new data back to the list-based control and from closing the editor.

Cell editing event classes

Each editable list-based control has a corresponding class that defines the event object for the cell editing events, as the following table shows:

List class	Event class
DataGrid	DataGridEvent
List	ListEvent
Tree	ListEvent

Notice that the event class for the List and Tree controls is ListEvent.

When defining the event listener for a list-based control, ensure that you specify the correct type for the event object passed to the event listener, as the following example shows for a DataGrid control:

```
public function myCellEndEvent(event:DataGridEvent):void {
    // Define event listener.
}
```

Accessing cell data and the item editor in an event listener

From within an event listener, you can access the current value of the cell being edited, the new value entered by the user, or the item editor used to edit the cell.

To access the current value of a cell, you use the `editedItemRenderer` property of the list-based control. The `editedItemRenderer` property contains the data that corresponds to the cell being edited. For List and Tree controls, this property contains the data provider element for the cell. For a DataGrid control, it contains the data provider element for the entire row of the DataGrid.

To access the new cell value and the item editor, you use the `itemEditorInstance` property of the list-based control. The `itemEditorInstance` property is not initialized until after the event listener for the `cellBeginEvent` listener executes. Therefore, you typically access the `itemEditorInstance` property only from within the event listener for the `itemEditEnd` event.

The following example shows an event listener for the `itemEditEnd` event that uses these properties:

```
<?xml version="1.0"?>
<!-- itemRenderers\events\EndEditEventAccessEditor.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Script>
        <![CDATA[

            import mx.controls.TextInput;
            import mx.events.DataGridEvent;
            import mx.collections.ArrayCollection;

            [Bindable]
            private var initDG:ArrayCollection = new ArrayCollection([
                {Artist:'Pavement', Album:'Slanted and Enchanted',
                    Price:11.99},
                {Artist:'Pavement', Album:'Brighten the Corners',
                    Price:11.99 }
            ]);

            // Define event listener for the itemEditEnd event.
            private function getCellInfo(event:DataGridEvent):void {

                // Get the cell editor and cast it to TextInput.
                var myEditor:TextInput =
                    TextInput(event.currentTarget.itemEditorInstance);

                // Get the new value from the editor.
                var newVal:String = myEditor.text;

                // Get the old value.
                var oldVal:String =
            event.currentTarget.editedItemRenderer.data[event.dataField];

                // Write out the cell coordinates, new value,
                // and old value to the TextArea control.
                cellInfo.text = "cell edited.\n";
                cellInfo.text += "Row, column: " + event.rowIndex + ", " +
                    event.columnIndex + "\n";
                cellInfo.text += "New value: " + newVal + "\n";
                cellInfo.text += "Old value: " + oldVal;
            }
        ]]>
    </fx:Script>
    <mx:TextArea id="cellInfo" width="300" height="150" />

    <mx:DataGrid id="myGrid"
        dataProvider="{initDG}"
        editable="true"
        itemEditEnd="getCellInfo(event);" >
        <mx:columns>
            <mx:DataGridColumn dataField="Artist"/>
            <mx:DataGridColumn dataField="Album"/>
            <mx:DataGridColumn dataField="Price"/>
        </mx:columns>
    </mx:DataGrid>
</s:Application>
```

In this example, you access the item editor, and cast it to the correct editor class. The default item editor is a TextInput control, so you cast it to TextInput. If you had defined a custom item editor, you would cast it to that class. After you have a reference to the item editor, you can access its properties to obtain the new cell value.

To access the old value of the cell, you use the `editedItemRenderer` property of the DataGrid control. You then use the `dataField` property of the event object to access the `data` property for the edited column.

Determining the reason for an itemEditEnd event

A user can end a cell editing session in several ways. In the body of the event listener for the `itemEditEnd` event, you can determine the reason for the event, and then handle it accordingly.

Each event class for a list-based control defines the `reason` property, which contains a value that indicates the reason for the event. The `reason` property has the following values:

Value	Description
`CANCELLED`	Specifies that the user canceled editing and that they do not want to save the edited data. Even if you call the `preventDefault()` method from within your event listener for the `itemEditEnd` event, Flex still calls the `destroyItemEditor()` method to close the editor.
`NEW_COLUMN`	(DataGrid only) Specifies that the user moved focus to a new column in the same row. In an event listener, you can let the focus change occur, or prevent it. For example, your event listener might check that the user entered a valid value for the cell currently being edited. If not, you can prevent the user from moving to a new cell by calling the `preventDefault()` method. In this case, the item editor remains open, and the user continues to edit the current cell. If you call the `preventDefault()` method and also call the `destroyItemEditor()` method, you block the move to the new cell, but the item editor closes.
`NEW_ROW`	Specifies that the user moved focus to a new row. You handle this value for the `reason` property similar to the way you handle the `NEW_COLUMN` value.
`OTHER`	Specifies that the list-based control lost focus, was scrolled, or is somehow in a state where editing is not allowed. Even if you call the `preventDefault()` method from within your event listener for the `itemEditEnd` event, Flex still calls the `destroyItemEditor()` method to close the editor.

The following example uses the itemEditEnd event to ensure that the user did not enter an empty String in a cell. If there is an empty String, the itemEditEnd event calls preventDefault() method to prohibit the user from removing focus from the cell until the user enters a valid value. However, if the reason property for the itemEditEnd event has the value CANCELLED, the event listener does nothing:

```
<?xml version="1.0"?>
<!-- itemRenderers\events\EndEditEventFormatter.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Script>
        <![CDATA[

            import mx.controls.TextInput;
            import mx.events.DataGridEvent;
            import mx.events.DataGridEventReason;
            import mx.formatters.NumberFormatter;
            import mx.collections.ArrayCollection;

            [Bindable]
            private var initDG:ArrayCollection = new ArrayCollection([
                {Artist:'Pavement', Album:'Slanted and Enchanted',
                    Price:11.99},
                {Artist:'Pavement', Album:'Brighten the Corners',
                    Price:11.99 }
            ]);

            private var myFormatter:NumberFormatter=new NumberFormatter();

            public function formatData(event:DataGridEvent):void {
                // Check the reason for the event.
                if (event.reason == DataGridEventReason.CANCELLED)
                {
                    // Do not update cell.
                    return;
                }
                // Get the new data value from the editor.
                var newData:String=
                    TextInput(event.currentTarget.itemEditorInstance).text;
                if(newData == "")
                {
                    // Prevent the user from removing focus,
                    // and leave the cell editor open.
                    event.preventDefault();
                    // Write a message to the errorString property.
                    // This message appears when the user
                    // mouses over the editor.
                    TextInput(myGrid.itemEditorInstance).errorString=
                        "Enter a valid string.";
                }
            }

        ]]>
    </fx:Script>

    <mx:DataGrid id="myGrid"
        dataProvider="{initDG}"
        editable="true"
        itemEditEnd="formatData(event);">
        <mx:columns>
            <mx:DataGridColumn dataField="Artist"/>
            <mx:DataGridColumn dataField="Album"/>
            <mx:DataGridColumn dataField="Price"/>
        </mx:columns>
    </mx:DataGrid>
</s:Application>
```

In this example, if the user's reason for the event is `CANCELLED`, the event listener does nothing.

If the reason is `NEW_COLUMN`, `NEW_ROW`, or `OTHER`, the event listener performs the following actions:

1 Checks if the new cell value is an empty String.

2 If it is an empty String, the event listener calls the `preventDefault()` method to prevent Flex from closing the editor and from updating the cell with the empty String.

3 Writes a message to the `errorString` property of the TextInput control. This message causes a red box to appear around the TextInput control, and the message appears as a tooltip when the user moves the mouse over the cell.

MX item editor examples

Example: Preventing a cell from being edited

From within an event listener for the `itemEditBeginning` event, you can inspect the cell being edited, and prevent the edit from occurring. This technique is useful when you want to prevent editing of a specific cell or cells, but allow editing of other cells.

For example, the DataGrid control uses the `editable` property to make all cells in the DataGrid control editable. You can override that for a specific column, using the `editable` property of a DataGridColumn, but you cannot enable or disable editing for specific cells.

To prevent cell editing, call the `preventDefault()` method from within your event listener for the `itemEditBeginning` event, as the following example shows:

```
<?xml version="1.0"?>
<!-- itemRenderers\events\EndEditEventPreventEdit.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Script>
        <![CDATA[

            import mx.events.DataGridEvent;
            import mx.collections.ArrayCollection;

            [Bindable]
            private var initDG:ArrayCollection = new ArrayCollection([
                {Artist:'Pavement', Album:'Slanted and Enchanted',
                    Price:11.99},
                {Artist:'Pavement', Album:'Brighten the Corners',
                    Price:11.99}
            ]);

            // Define event listener for the cellEdit event
            // to prohibit editing of the Album column.
            private function disableEditing(event:DataGridEvent):void {
                if(event.columnIndex==1)
                {
                    event.preventDefault();
                }
            }

        ]]>
    </fx:Script>

    <mx:DataGrid id="myGrid"
        dataProvider="{initDG}"
        editable="true"
        itemEditBeginning="disableEditing(event);" >
        <mx:columns>
            <mx:DataGridColumn dataField="Artist"/>
            <mx:DataGridColumn dataField="Album"/>
            <mx:DataGridColumn dataField="Price"/>
        </mx:columns>
    </mx:DataGrid>
</s:Application>
```

Although the preceding example uses the column index, you could inspect any property of the DataGrid, or of the cell being edited, to make your decision about allowing the user to edit the cell.

Example: Modifying data passed to or received from an item editor

You can use the `itemEditBegin` and `itemEditEnd` events to examine the data passed to and from the item editor, and modify it if necessary. For example, you could reformat the data, extract a part of the data for editing, or examine the data to validate it.

In the next example, you use a NumericStepper control to edit the Price column of a DataGrid control. The `itemEditBegin` event modifies the data passed to the NumericStepper to automatically add 20% to the price when you edit it. Use the NumericStepper control to modify the updated price as necessary.

```
<?xml version="1.0"?>
<!-- itemRenderers\events\BeginEditEventAccessEditor.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
      <![CDATA[
        import mx.events.DataGridEvent;
        import mx.controls.NumericStepper;
        import mx.collections.ArrayCollection;
        import mx.controls.listClasses.IDropInListItemRenderer;

        [Bindable]
        private var myDP:ArrayCollection = new ArrayCollection([
            {Artist:'Pavement', Album:'Slanted and Enchanted', Price:11.99},
            {Artist:'Pavement', Album:'Crooked Rain, Crooked Rain', Price:10.99},
            {Artist:'Pavement', Album:'Wowee Zowee', Price:12.99},
            {Artist:'Pavement', Album:'Brighten the Corners', Price:11.99},
            {Artist:'Pavement', Album:'Terror Twilight', Price:11.99}
        ]);

        // Handle the itemEditBegin event.
        private function modifyEditedData(event:DataGridEvent):void
        {
            // Get the name of the column being editted.
            var colName:String = myDataGrid.columns[event.columnIndex].dataField;

            if(colName=="Price")
            {
                // Handle the event here.
                event.preventDefault();

                // Creates an item editor.
                myDataGrid.createItemEditor(event.columnIndex,event.rowIndex);

                // All item editors must implement the IDropInListItemRenderer interface
                // and the listData property.
                // Initialize the listData property of the editor.
                IDropInListItemRenderer(myDataGrid.itemEditorInstance).listData =
                    IDropInListItemRenderer(myDataGrid.editedItemRenderer).listData;

                // Copy the cell value to the NumericStepper control.
                myDataGrid.itemEditorInstance.data = myDataGrid.editedItemRenderer.data;
                // Add 20 percent to the current price.
                NumericStepper(myDataGrid.itemEditorInstance).value +=
                    0.2 * NumericStepper(myDataGrid.itemEditorInstance).value;
           }
        }
      ]]>
    </fx:Script>
    <mx:DataGrid id="myDataGrid" dataProvider="{myDP}"
        editable="true"
        itemEditBegin="modifyEditedData(event);"
        rowHeight="60">
        <mx:columns>
            <mx:DataGridColumn dataField="Artist" />
            <mx:DataGridColumn dataField="Album" width="130" />
            <mx:DataGridColumn dataField="Price" editorDataField="value">
                <mx:itemEditor>
                    <fx:Component>
                        <mx:NumericStepper stepSize="0.01" maximum="500"/>
                    </fx:Component>
                </mx:itemEditor>
            </mx:DataGridColumn>
        </mx:columns>
    </mx:DataGrid>
</s:Application>
```

You could use one of the Flex formatter classes to format data returned from an item editor. In the following example, you let the user edit the Price column of a DataGrid control. You then define an event listener for the `itemEditEnd` event that uses the NumberFormatter class to format the new cell value so that it contains only two digits after the decimal point, as the following code shows:

```
<?xml version="1.0"?>
<!-- itemRenderers\events\EndEditEventFormatter.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx" >

    <fx:Script>
        <![CDATA[

            import mx.controls.TextInput;
            import mx.events.DataGridEvent;
            import mx.events.DataGridEventReason;
            import mx.formatters.NumberFormatter;
            import mx.collections.ArrayCollection;

            [Bindable]
            private var initDG:ArrayCollection = new ArrayCollection([
                {Artist:'Pavement', Album:'Slanted and Enchanted',
                    Price:11.99},
                {Artist:'Pavement', Album:'Brighten the Corners',
                    Price:11.99 }
            ]);

            // Define the number formatter.
            private var myFormatter:NumberFormatter=new NumberFormatter();

            // Define the eventlistner for the itemEditEnd event.
            public function formatData(event:DataGridEvent):void {
                // Check the reason for the event.
                if (event.reason == DataGridEventReason.CANCELLED)
                {
                    // Do not update cell.
                    return;
                }
                // Get the new data value from the editor.
                var newData:String=
                    TextInput(event.currentTarget.itemEditorInstance).text;
                // Determine if the new value is an empty String.
                if(newData == "") {
                    // Prevent the user from removing focus,
                    // and leave the cell editor open.
                    event.preventDefault();
                    // Write a message to the errorString property.
                    // This message appears when the user
                    // mouses over the editor.
                    TextInput(myGrid.itemEditorInstance).errorString=
                        "Enter a valid string.";
                    return;
                }
                // For the Price column, return a value
                // with a precision of 2.
                if(event.dataField == "Price") {
                    myFormatter.precision=2;
                    TextInput(myGrid.itemEditorInstance).text=
                        myFormatter.format(newData);
                }
            }
        ]]>
    </fx:Script>

    <mx:DataGrid id="myGrid"
        dataProvider="{initDG}"
        editable="true"
        itemEditEnd="formatData(event);" >
        <mx:columns>
            <mx:DataGridColumn dataField="Artist"/>
            <mx:DataGridColumn dataField="Album"/>
            <mx:DataGridColumn dataField="Price"/>
        </mx:columns>
    </mx:DataGrid>
</s:Application>
```

Example: Using an item renderer as an item editor

If you set the `rendererIsEditor` property of the DataGrid, List, or Tree control to `true`, the control uses the default TextInput control as the item editor, or the item renderer that specifies the `itemRenderer` property. If you specify an item renderer, you must ensure that you include editable controls in it so that the user can edit values.

For example, the following item renderer displays information in the cell by using the TextInput control, and lets the user edit the cell's contents:

```
<?xml version="1.0"?>
<!-- itemRenderers\dataGrid\myComponents\MyContactEditable.mxml -->
<mx:VBox xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
   <fx:Script>
        <![CDATA[
            // Define a property for returning the new value to the cell.
            [Bindable]
            public var newContact:String;
        ]]>
    </fx:Script>
    <mx:Label id="title" text="{data.label1}"/>
    <mx:Label id="contactLabel" text="Last Contacted By:"/>
    <mx:TextInput id="contactTI"
        editable="true"
        text="{data.Contact}"
        change="newContact=contactTI.text;"/>
</mx:VBox>
```

You can use this item renderer with a DataGrid control, as the following example shows:

```
<?xml version="1.0"?>
<!-- itemRenderers\dataGrid\MainAppEditable.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    height="700" width="700">

    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;

            [Bindable]
            private var initDG:ArrayCollection = new ArrayCollection([
                {label1: "Order #2314", Contact: "John Doe",
                    Confirmed: false, Photo: "john_doe.jpg", Sent: false},
                {label1: "Order #2315", Contact: "Jane Doe",
                    Confirmed: true, Photo: "jane_doe.jpg", Sent: false}
            ]);
        ]]>
    </fx:Script>
    <mx:DataGrid id="myDG"
        width="500" height="250"
        dataProvider="{initDG}"
        variableRowHeight="true"
        editable="true">
        <mx:columns>
            <mx:DataGridColumn dataField="Photo"
```

```
                editable="false"/>
            <mx:DataGridColumn dataField="Contact"
                width="200"
                editable="true"
                rendererIsEditor="true"
                itemRenderer="myComponents.MyContactEditable"
                editorDataField="newContact"/>
            <mx:DataGridColumn dataField="Confirmed"
                editable="true"
                rendererIsEditor="true"
                itemRenderer="mx.controls.CheckBox"
                editorDataField="selected"/>
            <mx:DataGridColumn dataField="Sent"
                editable="true"
                rendererIsEditor="false"
                itemEditor="mx.controls.CheckBox"
                editorDataField="selected"/>
        </mx:columns>
    </mx:DataGrid>
</s:Application>
```

In the previous example, you use the item renderer as the item editor by setting the `rendererIsEditor` property to `true` in the second and third columns of the DataGrid control.

Example: Using a data validator in a custom item editor

Just as you can validate data in other types of controls, you can validate data in the cells of list-based controls. To do so, you can create an item renderer or item editor that incorporates a data validator. For more information about data validators, see "Validating Data" on page 1964.

The following example shows the code for the validating item editor component. It uses a TextInput control to edit the field. In this example, you assign a PhoneNumberValidator validator to the `text` property of the TextInput control to validate the user input:

```
<?xml version="1.0"?>
<!-- itemRenderers\validator\myComponents\EditorPhoneValidator.mxml -->
<mx:VBox xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Script>
        <![CDATA[
            // Define a property for returning the new value to the cell.
            [Bindable]
            public var returnPN:String;
        ]]>
    </fx:Script>

    <fx:Declarations>
        <mx:PhoneNumberValidator id="pnV"
            source="{newPN}"
            property="text"
            trigger="{newPN}"
            triggerEvent="change"
            required="true"/>
    </fx:Declarations>

    <mx:TextInput id="newPN"
        text="{data.phone}"
        updateComplete="returnPN=newPN.text;"
        change="returnPN=newPN.text;"/>
</mx:VBox>
```

If the user enters an incorrect phone number, the PhoneNumberValidator draws a red box around the editor and shows a validation error message when the user moves the mouse over it.

The following example shows the code for the application that uses this item editor:

```
<?xml version="1.0" ?>
<!-- itemRenderers\validator\MainDGValidatorEditor.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;

            [Bindable]
            private var initDG:ArrayCollection = new ArrayCollection([
                {name: 'Bob Jones', phone: '413-555-1212',
                    email: 'bjones@acme.com'},
                {name: 'Sally Smith', phone: '617-555-5833',
                    email: 'ssmith@acme.com'},
            ]);
        ]]>
    </fx:Script>

    <mx:DataGrid id="dg"
        width="500" height="200"
        editable="true"
        dataProvider="{initDG}">
        <mx:columns>
            <mx:DataGridColumn dataField="name"
                headerText="Name" />
            <mx:DataGridColumn dataField="phone"
                headerText="Phone"
                itemEditor="myComponents.EditorPhoneValidator"
                editorDataField="returnPN"/>
            <mx:DataGridColumn dataField="email" headerText="Email" />
        </mx:columns>
    </mx:DataGrid>
</s:Application>
```

Examples using MX item editors with the list-based controls

Example: Using an item editor with an MX DataGrid control

For examples of using item editors with the DataGrid control, see “Returning data from an MX item editor” on page 1049.

Example: Using a custom item editor with an MX List control

You can add an item editor to a List control to let users edit the information for each state, as the following item editor shows:

```
<?xml version="1.0"?>
<!-- itemRenderers\list\myComponents\EditorStateInfo.mxml -->
<mx:VBox xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <mx:TextInput id="newLabel" text="{data.label}" />
    <mx:TextInput id="newData" text="{data.data}" />
    <mx:TextInput id="newWebPage" text="{data.webPage}" />
</mx:VBox>
```

You define an item editor that contains three TextInput controls that let the user edit the state name, capital, or web address. This item editor returns three values, so you write an event listener for the itemEditEnd event to write the values to the data provider of the List control, as the following example shows:

```
<?xml version="1.0"?>
<!-- itemRenderers\list\MainListStateRendererEditor.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    height="700" width="700">
    <fx:Script>
        <![CDATA[
            import mx.events.ListEvent;
            import myComponents.EditorStateInfo;

            // Define the event listener.
            public function processData(event:ListEvent):void {
                // Disable copying data back to the control.
                event.preventDefault();
                // Get new label from editor.
                myList.editedItemRenderer.data.label =
    EditorStateInfo(event.currentTarget.itemEditorInstance).newLabel.text;
                // Get new data from editor.
                myList.editedItemRenderer.data.data =
    EditorStateInfo(event.currentTarget.itemEditorInstance).newData.text;
                // Get new webPage from editor.
                myList.editedItemRenderer.data.webPage =
    EditorStateInfo(event.currentTarget.itemEditorInstance).newWebPage.text;
                // Close the cell editor.
                myList.destroyItemEditor();

                // Notify the list control to update its display.
        myList.dataProvider.itemUpdated(myList.editedItemRenderer);
            }
        ]]>
    </fx:Script>
    <mx:List id="myList"
        height="180" width="250"
        editable="true"
        itemRenderer="myComponents.RendererState"
        itemEditor="myComponents.EditorStateInfo"
        variableRowHeight="true"
        itemEditEnd="processData(event);">
        <mx:dataProvider>
            <fx:Object label="Alaska"
                data="Juneau"
                webPage="http://www.state.ak.us/"/>
            <fx:Object label="Alabama"
                data="Montgomery"
                webPage="http://www.alabama.gov/" />
            <fx:Object label="Arkansas"
                data="Little Rock"
                webPage="http://www.state.ar.us/"/>
        </mx:dataProvider>
    </mx:List>
</s:Application>
```

This example uses the RendererState.mxml renderer. You can see that renderer in the section “Example: Using an item renderer with an MX List control” on page 1043.

Using a DateField or ComboBox control as a drop-in item editor

You can use a DateField or ComboBox control as a drop-in item editor with the List control. However, when the data provider is a collection of Objects, you have to set the `labelField` property of the List control to the name of the field in the data provider modified by the DateField or ComboBox control, as the following example shows:

```
<?xml version="1.0"?>
<!-- itemRenderers\list\ListEditorDateField.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[

            import mx.collections.*;
            import mx.controls.DateField;
            import mx.collections.ArrayCollection;

            [Bindable]
            private var catalog:ArrayCollection = new ArrayCollection([
                {confirmed: new Date(), Location: "Spain"},
                {confirmed: new Date(2006,0,15), Location: "Italy"},
                {confirmed: new Date(2004,9,24), Location: "Bora Bora"},
                {confirmed: new Date(), Location: "Vietnam"}
            ]);
        ]]>
    </fx:Script>
    <mx:List id="myList"
        width="300" height="300"
        rowHeight="50"
        dataProvider="{catalog}"
        editable="true"
        labelField="confirmed"
        itemEditor="mx.controls.DateField"
        editorDataField="selectedDate"/>
</s:Application>
```

In this example, you specify `"confirmed"` as the value of the `labelField` property to specify that the DateField control modifies that field of the data provider.

Example: Using a custom item editor with an MX Tree control

In a Tree control, you often display a single label for each node in the tree. However, the data provider for each node may contain additional data that is normally hidden from view.

In this example, you use the Tree control to display contact information for different companies. The Tree control displays the company name as a branch node, and different department names within the company as leaf nodes. Selecting any node opens a custom item editor that lets you modify the phone number or contact status of the company or for any department in the company.

The top node in the Tree control is not editable. Therefore, this example uses the `itemEditBeginning` event to determine if the user selects the top node. If selected, the event listener for the `itemEditBeginning` event prevents editing from occurring, as the following example shows:

```
<?xml version="1.0"?>
<!-- itemRenderers\tree\MainTreeEditor.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    width="600" height="600">
    <fx:Script>
        <![CDATA[

        import mx.events.ListEvent;
        import myComponents.TreeEditor;

        private var contacts1:Object =
          {label: "top", children: [
            {label: "Acme", status: true, phone: "243-333-5555", children: [
              {label: "Sales", status: true, phone: "561-256-5555"},
              {label: "Support", status: false, phone: "871-256-5555"}
            ]},
            {label: "Ace", status: true, phone: "444-333-5555", children: [
              {label: "Sales", status: true, phone: "232-898-5555"},
              {label: "Support", status: false, phone: "977-296-5555"},
            ]},
            {label: "Platinum", status: false, phone: "521-256-5555"}
        ]};

        private function initCatalog(cat:Object):void {
            myTree.dataProvider = cat;
        }

        // Define the event listener for the itemEditBeginning event
        // to disable editing when the user selects
        // the top node in the tree.
        private function disableEditing(event:ListEvent):void {
            if(event.rowIndex==0) {
                event.preventDefault();
            }
        }

        // Define the event listener for the itemEditEnd event
        // to copy the updated data back to the data provider
        // of the Tree control.
        public function processData(event:ListEvent):void {

            // Disable copying data back to the control.
            event.preventDefault();
            // Get new phone number from editor.
            myTree.editedItemRenderer.data.phone =
    TreeEditor(event.currentTarget.itemEditorInstance).contactPhone.text;
            // Get new status from editor.
            myTree.editedItemRenderer.data.status =
    TreeEditor(event.currentTarget.itemEditorInstance).confirmed.selected;
            // Close the cell editor.
            myTree.destroyItemEditor();

            // Notify the list control to update its display.
    myTree.dataProvider.itemUpdated(myTree.editedItemRenderer);
        }
        ]]>
    </fx:Script>

    <mx:Tree id="myTree"
        width="400" height="400"
        editable="true"
        itemEditor="myComponents.TreeEditor"
        editorHeightOffset="75" editorWidthOffset="-100"
        editorXOffset="40" editorYOffset="30"
        creationComplete="initCatalog(contacts1);"
        itemEditBeginning="disableEditing(event);"
        itemEditEnd="processData(event);"/>
</s:Application>
```

You specify the custom item editor using the `itemEditor` property of a Tree control. You also use the `editorHeightOffset`, `editorWidthOffset`, `editorXOffset`, and `editorYOffset` properties to position the item editor.

The following item editor, defined in the file TreeEditor.mxml, lets you edit the data associated with each item in a Tree control:

```
<?xml version="1.0" encoding="iso-8859-1"?>
<!-- itemRenderers/tree/myComponents/TreeEditor.mxml -->
<mx:VBox xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[
            // Define variables for the new data.
            public var newPhone:String;
            public var newConfirmed:Boolean;
        ]]>
    </fx:Script>
    <!-- Display item label.-->
    <mx:Label text="{data.label}"/>
    <!-- Display the text 'Phone:' and let the user edit it.-->
    <mx:HBox>
        <mx:Text text="Phone:"/>
        <mx:TextInput id="contactPhone"
            width="150"
            text="{data.phone}"
            change="newPhone=contactPhone.text;"/>
    </mx:HBox>
    <!-- Display the status using a CheckBox control
        and let the user edit it.-->
    <mx:CheckBox id="confirmed"
        label="Confirmed"
        selected="{data.status}"
        click="newConfirmed=confirmed.selected;"/>
</mx:VBox>
```

Introduction to charts

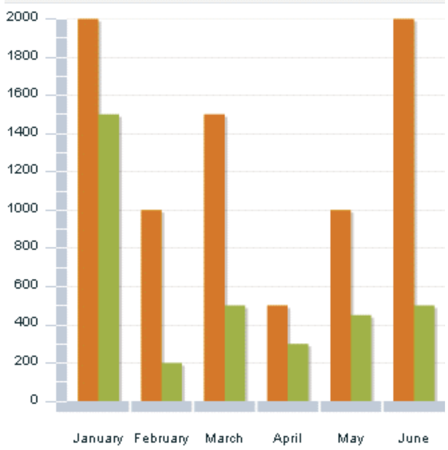
Displaying data in a chart or graph can make data interpretation much easier for users of the applications that you develop with the Adobe® Flex® product line. Rather than present a simple table of numeric data, you can display a bar, pie, line, or other type of chart using colors, captions, and a two-dimensional representation of your data.

About charting

Data visualization lets you present data in a way that simplifies data interpretation and data relationships. Charting is one type of data visualization in which you create two-dimensional representations of your data. Flex supports the most common types of two-dimensional charts (such as bar, column, and pie charts) and gives you a great deal of control over the appearance of charts.

A simple chart shows a single data series, where a series is a group of related data points. For example, a data series might be monthly sales revenues or daily occupancy rates for a hotel.

Another chart might add a second data series. For example, you might include the percentage growth of profits over the same four business quarters. The following chart shows two data series—one for sales and one for profit.



Using the charting controls

Flex charting controls lets you create some of the most common chart types, and also lets you customize the appearance of your charts. The charting controls are located in the mx.charts.* package.

The following table lists the supported chart types, the name of the control class, and the name of the series class that you use to define what data appears in each chart.

Chart type	**Chart control class**	**Chart series class**
Area	AreaChart	AreaSeries
Bar	BarChart	BarSeries
Bubble	BubbleChart	BubbleSeries
Candlestick	CandlestickChart	CandlestickSeries
Column	ColumnChart	ColumnSeries
HighLowOpenClose	HLOCChart	HLOCSeries

Chart type	Chart control class	Chart series class
Line	LineChart	LineSeries
Pie	PieChart	PieSeries
Plot	PlotChart	PlotSeries

All chart controls, except the PieChart class, are subclasses of the CartesianChart class. Cartesian charts are charts that typically represent a set of data points in rectangular-shaped, two-dimensional space. The PieChart class is a subclass of the PolarChart class, which represents data in circular space.

All chart controls inherit basic charting characteristics from the ChartBase class.

A chart control typically has the following structure in MXML:

```
<mx:chart_type>
    <!-- Define one or more series. -->
    <mx:series>
        <mx:Series1/>
        ...
    </mx:series>

    <!-- Define the axes. -->
    <mx:horizontalAxis>
        <mx:axis_type/>
    </mx:horizontalAxis>
    <mx:verticalAxis>
        <mx:axis_type/>
    </mx:verticalAxis>

    <!-- Style the axes and ticks marks. -->
    <mx:horizontalAxisRenderers>
        <mx:AxisRenderer/>
    </mx:horizontalAxisRenderers>
    <mx:verticalAxisRenderers>
        <mx:AxisRenderer/>
    </mx:verticalAxisRenderers/>

    <!-- Add grid lines and other elements to the chart. -->
    <mx:annotationElements>
        <array of elements/>
    </mx:annotationElements>
    <mx:backgroundElements>
        <array of elements/>
    </mx:backgroundElements/>
</mx:chart_type>

<!-- Optionally define the legend. -->
<mx:Legend/>
```

The following table describes the parts of the chart in more detail:

Part	**Description**
Chart	(Required) Defines a data provider for the chart. Also defines the chart type and sets data tips, mouse sensitivity, gutter styles, and axis styles. This is the top-level tag for a chart control. All other tags are child tags of this tag.
Series	(Required) Defines one or more data series to be displayed on the chart. Also sets the strokes, fills, and renderers (or *skins*) of the data series, as well as the strokes and fills used by the chart's legend for each series. You can use different series types in the same chart. Each series in a chart can have its own data provider, or they can share the data provider set on the chart object.
Axes	Sets the axis type (numeric or category) for each axis. Also defines the axis labels, titles, and style properties such as padding.
Axes renderers	(Optional) Sets tick placement and styles, enables or disables labels, and defines axis lines, label rotation, and label gap.
Elements	(Optional) Defines grid lines and extra elements to appear on the chart.

For each chart type, Flex supplies a corresponding chart control and chart series. The chart control defines the chart type, the data provider that supplies the chart data, the grid lines, the text for the chart axes, and other properties specific to the chart type. The `dataProvider` property of the chart control determines what data the chart uses.

A *data provider* is a collection of objects. It can be an Array of objects or any object that implements the collections API. A data provider can also be an XMLList object with XML nodes, such as the result of an E4X query.

The chart components use a flat, or list-based, data provider similar to a one-dimensional array. The data provider can contain objects such as Strings and Numbers, or even other objects. For more information on supplying chart data, see “Defining chart data” on page 1090.

You use the chart series to identify which data from the data provider the chart displays. A data provider can contain more data than you want to show in your chart, so you use the chart's series to specify which points you want to use from the data provider. You can specify more than one series. You can also use the chart series to define the appearance of the data in the chart.

All chart series inherit the data provider from the chart unless they have a data provider explicitly set on themselves. If you set the value of the `dataProvider` property on the chart control, you are not required to set the property value on the series. You can, however, define different data providers for each series in a chart.

For example, to create a pie chart, you use the PieChart control with the PieSeries chart series. To create an area chart, you use the AreaChart control with the AreaSeries chart series, as the following example shows:

```
<?xml version="1.0"?>
<!-- charts/BasicAreaOneSeries.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    height="600">
    <fx:Script><![CDATA[
        import mx.collections.ArrayCollection;
        [Bindable]
        public var expenses:ArrayCollection = new ArrayCollection([
            {Month:"Jan", Profit:2000, Expenses:1500, Amount:450},
            {Month:"Feb", Profit:1000, Expenses:200, Amount:600},
            {Month:"Mar", Profit:1500, Expenses:500, Amount:300}
        ]);
    ]]></fx:Script>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Area Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:AreaChart id="myChart" dataProvider="{expenses}"
     showDataTips="true">
        <mx:horizontalAxis>
           <mx:CategoryAxis
                dataProvider="{expenses}"
                categoryField="Month"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:AreaSeries
                yField="Profit"
                displayName="Profit"/>
        </mx:series>
     </mx:AreaChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

This example defines an array containing a single `<mx:AreaSeries>` tag. The `<mx:AreaSeries>` tag specifies the single data series that is displayed in the chart.

You can add a second `<mx:AreaSeries>` tag to display two data series, as the following example shows:

```
<?xml version="1.0"?>
<!-- charts/BasicArea.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">

    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Area Chart">
      <s:layout>
          <s:VerticalLayout/>
      </s:layout>
     <mx:AreaChart id="myChart"
        showDataTips="true"
        dataProvider="{srv.lastResult.data.result}">
        <mx:horizontalAxis>
           <mx:CategoryAxis
               categoryField="month"
               displayName="Month"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:AreaSeries yField="profit" displayName="Profit"/>
           <mx:AreaSeries yField="expenses" displayName="Expenses"/>
        </mx:series>
     </mx:AreaChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

You are not required to define a data provider on the chart control itself. Instead, you can define a different data provider for each element in a chart control that requires one. Each series can have its own data provider, as well as each axis, as the following example shows:

```
<?xml version="1.0"?>
<!-- charts/MultipleDataProviders.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    height="600">

  <fx:Script><![CDATA[
     import mx.collections.ArrayCollection;
     [Bindable]
     public var profit04:ArrayCollection = new ArrayCollection([
        {Month:"Jan", Profit:2000},
        {Month:"Feb", Profit:1000},
        {Month:"Mar", Profit:1500}
     ]);
     [Bindable]
     public var profit05:ArrayCollection = new ArrayCollection([
        {Month:"Jan", Profit:2200},
        {Month:"Feb", Profit:1200},
        {Month:"Mar", Profit:1700}
     ]);
     [Bindable]
     public var profit06:ArrayCollection = new ArrayCollection([
        {Month:"Jan", Profit:2400},
        {Month:"Feb", Profit:1400},
        {Month:"Mar", Profit:1900}
     ]);
  ]]></fx:Script>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Column Chart">
     <s:layout>
         <s:VerticalLayout/>
     </s:layout>
     <mx:ColumnChart id="myChart" showDataTips="true">
        <mx:horizontalAxis>
           <mx:CategoryAxis dataProvider="{profit04}" categoryField="Month"/>
        </mx:horizontalAxis>
        <mx:series>
```

```
           <mx:ColumnSeries
                dataProvider="{profit04}"
                yField="Profit"
                xField="Month"
                displayName="2004"/>
           <mx:ColumnSeries
                dataProvider="{profit05}"
                yField="Profit"
                xField="Month"
                displayName="2005"/>
           <mx:ColumnSeries
                dataProvider="{profit06}"
                yField="Profit"
                xField="Month"
                displayName="2006"/>
        </mx:series>
     </mx:ColumnChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

To dynamically size the chart to the size of its container, set the `width` and `height` attributes to a percentage value, as the following example shows:

```
<?xml version="1.0"?>
<!-- charts/BasicBarSize.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    height="600">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

  <fx:Script>
    <![CDATA[
     import mx.collections.ArrayCollection;
     [Bindable]
     public var expenses:ArrayCollection = new ArrayCollection([
        {Month:"Jan", Profit:2000, Expenses:1500},
        {Month:"Feb", Profit:1000, Expenses:200},
        {Month:"Mar", Profit:1500, Expenses:500}
     ]);
    ]]>
  </fx:Script>
     <mx:BarChart id="myChart"
        dataProvider="{expenses}"
        height="100%"
        width="100%"
        showDataTips="true">
        <mx:verticalAxis>
           <mx:CategoryAxis
                dataProvider="{expenses}"
                categoryField="Month"/>
        </mx:verticalAxis>
        <mx:series>
           <mx:BarSeries
                yField="Month"
                xField="Profit"
                displayName="Profit"/>
           <mx:BarSeries
                yField="Month"
                xField="Expenses"
                displayName="Expenses"/>
        </mx:series>
     </mx:BarChart>
     <mx:Legend dataProvider="{myChart}"/>
</s:Application>
```

If the chart is inside a container (such as a Panel), set the size of the chart's parent containers to percentage values too.

About the series classes

The chart series classes let you specify what data to render in a chart control. All series classes are subclasses of the Series class.

Each chart type has its own series class; for example, a BarChart control has a BarSeries class that defines the data to render in the BarChart. A PieChart control has a PieSeries.

The primary purpose of a series is to define what data to render in the chart. You use the series to define what field in a data provider the chart should use to render chart items on the X and Y axes. You use the `xField` property (for the horizontal axis) and the `yField` property (for the vertical axis) to define these fields.

Each series is made up of an Array of series items. The classes that define the series items are specific to each series type. For example, a BarSeries is made up of BarSeriesItem objects. A ColumnSeries is made up of ColumnSeriesItem objects. The series items encapsulate all the information about the particular data point, including the minimum value, the x value, and the y value.

When you create a new series, you typically define the `displayName` of that series. This property represents the series to the user in labels such as DataTip objects.

A BarChart typically specifies one or more BarSeries objects that define what set of bars to render in the chart. By default, bars and columns are clustered. However, you can also define alternate ways to group, or "stack", series in the chart control. For example, AreaSeries, ColumnSeries, and BarSeries can be stacked or overlaid. They can also render as 100% charts. You can further control how multiple series are grouped by using sets. For example, for a group of BarSeries objects, you use the BarSet class; for a group of ColumnSeries objects, you use the ColumnSet class. For more information on grouping series, see "Stacking charts" on page 1308.

Most charts use only one kind of series. However, you can specify multiple types of series for a chart. For example, you can create a chart that has a series of bars in addition to a trend line that "floats" over it. This is useful for rendering trend-lines or showing different types of data on a single chart for comparison analysis. For more information, see "Using multiple data series" on page 1163.

You use the series classes to define the appearance of the chart items. You can change the fill of all series items by using the `fill` property on the series. In addition, you can define the fill of each item in a series by using the `fills` property. You can also customize the fill that each chart item has based on its value by using the `fillFunction` on the series. For more information “Using fills with chart controls” on page 1197.

You can also apply filters to series to give them effects such as drop shadows, blurs, and glows. For more information, see “Using filters with chart controls” on page 1213.

You can add data labels to series items. You do this by setting the value of the `labelPosition` property on the series. For most series, possible values of `labelPosition` are `inside` and `outside`, which draw the labels inside the chart item and outside the chart item, respectively. For a PieSeries, you can also set the `labelPosition` property to other values that include `callout` and `insideWithCallout`.

You can customize data labels by using a `labelFunction`. This callback function takes arguments that define the series item and returns a String that is then rendered on the series item.

For information about adding data labels to your charts, see “Using data labels” on page 1277.

Series also let you set a `minField` value. This property lets you specify a minimum value that the series displays. For more information, see “Using the minField property” on page 1306.

About the axis classes

Flex charting controls support the following types of axes:

CategoryAxis CategoryAxis class maps a set of values (such as stock ticker symbols, state names, or demographic categories) to the axis. You use the `<mx:CategoryAxis>` tag to define axis labels that are grouped by logical associations and that are not necessarily numeric. For example, the month names used in the chart in “About charting” on page 1075 could be defined as a CategoryAxis class.

LinearAxis A LinearAxis class maps numeric data to the axis. You use the `<mx:LinearAxis>` child tag of the `<mx:horizontalAxis>` or `<mx:verticalAxis>` tags to customize the range of values displayed along the axis, and to set the increment between the axis labels of the tick marks.

LogAxis A LogAxis class maps numeric data to the axis logarithmically. You use the `<mx:LogAxis>` child tag of the `<mx:horizontalAxis>` or `<mx:verticalAxis>` tags. Labels on the logarithmic axis are even powers of 10.

DateTimeAxis A DateTimeAxis class maps time-based values, such as hours, days, weeks, or years, along a chart axis. You use the `<mx:DateTimeAxis>` tag to define the axis labels.

The DateTimeAxis, LogAxis, and LinearAxis are all of type NumericAxis, because they are used to represent numeric values. In many cases, you are required to define only one axis as being a NumericAxis or a CategoryAxis. Flex assumes that all axes not explicitly defined are of type LinearAxis. However, to use decorations such as DataTip labels and legends, you might be required to explicitly define both axes.

There are exceptions. For a PlotChart control, both axes are considered a LinearAxis, because the data point is the intersection of two coordinates. So, you are not required to specify either axis, although you can do so to provide additional settings, such as minimum and maximum values. When you create PieChart controls, you also do not specify either axis, because PieChart controls use a single set of data points to draw wedges that represent a percentage of the whole. In PieChart controls, you define a `nameField` on the chart’s data series, rather than a `categoryField` or `name` on the axes for labels and legends.

Each axis can have one or more corresponding AxisRenderer objects (specified by the `horizontalAxisRenderers` or `verticalAxisRenderers` properties) that define the appearance of axis labels and tick marks. In addition to defining formats, you can use an AxisRenderer class to customize the value of the axis labels. For more information, see “Formatting charts” on page 1169.

The appearance and contents of *axis labels* are defined by the `<mx:horizontalAxis>` (x-axis) and `<mx:verticalAxis>` (y-axis) tags and the renderers for these tags (`<mx:AxisRenderer>` tags within the `<mx:horizontalAxisRenderers>` and `<mx:verticalAxisRenderers>` tags). These tags not only define the data ranges that appear in the chart, but also map the data points to their names and labels. This mapping has a large impact on how the Data Management Service chart renders the values of DataTip labels, axis labels, and tick marks.

By default, Flex uses the chart type and orientation to calculate the labels that appear along the x-axis and y-axis of the chart. The labels of a column chart, for example, have the following default values:

The x-axis The minimum number of labels is 0, and the maximum is the number of items in the data series that is being charted.

The y-axis The minimum value on the y-axis is small enough for the chart data, and the maximum value is large enough based to accomodate the chart data.

For more information about chart axes, see "Working with axes" on page 1247.

About charting events

The chart controls include events that accommodate user interaction with data points in charts. These events are described in "Events and effects in charts" on page 1324.

Creating charts in ActionScript

You can create, destroy, and manipulate charts using ActionScript just as you can any other Flex component.

When working in Script blocks or in separate ActionScript class files, you must be sure to import all appropriate classes. The following set of import statements defines the most common cases:

```
import mx.collections.*;
import mx.charts.*;
import mx.charts.series.*;
import mx.charts.renderers.*;
import mx.charts.events.*;
```

To create a chart in ActionScript, use the `new` keyword. You can set properties on the chart object as you would in MXML. You assign a data provider with the `dataProvider` property. To add a data series to the chart, you define a new data series of the appropriate type. To apply the series to your chart, use the chart's `series` property. You can specify the category axis settings using the CategoryAxis class. The following example defines a BarChart control with two series:

```
<?xml version="1.0"?>
<!-- charts/CreateChartInActionScript.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="init()"
    height="600">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

  <fx:Script><![CDATA[
     import mx.collections.ArrayCollection;
     import mx.charts.BarChart;
     import mx.charts.series.BarSeries;
     import mx.charts.CategoryAxis;
     import mx.charts.Legend;
     [Bindable]
     public var expenses:ArrayCollection = new ArrayCollection([
        {Month:"Jan", Profit:2000, Expenses:1500},
        {Month:"Feb", Profit:1000, Expenses:200},
        {Month:"Mar", Profit:1500, Expenses:500}
     ]);
     public var myChart:BarChart;
     public var series1:BarSeries;
     public var series2:BarSeries;
     public var legend1:Legend;
     public function init():void {
        /* Create the chart object and set some
           basic properties. */
        myChart = new BarChart();
        myChart.showDataTips = true;
        myChart.dataProvider = expenses;
        /* Define the category axis. */
        var vAxis:CategoryAxis = new CategoryAxis();
        vAxis.categoryField = "Month" ;
        vAxis.dataProvider =  expenses;
        myChart.verticalAxis = vAxis;
        /* Add the series. */
        var mySeries:Array=new Array();
        series1 = new BarSeries();
        series1.xField="Profit";
        series1.yField="Month";
        series1.displayName = "Profit";
        mySeries.push(series1);
        series2 = new BarSeries();
        series2.xField="Expenses";
        series2.yField="Month";
        series2.displayName = "Expenses";
        mySeries.push(series2);
        myChart.series = mySeries;
        /* Create a legend. */
        legend1 = new Legend();
        legend1.dataProvider = myChart;
        /* Attach chart and legend to the display list. */
        p1.addElement(myChart);
        p1.addElement(legend1);
     }
  ]]></fx:Script>
  <s:Panel id="p1" title="BarChart Created in ActionScript">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  </s:Panel>
</s:Application>
```

This example replaces the existing Array of series with the new series.

You can use a similar technique to add data series to your charts rather than replacing the existing ones. The following example creates two ColumnSeries and sets their data providers. It then creates an Array that holds the existing chart series, and pushes the new series into that Array. Finally, it sets the value of the chart's `series` property to be the new Array of series.

```
<?xml version="1.0"?>
<!-- charts/AddingSeries.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv_fred.send();srv_fe.send();srv_strk.send();"
    height="600">
    <fx:Declarations>
         <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/stocks.aspx -->
         <!-- View source of the following pages to see the structure of the data that Flex
uses in this example. -->
       <mx:HTTPService id="srv_fred" url="http://aspexamples.adobe.com/chart_examples/stocks-
xml.aspx?tickerSymbol=FRED"/>
         <mx:HTTPService id="srv_fe" url="http://aspexamples.adobe.com/chart_examples/stocks-
xml.aspx?tickerSymbol=FE"/>
       <mx:HTTPService id="srv_strk" url="http://aspexamples.adobe.com/chart_examples/stocks-
xml.aspx?tickerSymbol=STRK"/>
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script><![CDATA[
        import mx.charts.series.ColumnSeries;
        import mx.collections.ArrayCollection;
        private var series1:ColumnSeries;
        private var series2:ColumnSeries;
        private function addMoreSeries():void {
            if (!series1 || !series2) {
                series1 = new ColumnSeries();
                series1.dataProvider = srv_fe.lastResult.data.result;
                series1.yField = "close";
                series1.xField = "date";
                series1.displayName = "FE";
                series2 = new ColumnSeries();
                series2.dataProvider = srv_strk.lastResult.data.result;
                series2.yField = "close";
                series2.xField = "date";
                series2.displayName = "STRK";
                var currentSeries:Array = myChart.series;
                currentSeries.push(series1);
                currentSeries.push(series2);
                myChart.series = currentSeries;
            }
        }
        private function resetApp():void {
            myChart.series = [ series0 ];
            series1 = null;
            series2 = null;
        }
    ]]></fx:Script>
    <s:Panel title="Column Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <mx:ColumnChart id="myChart" showDataTips="true">
            <mx:horizontalAxis>
                <mx:DateTimeAxis dataUnits="days"/>
            </mx:horizontalAxis>
            <mx:series>
                <mx:ColumnSeries dataProvider="{srv_fred.lastResult.data.result}"
                    id="series0"
                    yField="close"
                    xField="date"
                    displayName="FRED"/>
            </mx:series>
        </mx:ColumnChart>
        <mx:Legend dataProvider="{myChart}"/>
    </s:Panel>
    <s:HGroup>
        <s:Button id="b1" label="Add More Series To Chart" click="addMoreSeries()"/>
        <s:Button id="b2" label="Reset" click="resetApp()"/>
    </s:HGroup>
</s:Application>
```

By using ActionScript, you can also define a variable number of series for your charts. The following example uses E4X syntax to extract an Array of unique names from the data. It then iterates over this Array and builds a new LineSeries for each name.

```
<?xml version="1.0"?>
<!-- charts/VariableSeries.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp();"
    height="600">

  <fx:Script><![CDATA[
        import mx.charts.series.LineSeries;
        import mx.charts.DateTimeAxis;
        [Bindable]
        private var myXML:XML =
            <dataset>
            <item>
                <who>Tom</who>
                <when>08/22/2006</when>
                <hours>5.5</hours>
            </item>
            <item>
                <who>Tom</who>
                <when>08/23/2006</when>
                <hours>6</hours>
            </item>
            <item>
                <who>Tom</who>
                <when>08/24/2006</when>
                <hours>4.75</hours>
            </item>
            <item>
                <who>Dick</who>
                <when>08/22/2006</when>
                <hours>6</hours>
            </item>
            <item>
                <who>Dick</who>
                <when>08/23/2006</when>
                <hours>8</hours>
            </item>
            <item>
                <who>Dick</who>
                <when>08/24/2006</when>
                <hours>7.25</hours>
            </item>
            <item>
                <who>Jane</who>
                <when>08/22/2006</when>
                <hours>6.5</hours>
            </item>
            <item>
                <who>Jane</who>
                <when>08/23/2006</when>
                <hours>9</hours>
            </item>
            <item>
                <who>Jane</who>
                <when>08/24/2006</when>
                <hours>3.75</hours>
            </item>
            </dataset>;
        public function initApp():void {
            var wholist:Array = new Array();
            for each(var property:XML in myXML.item.who) {
                // Create an Array of unique names.
                if (wholist[property] != property)
                    wholist[property] = property;
            }
            // Iterate over names and create a new series
            // for each one.
            for (var s:String in wholist) {
                // Use all items whose name matches s.
                var localXML:XMLList = myXML.item.(who==s);
                // Create the new series and set its properties.
                var localSeries:LineSeries = new LineSeries();
                localSeries.dataProvider = localXML;
                localSeries.yField = "hours";
                localSeries.xField = "when";
                // Set values that show up in dataTips and Legend.
                localSeries.displayName = s;
                // Back up the current series on the chart.
                var currentSeries:Array = myChart.series;
                // Add the new series to the current Array of series.
                currentSeries.push(localSeries);
                // Add the new Array of series to the chart.
                myChart.series = currentSeries;
            }
            // Create a DateTimeAxis horizontal axis.
            var hAxis:DateTimeAxis = new DateTimeAxis();
            hAxis.dataUnits = "days";
            // Set this to false to display the leftmost label.
            hAxis.alignLabelsToUnits = false;
            // Take the date in its current format and create a Date
            // object from it.
            hAxis.parseFunction = createDate;
            myChart.horizontalAxis = hAxis;
        }
        public function createDate(s:String):Date {
            // Reformat the date input to create Date objects
            // for the axis.
```

```
            var a:Array = s.split("/");

            // The existing String s is in the format "MM/DD/YYYY".
            // To create a Date object, you pass "YYYY,MM,DD",
            // where MM is zero-based, to the Date() constructor.
            var newDate:Date = new Date(a[2],a[0]-1,a[1]);
            return newDate;
        }
    ]]></fx:Script>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Line Chart with Variable Number of Series">
     <s:layout>
         <s:HorizontalLayout/>
     </s:layout>
     <mx:LineChart id="myChart" showDataTips="true"/>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

Defining chart data

The chart controls have a `dataProvider` property that defines the data for the chart.

The data provider creates a level of abstraction between Flex components and the data that you use to populate them. You can populate multiple charts from the same data provider, switch data providers for a chart at run time, and modify the data provider so that changes are reflected by all charts using the data provider.

You can set the data provider on the chart, in which case all series inherit that data provider. Or you can set the data provider on each series in the chart.

Using chart data

To use the data from a data provider in your chart control, you map the `xField` and `yField` properties of the chart series to the fields in the data provider. The `xField` property defines the data for the horizontal axis, and the `yField` property defines the data for the vertical axis.

In ActionScript object syntax, assume your data provider has the following structure:

```
{month: "Feb", profit: 1000, expenses: 200, amount: 60}
```

In XML, the data might appear like the following:

```
<data>
    <result month="Feb">
        <profit>1000</profit>
        <expenses>200</expenses>
        <amount>60</amount>
    </result>
</data>
```

You can use the `profit` and `expenses` fields and ignore the `month` field by mapping the `xField` property of the series object to one field and the `yField` property of the series object to another field, as the following example shows:

```
<mx:PlotSeries xField="profit" yField="expenses"/>
```

The result is that each data point is the intersection of the `profit` and `expenses` fields from the data provider.

To place the data points into a meaningful grouping, you can choose a separate property of the data provider as the `categoryField`. In this case, to sort each data point by month, you map the `month` field to the `categoryField` property of the horizontal axis:

```
<mx:horizontalAxis>
    <mx:CategoryAxis
        dataProvider="{srv.lastResult.data.result}"
        categoryField="month"
    />
</mx:horizontalAxis>
```

In some cases, depending on the type of chart and the type of data you are representing, you use either the `xField` property or the `yField` property to define the data series. In a ColumnChart control, for example, the `yField` property defines the height of the column. You do not have to specify an `xField` property. To get an axis label for each column, you specify a `categoryField` property for the `horizontalAxis`.

The data provider can contain complex objects, or objects within objects. For example, a data provider object can have the following structure:

```
{month: "Aug", close: {High:45.87,Low:12.2}, open:25.19}
```

In this case, you cannot simply refer to the field of the data provider by using a `categoryField`, `xField`, or similar flat naming convention. Rather, you use the `dataFunction` of the series or axis to drill down into the data provider. For more information on working with complex data, see "Structure of chart data" on page 1113.

When you use chart data, keep the following in mind:

- You usually match a series with a data provider field if you want to display that series. However, this is not always true. If you do not specify an `xField` for a ColumnSeries, Flex assumes the index is the value. If you do not specify a `yField`, Flex assumes the data provider is a collection of *y* values, rather than a collection of objects that have *y* values. For example, the following series renders correctly for a ColumnChart control:

  ```
  <mx:ColumnSeries dataProvider="{[1,2,3,4,5]}"/>
  ```

- Some series use only one field from the data provider, while others can use two or more. For example, you specify only a `field` property for a PieSeries object, but you can specify an `xField` and a `yField` for a PlotSeries object and an `xField`, `yField`, and `radiusField` for a BubbleSeries object.
- Most of the series can determine suitable defaults for their nonprimary dimensions if no field is specified. For example, if you do not explicitly set an `xField` for the ColumnSeries, LineSeries, and AreaSeries, Flex maps the data to the chart's categories in the order in which the data appears in the data provider. Similarly, a BarSeries maps the data to the categories if you do not set a `yField`.

For a complete list of the fields that each data series can use, see the data series's class entry in *ActionScript 3.0 Reference for the Adobe Flash Platform*. For more information on data providers, see "Data provider controls" on page 645.

Sources of chart data

You can supply data to a data provider in the following ways:

- Define it in a `<fx:Script>` block.
- Define it in an external XML, ActionScript, or text file.
- Return it by using a WebService call.
- Return it by using a RemoteObject component.
- Return it by using an HTTPService component.
- Define it in MXML.

There are some limitations on the structure of the chart data, and how to reference chart data if it is constructed with complex objects. For more information, see “Structure of chart data” on page 1113.

For more information on data providers, see “Data providers and collections” on page 898.

Using static Arrays as data providers

Using a static Array of objects for the data provider is the simplest approach. You typically create an Array of objects, as the following example shows:

```
<?xml version="1.0"?>
<!-- charts/ArrayOfObjectsDataProvider.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    height="600">

  <fx:Script><![CDATA[
     [Bindable]
     private var expenses:Array = [
        {Month:"January",Profit:2000,Expenses:1500,Amount:450},
        {Month:"February",Profit:1000,Expenses:200,Amount:600},
        {Month:"March",Profit:1500,Expenses:500,Amount:300},
        {Month:"April",Profit:500,Expenses:300,Amount:500},
        {Month:"May",Profit:1000,Expenses:450,Amount:250},
        {Month:"June",Profit:2000,Expenses:500,Amount:700}
     ];
  ]]></fx:Script>

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Column Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:ColumnChart id="myChart"
        dataProvider="{expenses}"
        showDataTips="true">
        <mx:horizontalAxis>
           <mx:CategoryAxis
                dataProvider="{expenses}"
                categoryField="Month"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:ColumnSeries
                xField="Month"
                yField="Profit"
                displayName="Profit"/>
           <mx:ColumnSeries
                xField="Month"
                yField="Expenses"
                displayName="Expenses"/>
        </mx:series>
     </mx:ColumnChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

You can also use MXML to define the content of an Array, as the following example shows:

```
<?xml version="1.0"?>
<!-- charts/ArrayOfMXMLObjectsDataProvider.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    height="600">
  <fx:Declarations>
      <fx:Array id="expenses">
         <fx:Object
            Month="January"
            Profit="2000"
            Expenses="1500"
            Amount="450"
         />
         <fx:Object
            Month="February"
            Profit="1000"
            Expenses="200"
            Amount="600"
         />
         <fx:Object
            Month="March"
            Profit="1500"
            Expenses="500"
            Amount="300"
         />
         <fx:Object
            Month="April"
            Profit="500"
            Expenses="300"
            Amount="500"
         />
         <fx:Object
```

```
            Month="May"
            Profit="1000"
            Expenses="450"
            Amount="250"
         />
         <fx:Object
            Month="June"
            Profit="2000"
            Expenses="500"
            Amount="700"
         />
      </fx:Array>
  </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Column Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:ColumnChart id="myChart"
        dataProvider="{expenses}"
        showDataTips="true">
        <mx:horizontalAxis>
           <mx:CategoryAxis
                dataProvider="{expenses}"
                categoryField="Month"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:ColumnSeries
                xField="Month"
                yField="Profit"
                displayName="Profit"/>
           <mx:ColumnSeries
                xField="Month"
                yField="Expenses"
                displayName="Expenses"/>
        </mx:series>
     </mx:ColumnChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

When defining data in an Array in MXML, be sure to wrap it in a `<fx:Declarations>` tag.

You can also define objects in MXML with a more verbose syntax, as the following example shows:

```
<?xml version="1.0"?>
<!-- charts/ArrayOfVerboseMXMLObjects.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    height="600">
  <fx:Declarations>
      <fx:Array id="expenses">
         <fx:Object>
           <fx:Month>January</fx:Month>
           <fx:Profit>2000</fx:Profit>
           <fx:Expenses>1500</fx:Expenses>
           <fx:Amount>450</fx:Amount>
         </fx:Object>
         <fx:Object>
           <fx:Month>February</fx:Month>
           <fx:Profit>1000</fx:Profit>
           <fx:Expenses>200</fx:Expenses>
           <fx:Amount>600</fx:Amount>
         </fx:Object>
         <fx:Object>
           <fx:Month>March</fx:Month>
           <fx:Profit>1500</fx:Profit>
           <fx:Expenses>500</fx:Expenses>
           <fx:Amount>300</fx:Amount>
         </fx:Object>
         <fx:Object>
           <fx:Month>April</fx:Month>
           <fx:Profit>500</fx:Profit>
           <fx:Expenses>300</fx:Expenses>
           <fx:Amount>300</fx:Amount>
         </fx:Object>
         <fx:Object>
           <fx:Month>May</fx:Month>
           <fx:Profit>1000</fx:Profit>
           <fx:Expenses>450</fx:Expenses>
           <fx:Amount>250</fx:Amount>
         </fx:Object>
         <fx:Object>
           <fx:Month>June</fx:Month>
           <fx:Profit>2000</fx:Profit>
           <fx:Expenses>500</fx:Expenses>
           <fx:Amount>700</fx:Amount>
         </fx:Object>
      </fx:Array>
  </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Column Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
```

```
     <mx:ColumnChart id="myChart" dataProvider="{expenses}" showDataTips="true">
        <mx:horizontalAxis>
           <mx:CategoryAxis
                dataProvider="{expenses}"
                categoryField="Month"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:ColumnSeries
                xField="Month"
                yField="Profit"
                displayName="Profit"/>
           <mx:ColumnSeries
                xField="Month"
                yField="Expenses"
                displayName="Expenses"/>
        </mx:series>
     </mx:ColumnChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

A disadvantage of using a simple Array as a chart's data provider is that you can use only the methods of the Array class to manipulate the data. In addition, when you use an Array as a data provider, the data in it must be static. Even if you make the Array bindable, when data in an Array changes, the chart does not reflect those changes. For more robust data manipulation and data binding, you can use a collection for the chart data provider, as described in "Using collections as data providers" on page 1096.

Using collections as data providers

Collections are a more robust data provider mechanism than Arrays. They provide operations that include the insertion and deletion of objects as well as sorting and filtering. Collections also support change notification. An ArrayCollection object provides an easy way to expose an Array as an ICollectionView or IList interface.

As with Arrays, you can use MXML to define the contents of a collection, as the following example shows:

```
<?xml version="1.0"?>
<!-- charts/ArrayCollectionOfMXMLObjectsDataProvider.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    height="600">

    <fx:Declarations>
        <s:ArrayCollection id="expenses">
             <fx:Object
                Month="January"
                Profit="2000"
                Expenses="1500"
                Amount="450"/>
             <fx:Object
                Month="February"
                Profit="1000"
                Expenses="200"
                Amount="600"/>
             <fx:Object
                Month="March"
                Profit="1500"
                Expenses="500"
                Amount="300"/>
             <fx:Object
                Month="April"
                Profit="500"
                Expenses="300"
                Amount="500"/>
             <fx:Object
                Month="May"
                Profit="1000"
                Expenses="450"
                Amount="250"/>
             <fx:Object
                Month="June"
                Profit="2000"
                Expenses="500"
                Amount="700"/>
          </s:ArrayCollection>
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Column Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:ColumnChart id="myChart"
        dataProvider="{expenses}"
        showDataTips="true">
        <mx:horizontalAxis>
           <mx:CategoryAxis
                dataProvider="{expenses}"
                categoryField="Month"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:ColumnSeries
                xField="Month"
                yField="Profit"
                displayName="Profit"/>
           <mx:ColumnSeries
                xField="Month"
                yField="Expenses"
                displayName="Expenses"/>
        </mx:series>
     </mx:ColumnChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

Or you can define an object in MXML using child tags rather than attributes:

```
<?xml version="1.0"?>
<!-- charts/ArrayCollectionOfVerboseMXMLObjects.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    height="600">
    <fx:Declarations>
      <s:ArrayCollection id="expenses">
         <fx:Object>
           <fx:Month>January</fx:Month>
           <fx:Profit>2000</fx:Profit>
           <fx:Expenses>1500</fx:Expenses>
           <fx:Amount>450</fx:Amount>
         </fx:Object>
         <fx:Object>
           <fx:Month>February</fx:Month>
           <fx:Profit>1000</fx:Profit>
           <fx:Expenses>200</fx:Expenses>
           <fx:Amount>600</fx:Amount>
         </fx:Object>
         <fx:Object>
           <fx:Month>March</fx:Month>
           <fx:Profit>1500</fx:Profit>
           <fx:Expenses>500</fx:Expenses>
           <fx:Amount>300</fx:Amount>
         </fx:Object>
         <fx:Object>
           <fx:Month>April</fx:Month>
           <fx:Profit>500</fx:Profit>
           <fx:Expenses>300</fx:Expenses>
           <fx:Amount>300</fx:Amount>
         </fx:Object>
         <fx:Object>
           <fx:Month>May</fx:Month>
           <fx:Profit>1000</fx:Profit>
           <fx:Expenses>450</fx:Expenses>
           <fx:Amount>250</fx:Amount>
         </fx:Object>
         <fx:Object>
           <fx:Month>June</fx:Month>
           <fx:Profit>2000</fx:Profit>
           <fx:Expenses>500</fx:Expenses>
           <fx:Amount>700</fx:Amount>
         </fx:Object>
      </s:ArrayCollection>
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Column Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:ColumnChart id="myChart"
        dataProvider="{expenses}"
        showDataTips="true">
        <mx:horizontalAxis>
           <mx:CategoryAxis
                dataProvider="{expenses}"
                categoryField="Month"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:ColumnSeries
                xField="Month"
                yField="Profit"
                displayName="Profit"/>
           <mx:ColumnSeries
                xField="Month"
                yField="Expenses"
                displayName="Expenses"/>
        </mx:series>
     </mx:ColumnChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

You can create an ArrayCollection object in ActionScript. If you define an ArrayCollection in this way, ensure that you import the mx.collections.ArrayCollection class, as the following example shows:

```
<?xml version="1.0"?>
<!-- charts/ArrayCollectionOfObjects.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    height="600">

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <fx:Script><![CDATA[
     import mx.collections.ArrayCollection;
     [Bindable]
     private var expenses:ArrayCollection = new ArrayCollection([
        {Month:"January", Profit:2000, Expenses:1500, Amount:450},
        {Month:"February", Profit:1000, Expenses:200, Amount:600},
        {Month:"March", Profit:1500, Expenses:500, Amount:300},
        {Month:"April", Profit:500, Expenses:300, Amount:500},
        {Month:"May", Profit:1000, Expenses:450, Amount:250},
        {Month:"June", Profit:2000, Expenses:500, Amount:700}
     ]);
  ]]></fx:Script>

  <s:Panel title="Column Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:ColumnChart id="myChart"
        dataProvider="{expenses}"
        showDataTips="true">
        <mx:horizontalAxis>
           <mx:CategoryAxis
                dataProvider="{expenses}"
                categoryField="Month"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:ColumnSeries
                xField="Month"
                yField="Profit"
                displayName="Profit"/>
           <mx:ColumnSeries
                xField="Month"
                yField="Expenses"
                displayName="Expenses"/>
        </mx:series>
     </mx:ColumnChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

If your data is in an Array, you can pass the Array to the ArrayCollection's constructor to convert it to an ArrayCollection. The following example creates an Array, and then converts it to an ArrayCollection:

```
<?xml version="1.0"?>
<!-- charts/ArrayConvertedToArrayCollection.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    height="600">

  <fx:Script><![CDATA[
     import mx.collections.ArrayCollection;
     private var expenses:Array = [
        {Month:"January", Profit:2000, Expenses:1500, Amount:450},
        {Month:"February", Profit:1000, Expenses:200, Amount:600},
        {Month:"March", Profit:1500, Expenses:500, Amount:300},
        {Month:"April", Profit:500, Expenses:300, Amount:500},
        {Month:"May", Profit:1000, Expenses:450, Amount:250},
        {Month:"June", Profit:2000, Expenses:500, Amount:700}
     ];
     [Bindable]
     public var expensesAC:ArrayCollection =
        new ArrayCollection(expenses);
  ]]></fx:Script>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Column Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:ColumnChart id="myChart"
        dataProvider="{expensesAC}"
        showDataTips="true">
        <mx:horizontalAxis>
           <mx:CategoryAxis
                dataProvider="{expensesAC}"
                categoryField="Month"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:ColumnSeries
                xField="Month"
                yField="Profit"
                displayName="Profit"/>
           <mx:ColumnSeries
                xField="Month"
                yField="Expenses"
                displayName="Expenses"/>
        </mx:series>
     </mx:ColumnChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

Similarly, you can use an `<s:ArrayCollection>` tag to perform the conversion:

```
<?xml version="1.0"?>
<!-- charts/ArrayConvertedToArrayCollectionMXML.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    height="600">

  <fx:Script><![CDATA[
     import mx.collections.ArrayCollection;
     [Bindable]
     private var expenses:Array = [
        {Month:"January", Profit:2000, Expenses:1500, Amount:450},
        {Month:"February", Profit:1000, Expenses:200, Amount:600},
        {Month:"March", Profit:1500, Expenses:500, Amount:300},
        {Month:"April", Profit:500, Expenses:300, Amount:500},
        {Month:"May", Profit:1000, Expenses:450, Amount:250},
        {Month:"June", Profit:2000, Expenses:500, Amount:700}
     ];
  ]]></fx:Script>
  <fx:Declarations>
      <s:ArrayCollection id="expensesAC" source="{expenses}"/>
  </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Column Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:ColumnChart id="myChart"
        dataProvider="{expensesAC}"
        showDataTips="true">
        <mx:horizontalAxis>
           <mx:CategoryAxis
                dataProvider="{expensesAC}"
                categoryField="Month"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:ColumnSeries
                xField="Month"
                yField="Profit"
                displayName="Profit"/>
           <mx:ColumnSeries
                xField="Month"
                yField="Expenses"
                displayName="Expenses"/>
        </mx:series>
     </mx:ColumnChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

The data in ArrayCollections can be bound to the chart's data provider so that the data can be updated in real-time. The following example creates an object with elapsed time and total memory usage every second. It then pushes that new object onto an ArrayCollection that is used as the data provider for a line chart. As a result, the chart itself updates every second showing memory usage of Adobe® Flash® Player or Adobe® AIR™ over time.

```
<?xml version="1.0"?>
<!-- charts/RealTimeArrayCollection.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    initialize="initTimer()"
    height="600">

  <fx:Script><![CDATA[
      import flash.utils.Timer;
      import flash.events.TimerEvent;
      import mx.collections.ArrayCollection;
      [Bindable]
      public var memoryUsage:ArrayCollection = new ArrayCollection();
      public function initTimer():void {
         // The first parameter in the Timer constructor
         // is the interval, in milliseconds.
         // The second parameter is how many times to run (0 is
         // infinity).
         var myTimer:Timer = new Timer(1000, 0);
         // Add the listener for the timer event.
         myTimer.addEventListener("timer", timerHandler);
         myTimer.start();
      }
      public function timerHandler(event:TimerEvent):void {
         var o:Object = new Object();
         // Get the number of milliseconds since Flash Player or AIR started.
         o.time = getTimer();
         // Get the total memory Flash Player or AIR is using.
         o.memory = flash.system.System.totalMemory;
         trace(o.time + ":" + o.memory);
         // Add new object to the ArrayCollection, which is bound
         // to the chart's data provider.
         memoryUsage.addItem(o);
      }
  ]]></fx:Script>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Memory Usage">
     <s:layout>
         <s:VerticalLayout/>
     </s:layout>
      <mx:LineChart id="chart"
        dataProvider="{memoryUsage}"
         showDataTips="true">
         <mx:horizontalAxis>
            <mx:LinearAxis/>
         </mx:horizontalAxis>
         <mx:verticalAxis>
            <mx:LinearAxis minimum="5000000"/>
         </mx:verticalAxis>
         <mx:series>
            <mx:LineSeries yField="memory"/>
         </mx:series>
      </mx:LineChart>
    </s:Panel>
</s:Application>
```

Data collections can be paged, which means that data is sent to the client in chunks as the application requests it. But Flex charting controls display all of the data all of the time, by default. As a result, when you use data collections with charts, you should disable the paging features or use non-paged views of the data collection for chart data.

For more information on using collections, see “Data providers and collections” on page 898.

Using an XML file as a data provider

You can define data provider data in a structured file. The following example shows the contents of the data.xml file:

```
<data>
    <result month="Jan-04">
        <apple>81768</apple>
        <orange>60310</orange>
        <banana>43357</banana>
    </result>
    <result month="Feb-04">
        <apple>81156</apple>
        <orange>58883</orange>
        <banana>49280</banana>
    </result>
</data>
```

You can load the file directly as a source of a Model, as the following example shows:

```
<?xml version="1.0"?>
<!-- charts/XMLFileDataProvider.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    height="600">
    <fx:Declarations>
        <fx:Model id="results" source="../assets/data.xml"/>
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Line Chart">
     <s:layout>
         <s:HorizontalLayout/>
     </s:layout>
     <mx:LineChart id="myChart"
        dataProvider="{results.result}" showDataTips="true">
        <mx:horizontalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:LineSeries yField="banana" displayName="Banana"/>
           <mx:LineSeries yField="apple" displayName="Apple"/>
           <mx:LineSeries yField="orange" displayName="Orange"/>
        </mx:series>
     </mx:LineChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

You can use more complex XML to define the data provider's data. For example, an XML-based data provider can have nested tags. In that case, however, you must use a `dataFunction` to define the fields that the chart uses. For more information, see "Structure of chart data" on page 1113.

To use an ArrayCollection as the chart's data provider, you convert the Model to an ArrayCollection, as the following example shows:

```
<?xml version="1.0"?>
<!-- charts/XMLFileToArrayCollectionDataProvider.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    height="600">

    <fx:Declarations>
        <fx:Model id="results" source="../assets/data.xml"/>
        <s:ArrayCollection id="myAC"
            source="{ArrayUtil.toArray(results.result)}"/>
    </fx:Declarations>
    <fx:Script>
        import mx.utils.ArrayUtil;
    </fx:Script>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Line Chart">
     <s:layout>
         <s:HorizontalLayout/>
     </s:layout>
     <mx:LineChart id="myChart"
        dataProvider="{myAC}" showDataTips="true">
        <mx:horizontalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:LineSeries yField="banana" displayName="Banana"/>
           <mx:LineSeries yField="apple" displayName="Apple"/>
           <mx:LineSeries yField="orange" displayName="Orange"/>
        </mx:series>
     </mx:LineChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

Using HTTPService as a data provider

You can define an XML file or any page that returns an XML result as a URL for an HTTPService component. You then bind the HTTPService result directly to the chart’s data provider, as the following example shows:

```
<?xml version="1.0"?>
<!-- charts/HTTPServiceDataProvider.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Line Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:LineChart id="myChart"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true">
        <mx:horizontalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:horizontalAxis>
        <mx:series>
          <mx:LineSeries
                yField="profit"
                displayName="Profit"/>
           <mx:LineSeries
                yField="expenses"
                displayName="Expenses"/>
         </mx:series>
     </mx:LineChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

As with most other non-visual components, be sure to wrap the `<mx:HTTPService>` tag in a `<fx:Declarations>` tag.

In this example, the target URL returns the following XML:

```
<data>
    <result month="Jan">
        <profit>2000</profit>
        <expenses>1500</expenses>
        <amount>450</amount>
    </result>
    <result month="Feb">
        <profit>1000</profit>
        <expenses>200</expenses>
        <amount>600</amount>
    </result>
    <result month="Mar">
        <profit>1500</profit>
        <expenses>500</expenses>
        <amount>300</amount>
    </result>
</data>
```

To use an ArrayCollection, you cast the HTTPService result, as the following example shows:

```
<?xml version="1.0"?>
<!-- charts/HTTPServiceToArrayCollectionDataProvider.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
        <mx:HTTPService id="srv"
            url="http://aspexamples.adobe.com/chart_examples/expenses-xml.aspx"
            useProxy="false"
            result="myData=ArrayCollection(srv.lastResult.data.result)"
        />
    </fx:Declarations>
  <fx:Script><![CDATA[
     import mx.collections.ArrayCollection;
     [Bindable]
     public var myData:ArrayCollection;
  ]]></fx:Script>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Line Chart">
```

```
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:LineChart id="myChart"
        dataProvider="{myData}" showDataTips="true">
        <mx:horizontalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:horizontalAxis>
        <mx:series>
          <mx:LineSeries
                yField="profit"
                displayName="Profit"/>
           <mx:LineSeries
                yField="expenses"
                displayName="Expenses"/>
        </mx:series>
     </mx:LineChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

You can also set the result format of the HTTPService to E4X, and then use it as a source for an XMLListCollection object, as the following example shows:

```
<?xml version="1.0"?>
<!-- charts/HTTPServiceToXMLListCollection.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
        <mx:HTTPService id="srv"
            url="http://aspexamples.adobe.com/chart_examples/expenses-xml.aspx"
            resultFormat="e4x"
        />
        <mx:XMLListCollection id="myAC"
            source="{srv.lastResult.result}"
        />
    </fx:Declarations>
  <fx:Script><![CDATA[
     import mx.utils.ArrayUtil;
  ]]></fx:Script>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Line Chart">
```

```
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:LineChart id="myChart"
        dataProvider="{myAC}" showDataTips="true">
        <mx:horizontalAxis>
           <mx:CategoryAxis categoryField="@month"/>
        </mx:horizontalAxis>
        <mx:series>
          <mx:LineSeries
                yField="profit"
                displayName="Profit"/>
           <mx:LineSeries
                yField="expenses"
                displayName="Expenses"/>
        </mx:series>
     </mx:LineChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

Another approach is to define the target URL of the HTTPService component as an HTML page that contains data. For example, you might have an HTML page with source that looks like the following:

```
<html>
<body>
<h1>This is a data page</h1>
<!-- data starts here -->
<entry>
    <month>Jan</month>
    <misc>15300</misc>
</entry>
<entry>
    <month>Feb</month>
    <misc>17800</misc>
</entry>
<entry>
    <month>Mar</month>
    <misc>20000</misc>
</entry>
<!-- data ends here -->
</body>
</html>
```

In your application, you can extract the data from the HTML page by using regular expressions. You can then assign the resulting string to an XMLList and use it as a data provider, as the following example shows:

```
<?xml version="1.0"?>
<!-- charts/HTMLDataProvider.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp()"
    height="600">
    <fx:Declarations>
        <mx:HTTPService id="serviceInput"
            resultFormat="text"
            url="http://aspexamples.adobe.com/chart_examples/testDataPage.html"
        />
    </fx:Declarations>

    <fx:Script><![CDATA[
        import mx.events.FlexEvent;
        import mx.rpc.events.ResultEvent;
        import mx.rpc.events.FaultEvent;

        [Bindable]
        public var chartData:XMLList;
        private function initApp():void {
            serviceInput.addEventListener(ResultEvent.RESULT, resultHandler);
            serviceInput.addEventListener(FaultEvent.FAULT, faultHandler);
            serviceInput.send();
        }
        public function resultHandler(evt:Event):void {
            // Extract the XML data from the HTML page.
            var htmlBlob:String = serviceInput.lastResult.toString();
            htmlBlob = htmlBlob.slice( htmlBlob.indexOf("<!-- data starts here -->", 0) +
                25, htmlBlob.length );
        htmlBlob = htmlBlob.slice( 0, htmlBlob.indexOf("<!-- data ends here -->", 0) );
            // Create an XMLList from the extracted XML data.
            chartData = new XMLList(htmlBlob);
        }
        public function faultHandler(evt:Event):void {
            trace(evt.toString());
        }
    ]]></fx:Script>

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Line chart with data extracted from HTML page">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
         <mx:LineChart id="chart"
            dataProvider="{chartData}" showDataTips="true">
             <mx:series>
                 <mx:LineSeries id="series1" yField="misc" xField="month"/>
             </mx:series>
             <mx:horizontalAxis>
                 <mx:CategoryAxis categoryField="month"/>
             </mx:horizontalAxis>
         </mx:LineChart>
     </s:Panel>
</s:Application>
```

To load the data from a URL on another domain, that target domain must have a crossdomain.xml policy file in place. That policy file must allow the domain on which your Flex application is running to access its data.

In this example, if you requested the data page, the data does not render in the brower because it is wrapped in tags that are outside of the HTML specification. If the data were meant to be displayed, it might be surrounded in HTML entities for the left and right angle brackets, like the following example shows:

```
<html>
<body>
<h1>This is a data page</h1>
<!-- data starts here -->
&lt;entry&gt;
    &lt;month&gt;Jan&lt;/month&gt;
    &lt;misc&gt;15300&lt;/misc&gt;
&lt;/entry&gt;
&lt;entry&gt;
    &lt;month&gt;Feb&lt;/month&gt;
    &lt;misc&gt;17800&lt;/misc&gt;
&lt;/entry&gt;
&lt;entry&gt;
    &lt;month&gt;Mar&lt;/month&gt;
    &lt;misc&gt;20000&lt;/misc&gt;
&lt;/entry>
<!-- data ends here -->
</body>
</html>
```

In that case, you could replace the HTML entities with angle brackets after the source was loaded, as the following example shows:

```
var tagPattern:RegExp = /<[^<>]*>/g;
htmlBlob = htmlBlob.replace(tagPattern, "");

var ltPattern:RegExp = /&lt;/g;
htmlBlob = htmlBlob.replace(ltPattern, "<");

var gtPattern:RegExp = /&gt;/g;
htmlBlob = htmlBlob.replace(gtPattern, ">");
```

Randomly generating chart data

A useful way to create data for use in sample charts is to generate random data. The following example generates test data for use with the chart controls:

```
<?xml version="1.0"?>
<!-- charts/RandomDataGeneration.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp()"
    height="600">

  <fx:Script><![CDATA[
     import mx.collections.*;
     // Define data provider array for the chart data.
     [Bindable]
     public var dataSet:ArrayCollection;
     // Define the number of elements in the array.
     public var dsLength:Number = 10;
     public function initApp():void {
        // Initialize data provider array.
        dataSet = new ArrayCollection(genData());
     }
     public function genData():Array {
        var result:Array = [];
        for (var i:int=0;i<dsLength;i++) {
           var localVals:Object = {
                valueA:Math.random()*100,
                valueB:Math.random()*100,
                valueX:Math.random()*100,
                valueY:Math.random()*100
           };
           // Push new object onto the data array.
           result.push(localVals);
        }
        return result;
     }
  ]]></fx:Script>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Plot Chart">
     <s:layout>
         <s:VerticalLayout/>
     </s:layout>
     <mx:PlotChart id="myChart"
        dataProvider="{dataSet}" showDataTips="true">
        <mx:series>
           <mx:PlotSeries
                xField="valueX"
                yField="valueY"
                displayName="Series 1"/>
           <mx:PlotSeries
                xField="valueA"
                yField="valueB"
                displayName="Series 2"/>
        </mx:series>
     </mx:PlotChart>
     <mx:Legend id="l1" dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

Structure of chart data

In most cases, the data that is used as the chart's data provider is made up of scalar values. For example, objects contain a single set of fields:

```
{month: "Aug", close: 45.87, open:25.19},
```

Or XML data contains a single set of child tags in a flat structure:

```
<stock>
    <month>Aug</month>
    <close>45.87</close>
    <open>25.19</open>
</stock>
```

In these cases, you assign the data provider's fields to items in the chart by using the `xField` and `yField` for the series, or the `categoryField` for the axis; for example:

```
<mx:ColumnSeries yField="close"/>
<mx:CategoryAxis categoryField="month"/>
```

However, the structure of the chart data can be made up of more complex objects, such as objects within objects or XML with nested child tags. For example, you can embed an object within an object:

```
{month: "Aug", close: {High:45.87,Low:12.2}, open:25.19}
```

Or use nested tags in an XML object:

```
<stock>
    <date>
        <month>Aug</month>
    </date>
    <price>
        <close>45.87</close>
        <open>25.19</open>
    </price>
</stock>
```

In these cases, you cannot refer to the target data by using the flat naming such as `yField="close"`. You also cannot use dot notation. For example, `yField="values.close"` or `categoryField="data.month"` are not valid. Instead, you must use a `dataFunction` method to define which ChartItem fields are populated by the data provider.

For the CategoryAxis class, the `dataFunction` has the following signature:

```
function_name(axis:AxisBase, item:Object):Object
```

Where *axis* is the base class for the current axis, and *item* is the item in the data provider.

For the Series class, the `dataFunction` has the following signature:

```
function_name(series:Series, item:Object, fieldName:String):Object
```

Where *series* is a reference to the current series, *item* is the item in the data provider, and *fieldName* is the field in the current ChartItem that will be populated.

The following example creates two functions that access complex data for both the axis and the series:

```
<?xml version="1.0"?>

            </mx:series>
        </mx:ColumnChart>
    </s:Panel>
</s:Application>
```

Changing chart data at run time

Using ActionScript, you can change a charting control's data at run time by using a variety of methods.

You can change a chart or a series data provider. To do this with an HTTPService as the source of your data provider, you change the URL and then call the HTTPService control's `send()` method again.

The following example changes the data provider when the user selects a new ticker symbol from the ComboBox control:

```
<?xml version="1.0"?>
<!-- charts/ChangeSrvDataProvider.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses 
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/stocks-
xml.aspx"/>
        <!-- To see data in an HTML table, go to 
http://aspexamples.adobe.com/chart_examples/stocks.aspx -->
    </fx:Declarations>
    <fx:Script><![CDATA[
        public function changeDataProvider(event:Event):void {
            srv.url = "http://aspexamples.adobe.com/chart_examples/stocks-xml.aspx" +
                "?" + "tickerSymbol=" + event.currentTarget.selectedItem;
                srv.send();
        }
    ]]></fx:Script>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:Panel title="Column Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <mx:ColumnChart id="myChart" dataProvider="{srv.lastResult.data.result}" 
showDataTips="true">
            <mx:horizontalAxis>
                <mx:DateTimeAxis dataUnits="days"/>
            </mx:horizontalAxis>
            <mx:series>
                <mx:ColumnSeries 
                    yField="close" xField="date" 
                    displayName="Closing Price of {cb1.selectedItem}"/>
            </mx:series>
        </mx:ColumnChart>
        <mx:Legend dataProvider="{myChart}"/>
    </s:Panel>
    <s:ComboBox id="cb1" change="changeDataProvider(event)">
        <s:ArrayCollection>
            <fx:String>FRED</fx:String>
            <fx:String>STRK</fx:String>
            <fx:String>FE</fx:String>
        </s:ArrayCollection>
    </s:ComboBox>
</s:Application>
```

The following example defines the data providers as ArrayCollections. It then binds the data provider to a local variable. The example then toggles the chart’s data provider using that local variable when the user clicks the button.

```
<?xml version="1.0"?>
<!-- charts/ChangeDataProvider.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    height="600">
    <fx:Script>
        <![CDATA[
        import mx.collections.ArrayCollection;
        [Bindable]
        public var expenses:ArrayCollection = new ArrayCollection([
            {Month:"Jan", Profit:2000, Expenses:1500, Amount:450},
            {Month:"Feb", Profit:1000, Expenses:200, Amount:600},
            {Month:"Mar", Profit:1500, Expenses:500, Amount:300}
        ]);
        [Bindable]
        public var expenses2:ArrayCollection = new ArrayCollection([
            {Month:"Jan", Profit:2400, Expenses:1509, Amount:950},
            {Month:"Feb", Profit:3000, Expenses:2200, Amount:400},
            {Month:"Mar", Profit:3500, Expenses:1200, Amount:200}
        ]);
        [Bindable]
        public var dp:ArrayCollection = expenses;
        public function changeDataProvider():void {
            if (dp==expenses) {
                dp = expenses2;
            } else {
                dp = expenses;
            }
        }
        ]]>
    </fx:Script>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:Panel title="Line Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <mx:LineChart id="myChart" dataProvider="{dp}" showDataTips="true">
            <mx:horizontalAxis>
                <mx:CategoryAxis
                    dataProvider="{dp}"
                    categoryField="Month"/>
            </mx:horizontalAxis>
            <mx:series>
                <mx:LineSeries
                    yField="Profit"
                    displayName="Profit"/>
                <mx:LineSeries
                    yField="Expenses"
                    displayName="Expenses"/>
                <mx:LineSeries
                    yField="Amount"
                    displayName="Amount"/>
            </mx:series>
        </mx:LineChart>
        <mx:Legend dataProvider="{myChart}"/>
    </s:Panel>
    <s:Button id="b1"
        label="Change Data Provider"
        click="changeDataProvider()"/>
</s:Application>
```

You can add or remove a data point from a series in ActionScript. The following example adds an item to the existing data provider when the user clicks the button:

```
<?xml version="1.0"?>
<!-- charts/AddDataItem.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns="*" height="600" width="700">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script><![CDATA[
        import mx.collections.ArrayCollection;
        [Bindable]
        public var dpac:ArrayCollection =  new ArrayCollection([
           {A:2000},
           {A:3000},
           {A:4000},
           {A:4000},
           {A:3000},
           {A:2000},
           {A:6000}
        ]);

        public function addDataItem():void {
            var o:Object = {"A":2000};
            dpac.addItem(o);
        }

        private function removeItem():void {
            var i:int = dpac.length;
            if (i > 0) {
                dpac.removeItemAt(i - 1);
            }
        }
    ]]></fx:Script>

  <s:Panel title="Column Chart">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
     <mx:ColumnChart id="myChart"
        showDataTips="true"
        height="400"
        width="600"
        dataProvider="{dpac}">
        <mx:series>
            <mx:ColumnSeries yField="A" displayName="Series 1"/>
        </mx:series>
     </mx:ColumnChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
  <s:HGroup>
      <s:Button label="Add Data Item" click="addDataItem();"/>
      <s:Button label="Remove Data Item" click="removeItem();"/>
  </s:HGroup>
</s:Application>
```

You can also change the fields of a series to change chart data at run time. You do this by changing the value of the data provider field (such as `xField` or `yField`) on the series object. To get a reference to the series, you use the series' `id` property or the chart control's series index. The following example toggles the data series when the user clicks on the Change Series button:

```
<?xml version="1.0"?>
<!-- charts/ToggleSeries.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    initialize="initApp();"
    height="600">
  <fx:Script><![CDATA[
     [Bindable]
     public var dataSet:Array;
     public var myStates:Array =
        ["Wisconsin","Ohio","Arizona","Penn"];
     public var curSeries:String;
     public function initApp():void {
        var newData:Array = [];
        for(var i:int=0;i<myStates.length;i++) {
           newData[i] = {
             Apples: Math.floor(Math.random()*150),
             Oranges: Math.floor(Math.random()*150),
             myState: myStates[i]
           }
        }
        dataSet = newData;
        curSeries = "apples";
     }
     public function changeData():void {
        var series:Object = myChart.series[0];
        if (curSeries == "apples") {
           curSeries="oranges";
           series.yField = "Oranges";
           series.displayName = "Oranges";
           series.setStyle("fill",0xFF9933);
        } else {
           curSeries="apples";
           series.yField = "Apples";
           series.displayName = "Apples";
           series.setStyle("fill",0xFF0000);
        }
     }
  ]]></fx:Script>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:Panel title="Column Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <mx:ColumnChart id="myChart"
            dataProvider="{dataSet}" showDataTips="true">
            <mx:horizontalAxis>
                <mx:CategoryAxis dataProvider="{dataSet}"
                    categoryField="myState"/>
            </mx:horizontalAxis>
            <mx:series>
                <mx:ColumnSeries yField="Apples" displayName="Apples">
                    <mx:fill>
                        <mx:SolidColor color="0xFF0000"/>
                    </mx:fill>
                </mx:ColumnSeries>
            </mx:series>
        </mx:ColumnChart>
        <mx:Legend dataProvider="{myChart}"/>
    </s:Panel>
    <s:Button id="b1" label="Toggle Series" click="changeData()"/>
</s:Application>
```

You can take advantage of data binding to make your chart reflect data changes in real time. The following example uses a Timer to define the intervals at which it checks for new data. Because the chart's data provider is bound to an ArrayCollection, whenever a new data point is added to the collection, the chart is automatically updated.

```
<?xml version="1.0"?>
<!-- charts/WatchingCollections.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    initialize="initData();"
    height="600">
    <fx:Declarations>
        <mx:SeriesInterpolate id="interp"
            elementOffset="0"
            duration="300"
            minimumElementDuration="0"
        />
    </fx:Declarations>

    <fx:Script><![CDATA[
        import mx.collections.ArrayCollection;
        [Bindable]
        public var dataSet:ArrayCollection;
        [Bindable]
        public var revenue:Number = 100;
        private var t:Timer;
        private function initData():void {
            dataSet = new ArrayCollection();
            t = new Timer(500);
        }
        private function startApp():void {
            t.addEventListener(TimerEvent.TIMER, addData);
            t.start();
        }
        private function addData(e:Event):void {
            /* Add a maximum of 100 data points before user has to click
               the Start button again. */
            if (dataSet.length > 100) {
                stopApp();
            }
            dataSet.addItem( { revenue: revenue } );
            revenue += Math.random() * 10 - 5;
        }

        private function stopApp():void {
            t.stop();
            t.removeEventListener(TimerEvent.TIMER, addData);
        }
    ]]></fx:Script>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:Panel title="Line Chart">
         <s:layout>
```

```
             <s:HorizontalLayout/>
         </s:layout>
        <mx:LineChart id="myChart" dataProvider="{dataSet}">
            <mx:series>
                <mx:LineSeries
                    yField="revenue"
                    showDataEffect="{interp}"
                    displayName="Revenue"/>
            </mx:series>
            <mx:horizontalAxis>
                <mx:LinearAxis autoAdjust="false"/>
            </mx:horizontalAxis>
        </mx:LineChart>
        <mx:Legend dataProvider="{myChart}"/>
    </s:Panel>
    <s:HGroup>
        <s:Button id="b1" label="Start" click="startApp()"/>
        <s:Button id="b2" label="Stop" click="stopApp()"/>
    </s:HGroup>
</s:Application>
```

You can also use system values to update charts at run time. The following example tracks the value of the `totalMemory` property in a LineChart control in real time:

```
<?xml version="1.0"?>
<!-- charts/MemoryGraph.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    initialize="initTimer()"
    height="600">
  <fx:Script><![CDATA[
      import flash.utils.Timer;
      import flash.events.TimerEvent;
      import mx.collections.ArrayCollection;
      [Bindable]
      public var memoryUsage:ArrayCollection = new ArrayCollection();
        public function initTimer():void {
           /* The first parameter in the Timer constructor
              is the interval, in milliseconds. The second
              parameter is how many times to run (0 is
              infinity). */
           var myTimer:Timer = new Timer(1000, 0);
           /* Add the listener for the timer event. */
           myTimer.addEventListener("timer", timerHandler);
           myTimer.start();
        }
        public function timerHandler(event:TimerEvent):void {
           var o:Object = new Object();
           /* Get the number of milliseconds since Flash
              Player started. */
           o.time = getTimer();
           /* Get the total memory Flash Player is using. */
           o.memory = flash.system.System.totalMemory;
           /* Add new object to the ArrayCollection, which
              is bound to the chart's data provider. */
```

```
                memoryUsage.addItem(o);
            }
    ]]></fx:Script>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:Panel id="p1" title="Memory Usage">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>

        <mx:LineChart id="chart"
            dataProvider="{memoryUsage}"
            showDataTips="true">
            <mx:horizontalAxis>
                <mx:LinearAxis/>
            </mx:horizontalAxis>
            <mx:verticalAxis>
                <mx:LinearAxis minimum="5000000"/>
            </mx:verticalAxis>
            <mx:series>
                <fx:Array>
                    <mx:LineSeries yField="memory"/>
                </fx:Array>
            </mx:series>
        </mx:LineChart>
    </s:Panel>
</s:Application>
```

Using charts in MX-only applications

An MX-only application is an application that does not use any classes from the spark.swc file in its library path. The main application's root tag is the MX Application class, and no components from the Spark component set are used.

You can use the Flex charting controls in MX-only applications. However, some charting components such as the BarChart and ColumnChart controls, use Spark components by default. As a result, to use charts in MX-only applications, you must apply the MXCharts.css theme to your application. This convenience theme file replaces the use of the Spark Label classes with the MX Label class for the `labelClass` style property.

To apply the MXCharts.css theme to your application on the command line, use the theme compiler option, as the following example shows:

```
mxmlc -theme+=../frameworks/projects/charts/MXCharts.css
```

In Flash Builder, to apply the MXCharts.css theme, use the Additional Compiler Arguments field on the Flex Compiler properties dialog box.

If you set the `compatibility-version` compiler option to 4.0.0, Flex applies the MXCharts.css theme by default.

Chart types

Adobe Flex provides different types of charting controls.

Using area charts

You use the AreaChart control to represent data as an area bounded by a line connecting the data values. The area underneath the line is filled in with a color or pattern. You can use an icon or symbol to represent each data point along the line, or you can show a simple line without icons.

The following example creates an AreaChart control:

```
<?xml version="1.0"?>
<!-- charts/BasicArea.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">

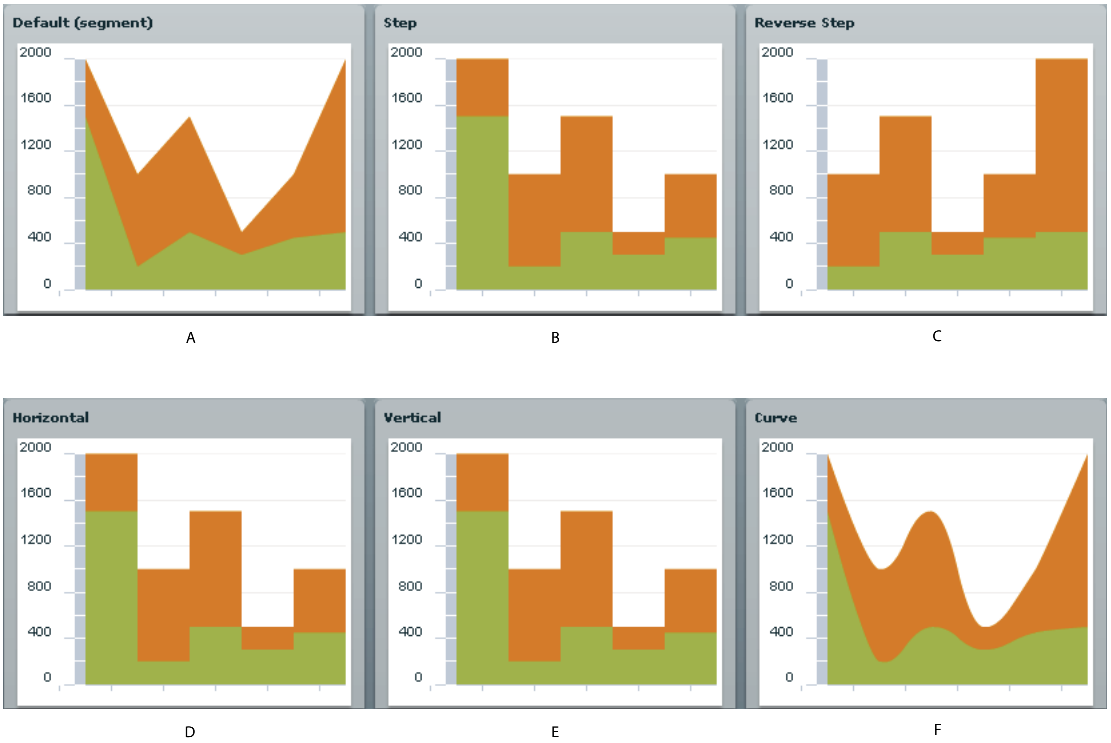
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Area Chart">
      <s:layout>
          <s:VerticalLayout/>
      </s:layout>
     <mx:AreaChart id="myChart"
        showDataTips="true"
        dataProvider="{srv.lastResult.data.result}">
        <mx:horizontalAxis>
           <mx:CategoryAxis
               categoryField="month"
               displayName="Month"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:AreaSeries yField="profit" displayName="Profit"/>
           <mx:AreaSeries yField="expenses" displayName="Expenses"/>
        </mx:series>
     </mx:AreaChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

An area chart is essentially a line chart with the area underneath the line filled in; therefore, area charts and line charts share many of the same characteristics. For more information, see “Using line charts” on page 1144.

You use the AreaSeries chart series with the AreaChart control to define the data for the chart. The following table describes properties of the AreaSeries chart series that you commonly use to define your chart:

Property	**Description**
`yField`	Specifies the field of the data provider that determines the y-axis location of each data point.
`xField`	Specifies the field of the data provider that determines the x-axis location of each data point. If you omit this field, Flex arranges the data points in the order of the data in the data provider.
`minField`	Specifies the field of the data provider that determines the y-axis location of the bottom of an area. This property is optional. If you omit it, the bottom of the area is aligned with the x-axis. This property has no effect on overlaid, stacked, or 100% stacked charts. For more information on using the `minField` property, see "Using the minField property" on page 1306.
`form`	Specifies the way in which the data series is shown in the chart. The following values are valid: • `segment` Draws lines as connected segments that are angled to connect at each data point in the series. This is the default. • `step` Draws lines as horizontal and vertical segments. At the first data point, draws a horizontal line, and then a vertical line to the second point. Repeats this action for each data point. • `reverseStep` Draws lines as horizontal and vertical segments. At the first data point, draws a vertical line, and then a horizontal line to the second point. Repeats this action for each data point. • `vertical` Draws only the vertical line from the *y*-coordinate of the first point to the *y*-coordinate of the second point at the *x*-coordinate of the second point. Repeats this action for each data point. • `horizontal` Draws only the horizontal line from the *x*-coordinate of the first point to the x-coordinate of the second point at the *y*-coordinate of the first point. Repeats this action for each data point. • `curve` Draws curves between data points.

The following example shows the available forms for an AreaChart control's series:



***A.** Segment (default)* ***B.** Step* ***C.** Reverse Step* ***D.** Horizontal* ***E.** Vertical* ***F.** Curve*

You can use the `type` property of the AreaChart control to represent a number of chart variations, including overlaid, stacked, 100% stacked, and high-low areas. For more information, see “Stacking charts” on page 1308.

To customize the fills of the series in an AreaChart control, you use the `areaFill` and `areaStroke` properties. For each fill, you specify a SolidColor and a SolidColorStroke object. The following example defines three custom SolidColor objects and three custom SolidColorStroke objects, and applies them to the three AreaSeries objects in the AreaChart control.

```
<?xml version="1.0"?>
<!-- charts/AreaChartFills.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">

    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
        <!-- Define custom colors for use as fills in the AreaChart control. -->
        <mx:SolidColor id="sc1" color="blue" alpha=".3"/>
        <mx:SolidColor id="sc2" color="red" alpha=".3"/>
        <mx:SolidColor id="sc3" color="green" alpha=".3"/>
        <!-- Define custom SolidColorStrokes. -->
        <mx:SolidColorStroke id="s1" color="blue" weight="2"/>
        <mx:SolidColorStroke id="s2" color="red" weight="2"/>
        <mx:SolidColorStroke id="s3" color="green" weight="2"/>
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:Panel title="AreaChart Control with Custom Fills Example"
        height="100%" width="100%">
        <s:layout>
            <s:HorizontalLayout/>
        </s:layout>
        <mx:AreaChart id="Areachart"
            height="100%" width="70%"
            paddingLeft="5" paddingRight="5"
            showDataTips="true"
            dataProvider="{srv.lastResult.data.result}">
            <mx:horizontalAxis>
                <mx:CategoryAxis categoryField="Month"/>
            </mx:horizontalAxis>
            <mx:series>
```

```
                <mx:AreaSeries
                    yField="profit"
                    displayName="Profit"
                    areaStroke="{s1}"
                    areaFill="{sc1}"/>
                <mx:AreaSeries
                    yField="expenses"
                    displayName="Expenses"
                    areaStroke="{s2}"
                    areaFill="{sc2}"/>
                <mx:AreaSeries
                    yField="amount"
                    displayName="Amount"
                    areaStroke="{s3}"
                    areaFill="{sc3}"/>
            </mx:series>
        </mx:AreaChart>
        <mx:Legend dataProvider="{Areachart}"/>
    </s:Panel>
</s:Application>
```

For more information on using fills, see “Using fills with chart controls” on page 1197. For more information on using the SolidColorStroke class, see “Using strokes with chart controls” on page 1192.

Using bar charts

You use the BarChart control to represent data as a series of horizontal bars whose length is determined by values in the data. You can use the BarChart control to represent a number of chart variations, including clustered bars, overlaid, stacked, 100% stacked, and high-low areas. For more information, see “Stacking charts” on page 1308.

You use the BarSeries chart series with the BarChart control to define the data for the chart. The following table describes the properties of the BarSeries chart series that you use to define your chart:

Property	Description
`yField`	Specifies the field of the data provider that determines the y-axis location of the base of each bar in the chart. If you omit this property, Flex arranges the bars in the order of the data in the data provider.
`xField`	Specifies the field of the data provider that determines the x-axis location of the end of each bar.
`minField`	Specifies the field of the data provider that determines the x-axis location of the base of a bar. This property has no effect in overlaid, stacked, or 100% stacked charts. For more information on using the `minField` property, see “Using the minField property” on page 1306.

The following example creates a simple BarChart control:

```
<?xml version="1.0"?>
<!-- charts/BasicBar.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">

    <fx:Declarations>
        <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
         <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
         <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Bar Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:BarChart id="myChart" dataProvider="{srv.lastResult.data.result}"
showDataTips="true">
        <mx:verticalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:verticalAxis>
        <mx:series>
           <mx:BarSeries
                yField="month"
                xField="profit"
                displayName="Profit"/>
           <mx:BarSeries
                yField="month"
                xField="expenses"
                displayName="Expenses"/>
        </mx:series>
     </mx:BarChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

A bar chart is essentially a column chart rotated 90 degrees clockwise; therefore, bar charts and column charts share many of the same characteristics. For more information, see “Using column charts” on page 1137.

Using bubble charts

You use the BubbleChart control to represent data with three values for each data point: a value that determines its position along the x-axis, a value that determines its position along the y-axis, and a value that determines the size of the chart symbol, relative to the other data points in the series.

The `<mx:BubbleChart>` tag takes additional properties, `minRadius` and `maxRadius`. These style properties specify the minimum and maximum radii of the chart elements, in pixels. The data point with the largest value will be less than the `maxRadius` and the data point with the smallest value will be larger than the `minRadius` property. For example, if you set the minRadius to 10 and the maxRadius to 50, all data points will have a radius between 10 and 50. The default value for `maxRadius` is 50 pixels. The default value for `minRadius` is 0 pixels. You can also control the `minRadius` and `maxRadius` properties by using properties of the same name on the BubbleSeries class.

You use the BubbleSeries chart series with the BubbleChart control to define the data for the chart. The following table describes the properties of the BubbleSeries chart series that you commonly use to define your chart:

Property	Description
`yField`	Specifies the field of the data provider that determines the y-axis location of each data point. This property is required.
`xField`	Specifies the field of the data provider that determines the x-axis location of each data point. This property is required.
`radiusField`	Specifies the field of the data provider that determines the radius of each symbol, relative to the other data points in the series. This property is required.

The following example draws a BubbleChart control and sets the maximum radius of bubble elements to 50:

```
<?xml version="1.0"?>
<!-- charts/BasicBubble.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">

    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
```

```
  <s:Panel title="Bubble Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:BubbleChart id="myChart"
        minRadius="1"
        maxRadius="50"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true">
        <mx:series>
           <mx:BubbleSeries
                xField="profit"
                yField="expenses"
                radiusField="amount"
                displayName="Profit"/>
        </mx:series>
     </mx:BubbleChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

To customize the styles of the bubbles in a BubbleChart control, you use the `fill` and `stroke` properties. You pass these a SolidColor and a SolidColorStroke object, respectively. The following example defines a custom SolidColor object and a custom SolidColorStroke object, and applies them to the BubbleSeries object in the BubbleChart control.

```
<?xml version="1.0"?>
<!-- charts/BubbleFills.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses 
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to 
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
        <!-- Define custom color and line style for the bubbles. -->
        <mx:SolidColor id="sc1" color="blue" alpha=".3"/>
        <mx:SolidColorStroke id="stroke1" color="blue" weight="2"/>
    </fx:Declarations>

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:Panel title="BubbleChart Control with Custom Bubble Styles">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <mx:BubbleChart id="myChart" showDataTips="true">
            <mx:series>
                <mx:BubbleSeries
                    dataProvider="{srv.lastResult.data.result}"
                    displayName="series1"
                    xField="profit"
                    yField="expenses"
                    radiusField="amount"
                    fill="{sc1}"
                    stroke="{stroke1}"/>
            </mx:series>
        </mx:BubbleChart>
        <mx:Legend dataProvider="{myChart}"/>
    </s:Panel>
</s:Application>
```

For more information on using fills, see “Using fills with chart controls” on page 1197. For more information on using the SolidColorStroke class, see “Using strokes with chart controls” on page 1192.

Using multiple series in BubbleChart controls

As with other chart controls, you can have multiple series in a BubbleChart control. There is an additional consideration when using multiple series in a BubbleChart control. You must decide whether you want the size of the bubbles in each series to be relative to bubbles in the other series or relative to only the other bubbles in their own series.

For example, you have two series, A and B. Series A has bubbles with radius values of 10, 20, and 30. Series B has bubbles with radius values of 2, 4, and 8. Your BubbleChart control can display bubbles in series A that are all larger than the bubbles in series B. You can also design a BubbleChart control so that the bubbles’ sizes in series A are not relative to bubbles in series B. Flex renders the bubble with a radius 10 in series A and the bubble with a radius of 2 in series B the same size.

If you want the size of the bubbles to be relative to each other in the different series, add both series in the series array, as the following example shows:

```
<?xml version="1.0"?>
<!-- charts/BubbleRelativeSize.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    height="600">
    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;
            [Bindable]
            private var s1:ArrayCollection = new ArrayCollection( [
                {"x": 20, "y": 10, "r":10 },
                {"x": 40, "y": 5, "r":20 } ,
                {"x": 60, "y": 0, "r":30 }]);

            [Bindable]
            private var s2:ArrayCollection = new ArrayCollection( [
                {"x": 20, "y": 50, "r":2 },
                {"x": 40, "y": 75, "r":4 },
                {"x": 60, "y": 100, "r":8 } ]);
    ]]>
    </fx:Script>

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:Panel title="Bubble Chart (Bubbles relative to other series)">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <mx:BubbleChart id="myChart"
            showDataTips="true">
            <mx:series>
                <mx:BubbleSeries
                    dataProvider="{s1}"
                    displayName="series1"
                    xField="x" yField="y"
                    radiusField="r"/>
                <mx:BubbleSeries
                    dataProvider="{s2}"
                    displayName="series2"
                    xField="x" yField="y"
                    radiusField="r"/>
            </mx:series>
        </mx:BubbleChart>
        <mx:Legend dataProvider="{myChart}"/>
    </s:Panel>
</s:Application>
```

If you want the size of the bubbles to be relative to each other in their own series, but not to other series, use a different radial axis for each series. To do this, you add a `<mx:radialAxis>` child tag to the `<mx:BubbleSeries>` tag in the MXML. This creates two series in the BubbleChart control whose bubble sizes are independent of one another. The following example shows a BubbleChart control with two independant series:

```
<?xml version="1.0"?>
<!-- charts/BubbleNonRelativeSize.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    height="600">
    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;
            [Bindable]
            private var s1:ArrayCollection = new ArrayCollection( [
                {"x": 20, "y": 10, "r":10 },
                {"x": 40, "y": 5, "r":20 } ,
                {"x": 60, "y": 0, "r":30 }]);

            [Bindable]
            private var s2:ArrayCollection = new ArrayCollection( [
                {"x": 20, "y": 50, "r":1 },
                {"x": 40, "y": 75, "r":2 },
                {"x": 60, "y": 100, "r":3 } ]);
    ]]>
    </fx:Script>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:Panel title="Bubble Chart (Bubbles not relative across series)">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <mx:BubbleChart id="myChart"
            showDataTips="true">
            <mx:series>
                <mx:BubbleSeries
                    dataProvider="{s1}"
                    displayName="series1"
                    xField="x"
                    yField="y"
                    radiusField="r">
                    <mx:radiusAxis>
                        <mx:LinearAxis/>
                    </mx:radiusAxis>
                </mx:BubbleSeries>
                <mx:BubbleSeries
                    dataProvider="{s2}"
                    displayName="series2"
                    xField="x"
                    yField="y"
                    radiusField="r">
                    <mx:radiusAxis>
                        <mx:LinearAxis/>
                    </mx:radiusAxis>
                </mx:BubbleSeries>
            </mx:series>
        </mx:BubbleChart>
        <mx:Legend dataProvider="{myChart}"/>
    </s:Panel>
</s:Application>
```

Using candlestick charts

The CandlestickChart control represents financial data as a series of candlesticks representing the high, low, opening, and closing values of a data series. The top and bottom of the vertical line in each candlestick represent the high and low values for the data point, while the top and bottom of the filled box represent the opening and closing values. Each candlestick is filled differently depending on whether the closing value for the data point is higher or lower than the opening value.

The CandlestickChart control's CandlestickSeries requires all four data points: high, low, open, and close. If you do not want to use opening value data points, you can use the HighLowOpenClose charts, which do not require a data point that represents the opening value. For more information, see "Using HighLowOpenClose charts" on page 1141.

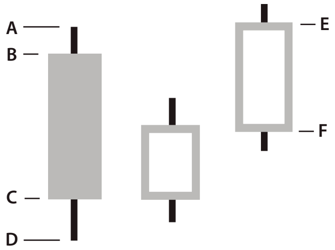
You use the CandlestickSeries chart series with the CandlestickChart control to define the data.

The following table describes the properties of the CandlestickSeries chart series that you commonly use to define your chart:

Property	Description
`closeField`	Specifies the field of the data provider that determines the y-axis location of the closing value of the element. This property defines the top or bottom of the candlestick.
`highField`	Specifies the field of the data provider that determines the y-axis location of the high value of the element. This property defines the top of the line inside the candlestick.
`lowField`	Specifies the field of the data provider that determines the y-axis location of the low value of the element. This property defines the bottom of the line inside the candlestick.
`openField`	Specifies the field of the data provider that determines the y-axis location of the opening value of the element. This property defines the position of the top or bottom of the candlestick.
`xField`	Specifies the field of the data provider that determines the x-axis location of the element. If set to the empty string (""), Flex renders the columns in the order in which they appear in the data provider. The default value is the empty string.

If the `closeField` is lower than the `openField`, Flex applies a solid fill to the candle. The color of this solid fill defaults to the color of the box's outline. It is defined by the `declineFill` style property. If the `closeField` is *higher* than the `openField`, Flex fills the candle with white by default.

The following image shows the properties that define the appearance of the candle. As you can see, the location of the `closeField` property can be either the top or the bottom of the candlestick, depending on whether it is higher or lower than the `openField` property:



A. *highField* ***B.*** *openField* ***C.*** *closeField* ***D.*** *lowField* ***E.*** *closeField* ***F.*** *openField*

The following example creates a CandlestickChart control:

```
<?xml version="1.0"?>
<!-- charts/BasicCandlestick.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">

    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/stocks-
xml.aspx"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/stocks.aspx -->
    </fx:Declarations>

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Candlestick Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:CandlestickChart id="mychart"
```

```
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true"
        height="400"
        width="400">
        <mx:horizontalAxis>
           <mx:DateTimeAxis dataUnits="days"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:CandlestickSeries
                openField="open"
                highField="high"
                lowField="low"
                closeField="close"
                displayName="TICKER"
                xField="date"/>
        </mx:series>
     </mx:CandlestickChart>
     <mx:Legend dataProvider="{mychart}"/>
  </s:Panel>
</s:Application>
```

You can change the color of the candle’s fill with the `fill` and `declineFill` properties of the series. The `fill` property defines the color of the candlestick when the `closeField` value is higher than the `openField` value. The `declineFill` property defines the color of the candlestick when the reverse is true. You can also define the properties of the high-low lines and candlestick borders by using the SolidColorStroke class, as the following example shows:

```
<?xml version="1.0"?>
<!-- charts/CandlestickStyles.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/stocks-
xml.aspx"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/stocks.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Candlestick Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:CandlestickChart id="mychart"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true"
        height="400"
        width="400">
        <mx:verticalAxis>
           <mx:LinearAxis title="linear axis" minimum="40" maximum="50"/>
        </mx:verticalAxis>
        <mx:horizontalAxis>
           <mx:DateTimeAxis dataUnits="days"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:CandlestickSeries
                openField="open"
                highField="high"
                lowField="low"
                closeField="close"
                displayName="TICKER"
                xField="date">
            <mx:fill>
                <mx:SolidColor color="green"/>
            </mx:fill>
            <mx:declineFill>
                <mx:SolidColor color="red"/>
            </mx:declineFill>
            <mx:stroke>
                <mx:SolidColorStroke weight="1" color="black"/>
            </mx:stroke>
           </mx:CandlestickSeries>
        </mx:series>
     </mx:CandlestickChart>
     <mx:Legend dataProvider="{mychart}"/>
  </s:Panel>
</s:Application>
```

Using column charts

The ColumnChart control represents data as a series of vertical columns whose height is determined by values in the data. You can use the ColumnChart control to create several variations of column charts, including simple columns, clustered columns, overlaid, stacked, 100% stacked, and high-low. For more information, see “Stacking charts” on page 1308.

You use the ColumnSeries chart series with the ColumnChart control to define the data for the chart. The following table describes the properties of the ColumnSeries chart series to define your chart:

Property	Description
yField	Specifies the field of the data provider that determines the y-axis location of the top of a column. This field defines the height of the column.
xField	Specifies the field of the data provider that determines the x-axis location of the column. If you omit this property, Flex arranges the columns in the order of the data in the data provider.
minField	Specifies the field of the data provider that determines the y-axis location of the bottom of a column. This property has no effect on overlaid, stacked, or 100% stacked charts. For more information on using the minField property, see “Using the minField property” on page 1306.

The following example creates a ColumnChart control with two series:

```
<?xml version="1.0"?>
<!-- charts/BasicColumn.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">

    <fx:Declarations>
        <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
         <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
         <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Column Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:ColumnChart id="myChart" dataProvider="{srv.lastResult.data.result}"
showDataTips="true">
        <mx:horizontalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:ColumnSeries
                xField="month"
                yField="profit"
                displayName="Profit"/>
           <mx:ColumnSeries
                xField="month"
                yField="expenses"
                displayName="Expenses"/>
        </mx:series>
     </mx:ColumnChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

To customize the styles of the columns in a ColumnChart control, you specify a SolidColor and a SolidColorStroke object for the `fill` and `stroke` properties, respectively. The following example defines a custom SolidColor object and a custom SolidColorStroke object, and applies them to the ColumnSeries object in the ColumnChart control.

```
<?xml version="1.0"?>
<!-- charts/BasicColumnFills.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
        <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
         <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
         <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
        <!-- Define custom colors for use as column fills. -->
        <mx:SolidColor id="sc1" color="blue" alpha=".3"/>
        <mx:SolidColor id="sc2" color="red" alpha=".3"/>
        <!-- Define custom SolidColorStrokes for the columns. -->
        <mx:SolidColorStroke id="s1" color="blue" weight="2"/>
        <mx:SolidColorStroke id="s2" color="red" weight="2"/>
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:Panel title="ColumnChart Control with Custom Column Styles">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <mx:ColumnChart id="myChart" dataProvider="{srv.lastResult.data.result}"
showDataTips="true">
            <mx:horizontalAxis>
                <mx:CategoryAxis categoryField="month"/>
            </mx:horizontalAxis>
            <mx:series>
                <mx:ColumnSeries
                    xField="month"
                    yField="profit"
                    displayName="Profit"
                    fill="{sc1}"
                    stroke="{s1}"/>
                <mx:ColumnSeries
                    xField="month"
                    yField="expenses"
                    displayName="Expenses"
                    fill="{sc2}"
                    stroke="{s2}"/>
            </mx:series>
        </mx:ColumnChart>
        <mx:Legend dataProvider="{myChart}"/>
    </s:Panel>
</s:Application>
```

For more information on using fills, see “Using fills with chart controls” on page 1197. For more information on using the SolidColorStroke class, see “Using strokes with chart controls” on page 1192.

Creating floating column charts

You can also create floating column charts by using the `minField` property of the chart's data series. This property lets you set the lower level of a column.

The following code creates a floating ColumnChart control:

```
<?xml version="1.0"?>
<!-- charts/MinFieldColumn.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    height="600">

  <fx:Script><![CDATA[
     import mx.collections.ArrayCollection;
     [Bindable]
     public var expenses:ArrayCollection = new ArrayCollection([
        {Month:"Jan", Revenue:1200, Expenses:500},
        {Month:"Feb", Revenue:1200, Expenses:550},
        {Month:"Mar", Revenue:1240, Expenses:475},
        {Month:"Apr", Revenue:1300, Expenses:600},
        {Month:"May", Revenue:1420, Expenses:575},
        {Month:"Jun", Revenue:1400, Expenses:600},
        {Month:"Jul", Revenue:1500, Expenses:600},
        {Month:"Aug", Revenue:1600, Expenses:750},
        {Month:"Sep", Revenue:1600, Expenses:735},
        {Month:"Oct", Revenue:1750, Expenses:750},
        {Month:"Nov", Revenue:1800, Expenses:800},
        {Month:"Dec", Revenue:2000, Expenses:850}
     ]);
  ]]></fx:Script>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Floating Column Chart">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
     <mx:ColumnChart
        dataProvider="{expenses}"
        showDataTips="true">
        <mx:horizontalAxis>
           <mx:CategoryAxis
                dataProvider="{expenses}"
                categoryField="Month"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:ColumnSeries
                yField="Revenue"
                minField="Expenses"
                displayName="Revenue"/>
        </mx:series>
     </mx:ColumnChart>
  </s:Panel>
</s:Application>
```

For more information, see “Using the minField property” on page 1306.

Using HighLowOpenClose charts

The HLOCChart control represents financial data as a series of lines representing the high, low, opening, and closing values of a data series. The top and bottom of the vertical line represent the high and low values for the data point, while the left tick mark represents the opening values and the right tick mark represents the closing values.

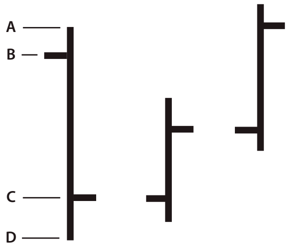
The HLOCChart control does not require a data point that represents the opening value. A related chart is the CandlestickChart control that represents similar data as candlesticks. For more information see “Using candlestick charts” on page 1134.

You use the HLOCSeries with the HLOCChart control to define the data for HighLowOpenClose charts.

The following table describes the properties of the HLOCChart control’s series that you commonly use to define your chart:

Property	**Description**
`closeField`	Specifies the field of the data provider that determines the *y*-axis location of the closing value of the element. This property defines the position of the right tick mark on the vertical line.
`highField`	Specifies the field of the data provider that determines the *y*-axis location of the high value of the element. This property defines the top of the vertical line.
`lowField`	Specifies the field of the data provider that determines the *y*-axis location of the low value of the element. This property defines the bottom of the vertical line.
`openField`	Specifies the field of the data provider that determines the y-axis location of the opening value of the element. This property defines the position of the left tick mark on the vertical line. This property is optional.
`xField`	Specifies the field of the data provider that determines the x-axis location of the element. If set to the empty string (""), Flex renders the columns in the order in which they appear in the data provider. The default value is the empty string.

Data points in an HLOCChart control do not require an `openField` property. If no `openField` property is specified, Flex renders the data point as a flat line with a single closing value indicator pointing to the right. If an `openField` property is specified, Flex renders the data point with another indicator pointing to the left, as the following image shows:



A. highField B. openField C. closeField D. lowField

The following example creates an HLOCChart control:

```
<?xml version="1.0"?>
<!-- charts/BasicHLOC.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/stocks-
xml.aspx"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/stocks.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="HighLowOpenClose Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:HLOCChart id="myChart"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true">
        <mx:verticalAxis>
           <mx:LinearAxis minimum="30" maximum="50"/>
        </mx:verticalAxis>
        <mx:horizontalAxis>
           <mx:DateTimeAxis dataUnits="days"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:HLOCSeries
                openField="open"
                highField="high"
                lowField="low"
                closeField="close"
                displayName="TICKER"
                xField="date">
           </mx:HLOCSeries>
        </mx:series>
     </mx:HLOCChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

You can change the stroke of the vertical lines by using a SolidColorStroke object on the series. To change the appearance of the opening and closing value tick marks on the vertical line, you use the `openTickStroke` and `closeTickStroke` style properties. The following example changes the stroke of the vertical line to 2 (the default value is 1) and the color of all the lines to black:

```
<?xml version="1.0"?>
<!-- charts/HLOCStyled.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/stocks-
xml.aspx"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/stocks.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="HLOC Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:HLOCChart id="myChart"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true">
        <mx:verticalAxis>
           <mx:LinearAxis minimum="30" maximum="50"/>
        </mx:verticalAxis>
        <mx:horizontalAxis>
           <mx:DateTimeAxis dataUnits="days"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:HLOCSeries
                openField="open"
                highField="high"
                lowField="low"
                closeField="close"
                xField="date"
                displayName="TICKER">
            <mx:stroke>
                <mx:SolidColorStroke color="#000000" weight="2"/>
            </mx:stroke>
            <mx:closeTickStroke>
                <mx:SolidColorStroke color="#000000" weight="1"/>
            </mx:closeTickStroke>
            <mx:openTickStroke>
                <mx:SolidColorStroke color="#000000" weight="1"/>
            </mx:openTickStroke>
           </mx:HLOCSeries>
        </mx:series>
     </mx:HLOCChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

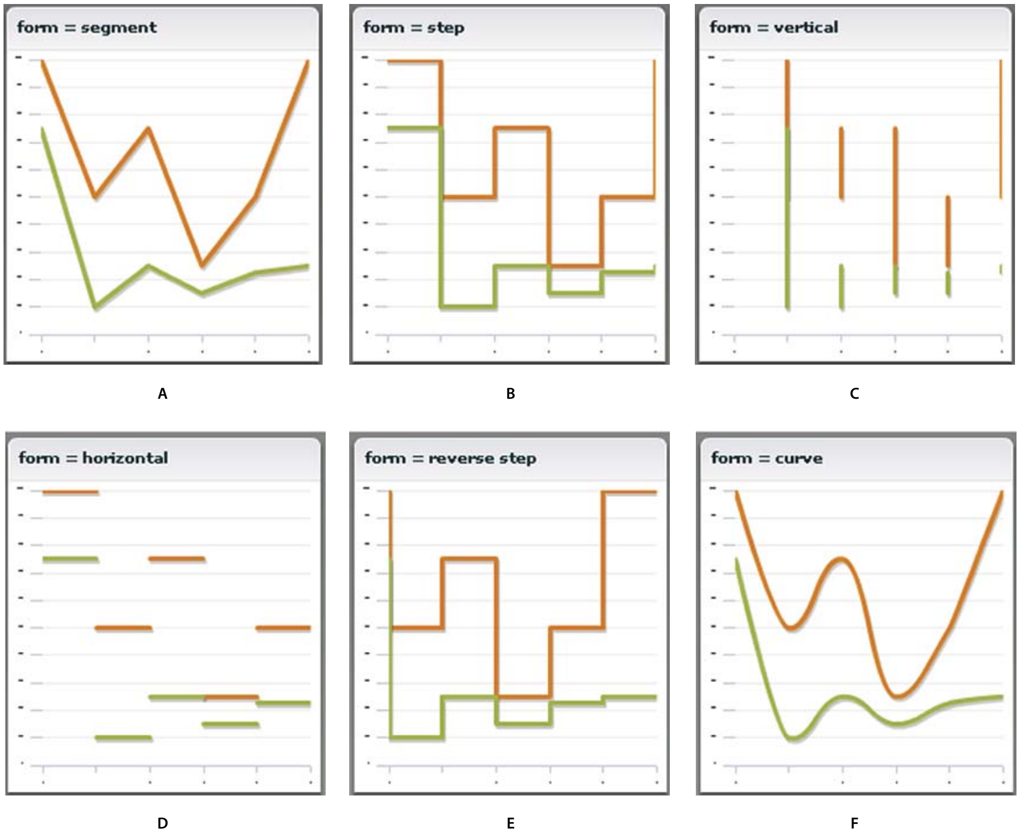
Using line charts

The LineChart control represents data as a series of points, in Cartesian coordinates, connected by a continuous line. You can use an icon or symbol to represent each data point along the line, or show a simple line without icons.

You use the LineSeries chart series with the LineChart control to define the data for the chart. The following table describes the properties of the LineSeries chart series that you commonly use to define your chart:

Property	Description
`yField`	Specifies the field of the data provider that determines the y-axis location of each data point. This is the height of the line at that location along the axis.
`xField`	Specifies the field of the data provider that determines the x-axis location of each data point. If you omit this field, Flex arranges the data points in the order of the data in the data provider.
`interpolateValues`	Specifies how to represent missing data. If you set the value of this property to `false`, the chart breaks the line at the missing value. If you specify a value of `true`, Flex draws a continuous line by interpolating the missing value. The default value is `false`.
`form`	Specifies the way in which the data series is shown in the chart. The following values are valid: • `segment` Draws lines as connected segments that are angled to connect at each data point in the series. This is the default. • `step` Draws lines as horizontal and vertical segments. At the first data point, draws a horizontal line, and then a vertical line to the second point. Repeats this for each data point. • `reverseStep` Draws lines as horizontal and vertical segments. At the first data point, draws a vertical line, and then a horizontal line to the second point. Repeats this for each data point. • `vertical` Draws the vertical line only from the *y*-coordinate of the first point to the *y*-coordinate of the second point at the *x*-coordinate of the second point. Repeats this for each data point. • `horizontal` Draws the horizontal line only from the *x*-coordinate of the first point to the *x*-coordinate of the second point at the *y*-coordinate of the first point. Repeats this for each data point. • `curve` Draws curves between data points.

The following example shows the available forms for a LineChart control's series:



***A.** segment (default)* ***B.** step* ***C.** vertical* ***D.** horizontal* ***E.** reverseStep* ***F.** curve*

The following example creates a LineChart control:

```
<?xml version="1.0"?>
<!-- charts/BasicLine.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
        <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
         <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
         <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Line Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:LineChart id="myChart"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true">
        <mx:horizontalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:LineSeries yField="profit" displayName="Profit"/>
           <mx:LineSeries yField="expenses" displayName="Expenses"/>
        </mx:series>
     </mx:LineChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

Formatting lines in a LineChart control

You can change the width and color of the lines for each series by using the `<mx:lineStroke>` tag. The default line is 3 pixels wide and has a shadow. The following example sets a custom color and width for the series SolidColorStroke object:

```
<?xml version="1.0"?>
<!-- charts/BasicLineStroke.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses 
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to 
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Line Chart With SolidColorStrokes">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:LineChart id="myChart" 
        dataProvider="{srv.lastResult.data.result}" 
        showDataTips="true">
        <mx:horizontalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:LineSeries yField="profit" displayName="Profit">
            <mx:lineStroke>
                <mx:SolidColorStroke 
                    color="0x0099FF" 
                    weight="20" 
                    alpha=".2"/>
            </mx:lineStroke>
           </mx:LineSeries>
           <mx:LineSeries yField="expenses" displayName="Expenses">
            <mx:lineStroke>
                <mx:SolidColorStroke 
                    color="0x0044EB" 
                    weight="20" 
                    alpha=".8"/>
            </mx:lineStroke>
           </mx:LineSeries>
        </mx:series>
     </mx:LineChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

You can also modify lines in a LineChart with ActionScript. You define a new SolidColorStroke, and apply it to the LineSeries by setting the `lineStroke` style property with the `setStyle()` method. For example:

```
/* First 3 arguments are color, weight, and alpha. */
var s1:SolidColorStroke = new SolidColorStroke(0x0099FF,20,.2);
series1.setStyle("lineStroke", s1);
```

For more information on using the SolidColorStroke class in charts, see “Using strokes with chart controls” on page 1192.

The default appearance of the lines in a LineChart control is with drop shadows. You can remove these shadows by setting the chart control’s `seriesFilters` property to an empty Array, as the following example shows:

```
<?xml version="1.0"?>
<!-- charts/LineChartNoShadows.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses 
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to 
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Line Chart with No Shadows">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:LineChart id="myChart" 
        dataProvider="{srv.lastResult.data.result}" 
        showDataTips="true">
        <mx:seriesFilters>
           <fx:Array/>
        </mx:seriesFilters>
        <mx:horizontalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:LineSeries 
                yField="profit" 
                displayName="Profit"/>
           <mx:LineSeries 
                yField="expenses" 
                displayName="Expenses"/>
           <mx:LineSeries 
                yField="amount" 
                displayName="Amount"/>
        </mx:series>
     </mx:LineChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

You can also set the value of the seriesFilters property programmatically, as the following example shows:

```
myLineChart.seriesFilters = [];
```

You can also specify a programmatic renderer (or *skin*) class for each series by setting the lineSegmentRenderer property of the LineSeries. The default renderer is the LineRenderer, but Flex also applies a shadow filter on all series. If you remove the shadow filter, as the previous example shows, but want a line with a drop shadow in your chart, you can set the lineSegmentRenderer to the ShadowLineRenderer class, as the following example shows:

```
<?xml version="1.0"?>
<!-- charts/LineChartOneShadow.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">

    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Line Chart with One Shadow">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:LineChart id="myChart"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true">

        <mx:seriesFilters>
           <fx:Array/>
        </mx:seriesFilters>

        <mx:horizontalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:horizontalAxis>

        <mx:series>
           <mx:LineSeries yField="profit" displayName="Profit"/>
           <mx:LineSeries yField="expenses" displayName="Expenses"/>
           <mx:LineSeries yField="amount"
                displayName="Amount"
                lineSegmentRenderer="mx.charts.renderers.ShadowLineRenderer"/>
        </mx:series>
     </mx:LineChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

For more information on using renderer classes to change the appearance of ChartItem objects such as the LineChart control's line segments, see "Skinning ChartItem objects" on page 1232.

Using vertical lines in a LineChart control

You can create LineChart controls that show vertical progression.

To make lines in a LineChart control display vertically rather than horizontally, you must do the following:

- Explicitly define the `xField` and `yField` properties for the LineSeries object.
- Set the `sortOnXField` property of the LineSeries object to `false`.

By default, data points in a series are sorted from left to right (on the x-axis) before rendering. This causes the LineSeries to draw horizontally. When you disable the `xField` sort and explicitly define a `yField` property, Flex draws the lines vertically rather than horizontally.

Flex does not sort any data vertically. As a result, you must ensure that your data is arranged correctly in the data provider. If it is not arranged correctly, Flex renders a zig-zagging line up and down the chart as it connects those dots according to position in the data provider.

The following example creates a LineChart control that displays vertical lines:

```
<?xml version="1.0"?>
<!-- charts/VerticalLineChart.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Vertical Line Chart">
     <s:layout>
         <s:HorizontalLayout/>
     </s:layout>
     <mx:LineChart id="myChart"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true">
        <mx:verticalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:verticalAxis>
        <mx:series>
           <mx:LineSeries
                xField="profit"
                yField="month"
                displayName="Profit"
                sortOnXField="false"/>
           <mx:LineSeries
                xField="expenses"
                yField="month"
                displayName="Expenses"
                sortOnXField="false"/>
        </mx:series>
     </mx:LineChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

Using pie charts

You use the PieChart control to define a standard pie chart. The data for the data provider determines the size of each wedge in the pie chart relative to the other wedges.

You use the PieSeries chart series with the PieChart control to define the data for the chart. The PieSeries can create standard pie charts or doughnut charts. PieChart controls also support labels that identify data points.

The following table describes the properties of the PieChart control's PieSeries chart series that you commonly use to define your chart:

Property	Description
`field`	Specifies the field of the data provider that determines the data for each wedge of the pie chart.
`labelPosition`	Specifies how to render data labels for the wedges.
`nameField`	Specifies the field of the data provider to use as the name for the wedge in DataTip objects and legends.

The following example defines a PieChart control:

```
<?xml version="1.0"?>
<!-- charts/BasicPie.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
        <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
         <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/budget-
xml.aspx"/>
         <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/budget.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Pie Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:PieChart id="myChart"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true">
        <mx:series>
           <mx:PieSeries
                field="amount"
                nameField="item"
                labelPosition="callout"/>
        </mx:series>
     </mx:PieChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

To customize the colors of the wedges in a PieChart control, you use the `fills` property. You pass this an Array of SolidColor objects. The following example defines an Array of custom SolidColor objects, and applies it to the PieSeries object in the PieChart control.

```
<?xml version="1.0"?>
<!-- charts/PieFilling.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses 
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/budget-
xml.aspx"/>
        <!-- To see data in an HTML table, go to 
http://aspexamples.adobe.com/chart_examples/budget.aspx -->
        <!-- Define custom colors for use as pie wedge fills. -->
        <mx:SolidColor id="sc1" color="blue" alpha=".3"/>
        <mx:SolidColor id="sc2" color="red" alpha=".3"/>
        <mx:SolidColor id="sc3" color="green" alpha=".3"/>
        <mx:SolidColor id="sc4" color="gray" alpha=".3"/>
        <mx:SolidColor id="sc5" color="black" alpha=".3"/>
        <mx:SolidColor id="sc6" color="yellow" alpha=".3"/>
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:Panel title="PieChart control with custom fills">
         <s:layout>
             <s:VerticalLayout/>
         </s:layout>
        <mx:PieChart id="pie" 
            dataProvider="{srv.lastResult.data.result}"
            showDataTips="true">
            <mx:series>
                <mx:PieSeries 
                    field="amount" 
                    nameField="item" 
                    labelPosition="callout"
                    fills="{[sc1, sc2, sc3, sc4, sc5, sc6]}"/>
            </mx:series>
        </mx:PieChart>
        <mx:Legend dataProvider="{pie}"/>
    </s:Panel>
</s:Application>
```

For more information on using fills, see “Using fills with chart controls” on page 1197.

You can also customize the lines that outline each wedge by using the `stroke` property of a PieSeries object. You set this property to an instance of the SolidColorStroke class. For more information on using the SolidColorStroke class, see “Using strokes with chart controls” on page 1192.

Using data labels with PieChart controls

PieChart controls support data labels that display information about each data point. All charts support DataTip objects, which display the value of a data point when the user moves the mouse over it. Data labels, on the other hand, are only supported by PieSeries, ColumnSeries, and BarSeries objects. Data labels are different from DataTip objects in that they are always visible and do not react to mouse movements.

To add data labels to your PieChart control, set the `labelPosition` property on the series to a valid value other than `none`. To remove labels from your pie chart, set the `labelPosition` property to `none`. The default value is `none`.

The following table describes the valid values of the `labelPosition` property for a PieSeries object. The PieSeries class supports more values for this property than the BarSeries and ColumnSeries classes.

Value	Description
`callout`	Draws labels in two vertical stacks on either side of the PieChart control. Shrinks the PieChart if necessary to make room for the labels. Draws key lines from each label to the associated wedge. Shrinks labels as necessary to fit the space provided. This property can only be used with a PieSeries object. You cannot use callouts with BarSeries and ColumnSeries objects.
`inside`	Draws labels inside the chart. Shrinks labels to ensure that they do not overlap each other. Any label that must be drawn too small, as defined by the `insideLabelSizeLimit` property, is hidden from view. When two labels overlap, Flex gives priority to labels for larger slices. not true any more???
`insideWithCallout`	Draws labels inside the pie, but if labels are shrunk below a legible size, Flex converts them to callout labels. You commonly set the value of the `labelPosition` property to `insideWithCallout` when the actual size of your chart is flexible and users might resize it. This property can only be used with a PieSeries object. You cannot use callouts with BarSeries and ColumnSeries objects.
`none`	Does not draw labels. This is the default value.
`outside`	Draws labels around the boundary of the PieChart control.

The following table describes the properties of the PieSeries object that you can use to manipulate the appearance of labels:

Property	Description
`calloutGap`	Defines how much space, in pixels, to insert between the edge of the pie and the data labels when rendering callouts. The default value is 10 pixels.
`calloutStroke`	Defines the line style used to draw the lines to callouts. For more information on defining line data points, see "Using strokes with chart controls" on page 1192.
`insideLabelSizeLimit`	Defines the size threshold, expressed in points, below which inside data labels are considered illegible. Below this threshold, data labels are either removed entirely or turned into callouts based on the setting of the series `labelPosition` property.

You can change the value of the data labels by using the `labelFunction` property of the PieSeries object to specify a callback function. For more information, see "Customizing data label values" on page 1283.

Creating doughnut charts

Flex lets you create doughnut charts out of PieChart controls. Doughnut charts are identical to pie charts, except that they have hollow centers and resemble wheels rather than filled circles.

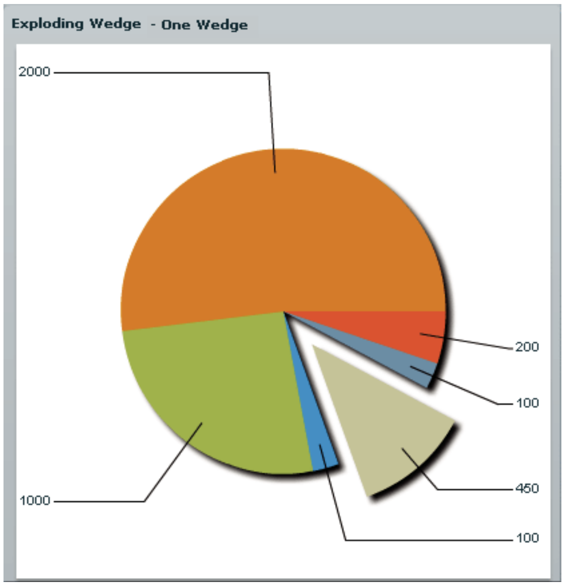
To create a doughnut chart, specify the `innerRadius` property on the PieChart control, as the following example shows:

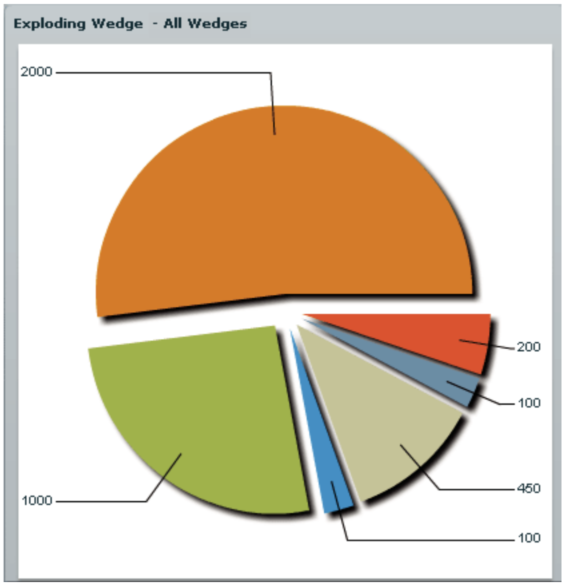
```
<?xml version="1.0"?>
<!-- charts/DoughnutPie.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
        <!-- View source of the following page to see the structure of the data that Flex uses 
in this example. -->
         <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/budget-
xml.aspx"/>
         <!-- To see data in an HTML table, go to 
http://aspexamples.adobe.com/chart_examples/budget.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Pie Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:PieChart id="myChart" 
        dataProvider="{srv.lastResult.data.result}" 
        showDataTips="true"
        innerRadius=".3">
        <mx:series>
           <mx:PieSeries 
                field="amount" 
                nameField="item" 
                labelPosition="callout"/>
        </mx:series>
     </mx:PieChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

The value of the `innerRadius` property is a percentage value of the “hole” compared to the entire pie’s radius. Valid values range from 0 to 1.

Creating exploding pie charts

The PieSeries chart series supports exploding wedges, both uniformly and on a per-wedge basis, so that you can achieve effects similar to the following:





The following table describes the properties that support exploding pie charts:

Property	Description
`explodeRadius`	A value from 0 to 1, representing the percentage of the available pie radius to use when exploding the wedges of the pie.
`perWedgeExplodeRadius`	An array of values from 0 to 1. The Nth value in this array is added to the value of `explodeRadius` to determine the explode amount of each individual wedge of the pie. Individual values can be left undefined, in which case the wedge will only explode according to the `explodeRadius` property.
`reserveExplodeRadius`	A value from 0 to 1, representing an amount of the available pie radius to reserve for animating an exploding wedge.

To explode all wedges of a pie chart evenly, you use the `explodeRadius` property on the PieSeries, as the following example shows:

```
<?xml version="1.0"?>
<!-- charts/ExplodingPie.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
        <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
         <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/budget-
xml.aspx"/>
         <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/budget.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Exploding Pie Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:PieChart id="pie"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true">
        <mx:series>
           <!--explodeRadius is a number between 0 and 1.-->
           <mx:PieSeries
                field="amount"
                nameField="item"
                explodeRadius=".12"/>
        </mx:series>
     </mx:PieChart>
     <mx:Legend dataProvider="{pie}"/>
  </s:Panel>
</s:Application>
```

To explode one or more wedges of the pie, you use an Array of `explodeRadius` values. Each value in the Array applies to the corresponding data point. In the following example, the fourth data point, the Car expense, is exploded:

```
<?xml version="1.0"?>
<!-- charts/ExplodingPiePerWedge.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
        <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
         <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/budget-
xml.aspx"/>
         <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/budget.aspx -->
    </fx:Declarations>
  <fx:Script><![CDATA[
     // Create a bindable Array of explode radii.
     [Bindable]
     public var explodingArray:Array = [0,0,0,.2,0,0]
  ]]></fx:Script>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Exploding Pie Chart Per Wedge">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:PieChart id="pie"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true">
        <mx:series>
           <!--Apply the Array of radii to the PieSeries.-->
           <mx:PieSeries
                field="amount"
                nameField="item"
                perWedgeExplodeRadius="{explodingArray}"
                labelPosition="callout"/>
        </mx:series>
     </mx:PieChart>
     <mx:Legend dataProvider="{pie}"/>
  </s:Panel>
</s:Application>
```

Using plot charts

You use the PlotChart control to represent data in Cartesian coordinates where each data point has one value that determines its position along the x-axis, and one value that determines its position along the y-axis. You can define the shape that Flex displays at each data point with the renderer for the data series.

You use the PlotSeries class with the PlotChart control to define the data for the chart. The following table describes the properties of the PlotSeries chart series that you commonly use to define your chart:

Property	Description
`yField`	Specifies the field of the data provider that determines the y-axis location of each data point.
`xField`	Specifies the field of the data provider that determines the x-axis location of each data point.
`radius`	Specifies the radius, in pixels, of the symbol at each data point. The default value is `5` pixels.

***Note:** Both the `xField` and `yField` properties are required for each PlotSeries in a PlotChart control.*

The following example defines three data series in a PlotChart control:

```
<?xml version="1.0"?>
<!-- charts/BasicPlot.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">

    <fx:Declarations>
        <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
         <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
         <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Plot Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:PlotChart id="myChart" dataProvider="{srv.lastResult.data.result}"
     showDataTips="true">
        <mx:series>
           <mx:PlotSeries
                xField="expenses"
                yField="profit"
                displayName="Plot 1"/>
           <mx:PlotSeries
                xField="amount"
                yField="expenses"
                displayName="Plot 2"/>
           <mx:PlotSeries
                xField="profit"
                yField="amount"
                displayName="Plot 3"/>
        </mx:series>
     </mx:PlotChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

To customize the styles of the points in a PlotChart control, you define a SolidColor and a SolidColorStroke object for the `fill` and `stroke` properties, respectively. The following example defines three SolidColor objects and three custom SolidColorStroke objects, and applies them to the PlotSeries objects in the PlotChart control.

```
<?xml version="1.0"?>
<!-- charts/PlotFills.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
        <!-- Define custom colors for use as plot point fills. -->
        <mx:SolidColor id="sc1" color="blue" alpha=".3"/>
        <mx:SolidColor id="sc2" color="red" alpha=".3"/>
        <mx:SolidColor id="sc3" color="green" alpha=".3"/>
        <!-- Define custom SolidColorStrokes. -->
        <mx:SolidColorStroke id="s1" color="blue" weight="1"/>
        <mx:SolidColorStroke id="s2" color="red" weight="1"/>
        <mx:SolidColorStroke id="s3" color="green" weight="1"/>
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:Panel title="Plot Chart with custom fills">
         <s:layout>
             <s:VerticalLayout/>
         </s:layout>
        <mx:PlotChart id="myChart"
            dataProvider="{srv.lastResult.data.result}"
            showDataTips="true">
            <mx:series>
                <mx:PlotSeries
                    xField="expenses"
                    yField="profit"
                    displayName="Plot 1"
                    fill="{sc1}"
                    stroke="{s1}"/>
                <mx:PlotSeries
                    xField="amount"
                    yField="expenses"
                    displayName="Plot 2"
                    fill="{sc2}"
                    stroke="{s2}"/>
                <mx:PlotSeries
                    xField="profit"
                    yField="amount"
                    displayName="Plot 3"
                    fill="{sc3}"
                    stroke="{s3}"/>
            </mx:series>
        </mx:PlotChart>
        <mx:Legend dataProvider="{myChart}"/>
    </s:Panel>
</s:Application>
```

For more information on using fills, see "Using fills with chart controls" on page 1197. For more information on using the SolidColorStroke class, see "Using strokes with chart controls" on page 1192.

By default, Flex displays the first data series in the chart as a diamond at each point. When you define multiple data series in a chart, Flex rotates the shape for the series (starting with a diamond, then a circle, then a square). If you have more series than there are default renderers, Flex begins again with the diamond.

The diamond shape, like the other shapes, is defined by a renderer class. The renderer classes that define these shapes are in the mx.charts.renderers package. The circle is defined by the CircleItemRenderer class. The following default renderer classes define the appearance of the data points:

- BoxItemRenderer
- CircleItemRenderer
- CrossItemRenderer
- DiamondItemRenderer
- ShadowBoxItemRenderer
- TriangleItemRenderer

You can control the image that is displayed by the chart for each data point by setting the `itemRenderer` style property of the series. The following example overrides the default renderers for the series:

```
<?xml version="1.0"?>
<!-- charts/PlotWithCustomRenderer.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Plot Chart With Custom Item Renderer">
     <s:layout>
         <s:VerticalLayout/>
     </s:layout>
     <mx:PlotChart id="myChart"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true">
        <mx:series>
           <mx:PlotSeries
                xField="expenses"
                yField="profit"
                displayName="Plot 1"
                itemRenderer="mx.charts.renderers.CrossItemRenderer"
                radius="10"/>
           <mx:PlotSeries
                xField="amount"
                yField="expenses"
                displayName="Plot 2"
                itemRenderer="mx.charts.renderers.DiamondItemRenderer"
                radius="10"/>
           <mx:PlotSeries
                xField="profit"
                yField="amount"
                displayName="Plot 3"
                itemRenderer=
                "mx.charts.renderers.TriangleItemRenderer"
                radius="10"/>
        </mx:series>
     </mx:PlotChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

You can also use graphics or custom classes to define each plot point. For more information, see “Creating custom renderers” on page 1235.

Using multiple data series

Charts that are subclasses of the CartesianChart class let you mix different data series in the same chart control. You can create a column chart with a trend line running through it or mix any data series with any other similar series.

You can use any combination of the following series objects in a CartesianChart control:

- AreaSeries
- BarSeries
- BubbleSeries
- CandlestickSeries
- ColumnSeries
- HLOCSeries
- LineSeries
- PlotSeries

The following example mixes a LineSeries and a ColumnSeries:

```
<?xml version="1.0"?>
<!-- charts/MultipleSeries.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv_fred.send();srv_strk.send();"
    height="600">
    <fx:Declarations>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/stocks.aspx -->
       <!-- View source of the following pages to see the structure of the data that Flex uses
in this example. -->
       <mx:HTTPService id="srv_fred" url="http://aspexamples.adobe.com/chart_examples/stocks-
xml.aspx?tickerSymbol=FRED"/>
       <mx:HTTPService id="srv_strk" url="http://aspexamples.adobe.com/chart_examples/stocks-
xml.aspx?tickerSymbol=STRK"/>
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Multiple Data Series" width="400" height="400">
     <s:layout>
         <s:VerticalLayout/>
     </s:layout>
     <mx:ColumnChart id="myChart"
        showDataTips="true"
        height="250"
        width="350">
        <mx:horizontalAxis>
           <mx:DateTimeAxis dataUnits="days"/>
        </mx:horizontalAxis>
        <mx:verticalAxis>
```

```
            <mx:LinearAxis minimum="40" maximum="50"/>
         </mx:verticalAxis>
         <mx:series>
            <mx:ColumnSeries
                 dataProvider="{srv_fred.lastResult.data.result}"
                 xField="date"
                 yField="close"
                 displayName="FRED">
            </mx:ColumnSeries>
            <mx:LineSeries
                 dataProvider="{srv_strk.lastResult.data.result}"
                 xField="date"
                 yField="close"
                 displayName="STRK">
            </mx:LineSeries>
         </mx:series>
      </mx:ColumnChart>
      <mx:Legend dataProvider="{myChart}"/>
   </s:Panel>
</s:Application>
```

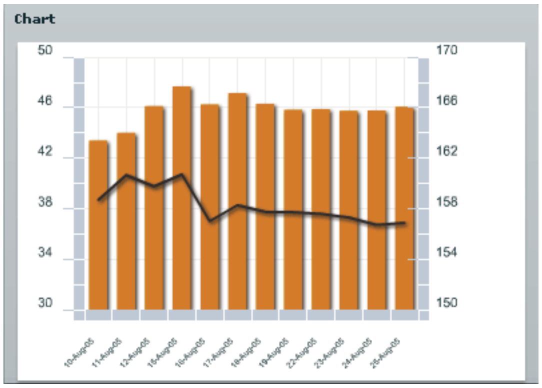
Using multiple series in the same chart works best when the data points are in a similar range (such as a stock price and its moving average). When the data points are in numerically very different ranges, the chart can be difficult to understand because, by default, the data is shown on a single axis. The solution to this problem is to use multiple axes, each with its own range. You can plot each data series on its own axis within the same chart using the techniques described in "Using multiple axes" on page 1164.

Using multiple axes

One potential problem when using more than one data series in a single chart is that if the scales of the data are very different, the data points might be plotted in very different areas on the chart's canvas. For example, one stock price could trade in the range of $100 to $150, while another stock price could fluctuate from $2 to $2.50. If you plot both stocks in the same chart, it would be difficult to see any correlation between the prices, even with a logarithmic axis.

To work around this problem, you can use multiple axes in your charts so that each data series is positioned relative to its own axis. All chart controls that are subclasses of CartesianChart support adding additional sets of data on a additional scales in the horizontal axis, vertical axis, or both. (This applies to all charts except the PieChart control.) You can use values on the additional axes to compare multiple sets of data that are on different scales, such as stock prices that trade in different ranges.

The following example shows a stock price that trades within a $40 to $45 range, and another stock price that trades within a $150 to $160 range. The values of the axis on the left show the range of values of the first stock, and the values of the axis on the right show the range of values of the second stock.



To use multiple axes in a chart, you first define the chart's series and their axes. For example, for a chart that mixes columns with a line, you would have a ColumnSeries and LineSeries. For each of these, you would likely also define the vertical axis, as the following example shows:

```
<mx:series>
    <mx:ColumnSeries id="cs1" dataProvider="{SMITH}" yField="close">
        <mx:verticalAxis>
            <mx:LinearAxis id="v1" minimum="40" maximum="50"/>
        </mx:verticalAxis>
    </mx:ColumnSeries>
    <mx:LineSeries id="cs2" dataProvider="{DECKER}" yField="close">
        <mx:verticalAxis>
            <mx:LinearAxis id="v2" minimum="150" maximum="170"/>
        </mx:verticalAxis>
    </mx:LineSeries>
</mx:series>
```

You then define the axis renderers, and bind their `axis` properties to the series' axes. In this case, you define two vertical axis renderers, and bind them to the LinearAxis objects.

```
<mx:verticalAxisRenderers>
    <mx:AxisRenderer placement="left" axis="{v1}"/>
    <mx:AxisRenderer placement="left" axis="{v2}"/>
</mx:verticalAxisRenderers>
```

Note that you control the location of the axis by using the `placement` property of the AxisRenderer. For vertical axis renderers, valid values are `left` and `right`. For horizontal axis renderers, valid values are `top` and `bottom`.

Axes can be independent of the series definition, too. For example, you can also point more than one series to the same axis. In this case, you could define a horizontal axis, as follows:

```
<mx:horizontalAxis>
    <mx:CategoryAxis id="h1" categoryField="date"/>
<mx:horizontalAxis>
```

And then bind it to the series, like this:

```
<mx:ColumnSeries id="cs1" horizontalAxis="{h1}" dataProvider="{SMITH}" yField="close">
...
<mx:LineSeries id="cs2" horizontalAxis="{h1}" dataProvider="{DECKER}" yField="close">
```

And you can bind an axis renderer to that same axis:

```
<mx:horizontalAxisRenderers>
    <mx:AxisRenderer placement="bottom" axis="{h1}"/>
</mx:horizontalAxisRenderers>
```

The final result is a chart with multiple axes, but whose series share some of the same properties defined by common axis renderers.

```

           </mx:ColumnSeries>
           <mx:LineSeries
                dataProvider="{srv_strk.lastResult.data.result}"
                xField="date"
                yField="close"
                displayName="STRK">
                  <mx:verticalAxis>
                     <mx:LinearAxis id="v2" minimum="40" maximum="50"/>
                  </mx:verticalAxis>
           </mx:LineSeries>
        </mx:series>
     </mx:ColumnChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

Even if the `verticalAxisRenderers` or `horizontalAxisRenderers` properties have not been specified, Cartesian charts will create default horizontal and vertical axis renderers based on the default axes of the chart.

When using multiple axes, it is important to recognize that it will not necessarily be immediately apparent which axis applies to which data set in the chart. As a result, you should try to style the axes so that they match the styles of the chart items.

The following example defines two colors and then uses those colors in the axis renderers and in the strokes and fills for the chart items:

```
<?xml version="1.0"?>
<!-- charts/StyledMultipleAxes.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv_fe.send();srv_strk.send()"
    height="600">
    <fx:Script>
        <![CDATA[
            [Bindable]
            public var c1:Number = 0x224488;
            [Bindable]
            public var c2:Number = 0x884422;
        ]]>
    </fx:Script>
    <fx:Declarations>

     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

You can customize labels by using the `labelFunction` property of the AxisRenderer class. This lets you control the labels if you use multiple axes. For more information, see “Customizing axis labels” on page 1270.

For CartesianChart controls, there is no limit to the number of axes you can have.

For PolarChart controls, such as a PieChart, you generally do not use multiple axes because even though each series could have its own angular axis, the angular axis is always from 0 to 360 (the size of the wedge).

Formatting charts

You can customize the look and feel of your Adobe® Flex® charting controls. You can format the appearance of almost all chart elements, from the font properties of an axis label to the width of the stroke in a legend.

To set style properties in your chart controls, you can use Cascading Style Sheets (CSS) syntax or set the style properties inline as tag attributes. As with all styles, you can call the setStyle() method to set any style on your chart elements.

For more information on using the `setStyle()` method, see “Using the setStyle() and getStyle() methods” on page 1540.

Applying chart styles

You can apply style properties to charts by using CSS or inline syntax. You can also apply styles to chart elements by using binding.

Applying styles with CSS

You can apply styles to charting components with CSS definitions. You can set chart properties such as fonts and tick marks, or series properties, such as the fills of the boxes in a ColumnChart.

A limitation of using CSS to style your charts is that the styleable chart properties often use compound values, such as strokes and gradient fills, that cannot be expressed by using CSS. The result is that you cannot express all values of chart styles by using CSS syntax.

To determine if an object's properties can be styled by using CSS, check to see if the class or its parent implements the IStyleClient interface. If it does, then you can set the values of the object's style properties with CSS. If it does not, then the class does not participate in the styles subsystem and you therefore cannot set its properties with CSS. In that case, the properties are public properties of the class and not style properties. You can apply properties with CSS by using pre-defined styles for some classes, such as the `verticalAxisStyleName` and `horizontalAxisStyleName`. For more information, see "Using predefined axis style properties" on page 1174.

Applying CSS to chart controls

You can use the control name in CSS to define styles for that control. This is referred to as a type selector, because the style you define is applied to all controls of that type. For example, the following style definition specifies the font for all BubbleChart controls:

```
<?xml version="1.0"?>
<!-- charts/BubbleStyles.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
    <fx:Style>
     @namespace mx "library://ns.adobe.com/flex/mx";

     mx|BubbleChart {
         fontFamily:Arial;
         fontSize:15;
         color:#FF0033;
      }
    </fx:Style>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
```

```
  <s:Panel title="Bubble Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:BubbleChart id="myChart"
        minRadius="1"
        maxRadius="50"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true">
        <mx:series>
           <mx:BubbleSeries
                xField="profit"
                yField="expenses"
                radiusField="amount"
                displayName="Profit"/>
        </mx:series>
     </mx:BubbleChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

Some styles, such as `fontSize` and `fontFamily`, are inheritable, which means that if you set them on the chart control, the axes labels, titles, and other text elements on the chart inherit those settings. To determine whether a style is inheritable, see that style's description in *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Axis labels appear next to the tick marks along the chart's axis. Titles appear parallel to the axis line. By default, the text on an axis uses the text styles of the chart control.

Axis elements use whatever styles are set on the chart control's type or class selector, but you can also specify different styles for each axis by using a class selector on the axis renderer or predefined axis style properties.

Applying different styles to each series

To apply different styles to each series in the charts with CSS, you use the `chartSeriesStyles` property. This property takes an Array of Strings. Each String specifies the name of a class selector in the style sheet. Flex applies each of these class selectors to a series.

To apply CSS to a series, you define a type or class selector for the chart that defines the `chartSeriesStyles` property. You then define each class selector named in the `chartSeriesStyles` property.

Essentially, you are defining a new style for each series in your chart. For example, if you have a ColumnChart control with two series, you can apply a different style to each series without having to explicitly set the styles on each series.

The following example defines the colors for two series in the ColumnChart control:

```
<?xml version="1.0"?>
<!-- charts/SeriesStyles.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">

    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>

  <fx:Style>
     @namespace mx "library://ns.adobe.com/flex/mx";

     mx|ColumnChart {
        chartSeriesStyles: PCCSeries1, PCCSeries2;
     }
     .PCCSeries1 {
        fill: #CCFF66;
     }
     .PCCSeries2 {
        fill: #CCFF99;
     }
  </fx:Style>

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

  <s:Panel title="Setting Styles on Series">
     <s:layout>
         <s:VerticalLayout/>
     </s:layout>
     <mx:ColumnChart id="column"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true">
        <mx:horizontalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:ColumnSeries
                xField="month"
                yField="profit"
                displayName="Profit"/>
           <mx:ColumnSeries
                xField="month"
                yField="expenses"
                displayName="Expenses"/>
        </mx:series>
     </mx:ColumnChart>
     <mx:Legend dataProvider="{column}"/>
  </s:Panel>
</s:Application>
```

Flex sets the `styleName` property of each series to the corresponding selector in the `chartSeriesStyles` Array. You do not have to explicitly set styles for each series. If you have more series than available `chartSeriesStyles` selectors, the chart begins again with the first style.

If you manually set the value of the `styleName` property on a particular series, that style takes priority over the styles that the `chartSeriesStyles` property specifies.

For PieChart controls, you can define the `fills` property of the series. The PieChart applies the values in this Array to the pie wedges. It starts with the first value if there are more wedges than values defined in the Array. The following example creates a PieChart that uses a spectrum of reds for the wedges:

```
<?xml version="1.0"?>
<!-- charts/PieWedgeFills.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">

    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/budget-
xml.aspx"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/budget.aspx -->
    </fx:Declarations>

  <fx:Style>
     @namespace mx "library://ns.adobe.com/flex/mx";

     mx|PieSeries {
         fills:#FF0000, #FF3333, #FF6666, #FF9999, #FFAAAA, #FFCCCC;
      }
  </fx:Style>
```

```
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

  <s:Panel title="Setting Pie Wedge Fills with CSS">
     <s:layout>
         <s:VerticalLayout/>
     </s:layout>
     <mx:PieChart id="pie"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true">
        <mx:series>
           <mx:PieSeries
                field="amount"
                nameField="item"
                labelPosition="callout"/>
        </mx:series>
     </mx:PieChart>
     <mx:Legend dataProvider="{pie}"/>
  </s:Panel>
</s:Application>
```

Using predefined axis style properties

The following predefined class selectors are available for axis styles:

- `horizontalAxisStyleName`
- `verticalAxisStyleName`

Flex applies each style to the corresponding axis.

In addition to these, the following two class selectors define an array of class selectors that define the style properties for the axes:

- `horizontalAxisStyleNames`
- `verticalAxisStyleNames`

In this case, Flex loops through the selectors and applies them to the axis renderers that correspond to their position in the Array.

In addition to these class selectors for the axis style properties, you can use the `axisTitleStyleName` and `gridLinesStyleName` class selectors to apply styles to axis titles and grid lines.

The following example removes tick marks from the horizontal axis:

```
<?xml version="1.0"?>
<!-- charts/PredefinedAxisStyles.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
  <fx:Style>
     @namespace mx "library://ns.adobe.com/flex/mx";

     mx|ColumnChart {
        horizontalAxisStyleName:myAxisStyles;
        verticalAxisStyleName:myAxisStyles;
     }
     .myAxisStyles {
        tickPlacement:none;
     }
  </fx:Style>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:Panel title="Using Predefined Axis Styles">
     <s:layout>
         <s:VerticalLayout/>
     </s:layout>
     <mx:ColumnChart id="column"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true">
        <mx:horizontalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:ColumnSeries
                xField="month"
                yField="profit"
               displayName="Profit"/>
           <mx:ColumnSeries
                xField="month"
                yField="expenses"
                displayName="Expenses"/>
        </mx:series>
     </mx:ColumnChart>
     <mx:Legend dataProvider="{column}"/>
  </s:Panel>
</s:Application>
```

Using class selectors for axis styles

To use a class selector to define styles for axis elements, define the custom class selector in an `<fx:Style>` block or external style sheet, and then use the `styleName` property of the AxisRenderer class to point to that class selector. Note that any time you want to use an AxisRenderer, you must explicitly set the axis to which it is applied with the renderer's `axis` property.

The following example defines the `MyStyle` style and applies that style to the elements on the horizontal axis:

```
<?xml version="1.0"?>
<!-- charts/AxisClassSelectors.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
  <fx:Declarations>
     <!-- View source of the following page to see the structure of the data that Flex uses in
this example. -->
     <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
     <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
  </fx:Declarations>
    <fx:Style>
        .myStyle {
            fontSize:9;
            color:red;
        }
    </fx:Style>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="AxisRenderer Class Selectors example">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:ColumnChart id="column"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true">
        <mx:horizontalAxisRenderers>
           <mx:AxisRenderer
```

```
                axis="{a1}"
                styleName="myStyle"/>
        </mx:horizontalAxisRenderers>
        <mx:horizontalAxis>
           <mx:CategoryAxis id="a1" categoryField="month"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:ColumnSeries
                xField="month"
                yField="profit"
                displayName="Profit"/>
           <mx:ColumnSeries
                xField="month"
                yField="expenses"
                displayName="Expenses"/>
        </mx:series>
     </mx:ColumnChart>
     <mx:Legend dataProvider="{column}"/>
  </s:Panel>
</s:Application>
```

Most charting-specific style properties are not inheritable, which means that if you set the property on a parent object, the child object does not inherit its value.

For more information on using CSS, see “About styles” on page 1492.

Applying styles inline

You can set many styleable elements of a chart as attributes of the MXML tag. For example, to set the styleable properties of an axis, you can use the `<mx:AxisRenderer>` tag rather than define a new style in CSS.

The following example sets the `fontSize` property of the horizontal axis to 7:

```
<mx:horizontalAxisRenderers>
    <mx:AxisRenderer fontSize="7" axis="{h1}"/>
</mx:horizontalAxisRenderers>
```

Notice that any time you want to use an AxisRenderer, you must explicitly set the axis to which it is applied with the renderer’s `axis` property.

You can also access the properties of renderers in ActionScript so that you can change their appearance at run time. For additional information about axis renderers, see “Working with axes” on page 1247.

Applying styles by binding tag definitions

You can define styles with MXML tags. You can then bind the values of the renderer properties to those tags. The following example defines the weight and color of the strokes, and then applies those strokes to the chart’s AxisRenderer class:

```
<?xml version="1.0"?>
<!-- charts/BindStyleValues.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
      <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
      <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/stocks-
xml.aspx"/>
      <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/stocks.aspx -->
      <mx:SolidColorStroke color="0x00FF00" weight="2" id="axis"/>
      <mx:SolidColorStroke color="0xFF0000" weight="1" id="ticks"/>
      <mx:SolidColorStroke color="0x0000FF" weight="1" id="mticks"/>
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="HLOC Chart">
        <s:layout>
            <s:VerticalLayout/>

  </s:Panel>
</s:Application>
```

Using ChartElement objects

The ChartElement class is the base class for anything that appears in the data area of the chart. All series objects (such as GridLines objects) are ChartElement objects. You can add ChartElement objects (such as images, grid lines, and strokes) to your charts by using the `backgroundElements` and `annotationElements` properties of the chart classes.

The `backgroundElements` property specifies an Array of ChartElement objects that appear beneath any data series rendered by the chart. The `annotationElements` property specifies an Array of ChartElement objects that appears above any data series rendered by the chart.

The ChartElement objects that you can add to a chart include supported image files, such as GIF, PNG, and JPEG.

The following example adds new grid lines as annotation elements to the chart and an image as the background element. When the user clicks the button, the annotation elements change:

```
<?xml version="1.0"?>
<!-- charts/AnnotationElements.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <fx:Script><![CDATA[
      import mx.graphics.SolidColor;
```

```
     import mx.charts.GridLines;
     [Embed(source="../assets/butterfly.gif")]
     public var butterfly:Class;
     public function updateGridLines():void {
        var bgi:GridLines = new GridLines();
        var s:SolidColorStroke = new SolidColorStroke(0xff00ff, 3);
        bgi.setStyle("horizontalStroke",s);
        var c:SolidColor = new SolidColor(0x990033, .2);
        bgi.setStyle("horizontalFill",c);
        var c2:SolidColor = new SolidColor(0x999933, .2);
        bgi.setStyle("horizontalAlternateFill",c2);
        myChart.annotationElements = [bgi]
        var b:Object = new butterfly();
        b.alpha = .2;
        b.height = 150;
        b.width = 150;
        myChart.backgroundElements = [ b ];
     }
 ]]></fx:Script>
 <s:Panel title="Annotation Elements Example">
       <s:layout>
           <s:VerticalLayout/>
       </s:layout>
    <mx:ColumnChart id="myChart"
       dataProvider="{srv.lastResult.data.result}"
       showDataTips="true">
       <mx:horizontalAxis>
          <mx:CategoryAxis categoryField="month"/>
       </mx:horizontalAxis>
       <mx:series>
          <mx:ColumnSeries
               xField="month"
               yField="profit"
               displayName="Profit"/>
          <mx:ColumnSeries
               xField="month"
               yField="expenses"
               displayName="Expenses"/>
       </mx:series>
       <mx:annotationElements>
          <mx:GridLines>
           <mx:horizontalStroke>
               <mx:SolidColorStroke
```

```
                    color="#191970"
                    weight="2"
                    alpha=".3"/>
            </mx:horizontalStroke>
           </mx:GridLines>
        </mx:annotationElements>
        <mx:backgroundElements>
           <s:Image
                source="@Embed('../assets/butterfly.gif')"
                alpha=".2"/>
        </mx:backgroundElements>
     </mx:ColumnChart>
     <!--
     <mx:Legend dataProvider="{myChart}"/>
     -->
  </s:Panel>
  <s:Button id="b1"
    click="updateGridLines()"
    label="Update Grid Lines"/>
</s:Application>
```

In ActionScript, you can add an image to the chart and manipulate its properties, as the following example shows:

```
<?xml version="1.0"?>
<!-- charts/BackgroundElementsWithActionScript.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send();addButterfly()"
    height="600">
  <fx:Declarations>
     <!-- View source of the following page to see the structure of the data that Flex uses in
this example. -->
     <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
     <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
  </fx:Declarations>
  <fx:Script><![CDATA[
      import mx.collections.ArrayCollection;
      import mx.graphics.SolidColor;
      import mx.charts.GridLines;
      import mx.charts.ColumnChart;
      [Embed(source="../assets/butterfly.gif")]
      public var butterfly:Class;
      public function addButterfly():void {
         var b:Object = new butterfly();
         b.alpha = .2;
         myChart.backgroundElements = [ b ];
      }
  ]]></fx:Script>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Background Elements with ActionScript">
        <s:layout>
```

```
            <s:VerticalLayout/>
        </s:layout>
     <mx:ColumnChart id="myChart" dataProvider="{srv.lastResult.data.result}"
showDataTips="true">
        <mx:horizontalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:ColumnSeries
                xField="month"
                yField="profit"
                displayName="Profit"/>
           <mx:ColumnSeries
                xField="month"
                yField="expenses"
                displayName="Expenses"/>
        </mx:series>
     </mx:ColumnChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

For more information on working with grid lines, see "Using chart grid lines" on page 1218.

You can also add data graphics to your charts by adding the CartesianDataCanvas and PolarDataCanvas controls to your background or annotation elements Arrays. For more information, see "Drawing on chart controls" on page 1387.

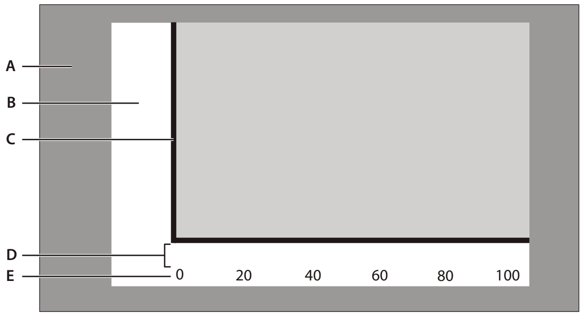
Setting padding properties

The padding properties of a chart define an area between the outside bounds of the chart control and its content. Flex draws only the background fill in the padding area.

You can set the padding values for a chart control by using the `paddingLeft` and `paddingRight` properties that the chart control inherits from the UIComponent class. You can also use the `paddingTop` and `paddingBottom` properties that the chart control inherits from the ChartBase class.

Flex charting control elements also have gutters. The *gutter* is the area between the padding area and the actual axis line. Flex draws labels, titles, and tick marks for the axes in the gutter of the chart. Chart controls adjust the gutters to accommodate these enhancements to the axis, but you can specify explicit gutter values.

The following example shows the locations of the gutters and the padding area on a chart:



A. *Padding area* ***B.*** *Gutter* ***C.*** *Axis* ***D.*** *Label gap* ***E.*** *Axis label*

The following style properties define the size of a chart’s gutters:

- `gutterLeft`
- `gutterRight`
- `gutterTop`
- `gutterBottom`

The default value of the gutter styles is `undefined`, which means that the chart determines appropriate values. Overriding the default value and explicitly setting gutter values can improve the speed of rendering charts, because Flex does not have to dynamically calculate the gutter size. However, it can also cause clipping of axis labels or other undesirable effects.

You set gutter styles on the chart control. The following example creates a region that is 50 pixels wide for the axis labels, titles, and tick marks, by explicitly setting the values of the `gutterLeft`, `gutterRight`, and `gutterBottom` style properties. It also sets the `paddingTop` property to 20.

```
<?xml version="1.0"?>
<!-- charts/GutterStyles.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses 
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to 
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
  <fx:Style>
     @namespace mx "library://ns.adobe.com/flex/mx";

     mx|ColumnChart {
        gutterLeft:50;
        gutterRight:50;
        gutterBottom:50;
        gutterTop:20;
     }
  </fx:Style>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Setting Gutter Properties as Styles">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:ColumnChart id="column"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true">
        <mx:horizontalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:ColumnSeries
                xField="month"
                yField="profit"
                displayName="Profit"/>
           <mx:ColumnSeries
                xField="month"
                yField="expenses"
                displayName="Expenses"/>
        </mx:series>
     </mx:ColumnChart>
     <mx:Legend dataProvider="{column}"/>
  </s:Panel>
</s:Application>
```

Alternatively, you can set the gutter properties inline, as the following example shows:

```
<?xml version="1.0"?>
<!-- charts/GutterProperties.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses 
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to 
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Setting Gutter Properties">
        <s:layout>
           <s:VerticalLayout/>
        </s:layout>
          <mx:ColumnChart id="column"
             dataProvider="{srv.lastResult.data.result}"
             showDataTips="true"
             gutterLeft="50"
             gutterRight="50"
             gutterBottom="50"
             gutterTop="20">
        <mx:horizontalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:ColumnSeries
                xField="month"
                yField="profit"
                displayName="Profit"/>
           <mx:ColumnSeries
                xField="month"
                yField="expenses"
                displayName="Expenses"/>
        </mx:series>
     </mx:ColumnChart>
     <mx:Legend dataProvider="{column}"/>
  </s:Panel>
</s:Application>
```

In addition to the gutter and padding properties, you can set the `labelGap` property of a chart's axes. The `labelGap` property defines the distance, in pixels, between the tick marks and the axis labels. You set the `labelGap` property on the AxisRenderer tag, as the following example shows:

```
<?xml version="1.0"?>
<!-- charts/LabelGaps.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">

    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:Panel title="Setting Label Gap Properties">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <mx:ColumnChart id="myChart"
            dataProvider="{srv.lastResult.data.result}"
            gutterLeft="50"
            gutterRight="50"
            gutterBottom="50"
            gutterTop="20"
            showDataTips="true">
            <mx:horizontalAxis>
```

```
                <mx:CategoryAxis id="a1" categoryField="month"/>
            </mx:horizontalAxis>
            <mx:horizontalAxisRenderers>
                <mx:AxisRenderer axis="{a1}" labelGap="20"/>
            </mx:horizontalAxisRenderers>
            <mx:verticalAxisRenderers>
                <mx:AxisRenderer axis="{a1}" labelGap="20"/>
            </mx:verticalAxisRenderers>
            <mx:series>
                <mx:ColumnSeries
                    xField="month"
                    yField="profit"
                    displayName="Profit"/>
                <mx:ColumnSeries
                    xField="month"
                    yField="expenses"
                    displayName="Expenses"/>
            </mx:series>
        </mx:ColumnChart>
        <mx:Legend dataProvider="{myChart}"/>
    </s:Panel>
</s:Application>
```

You can specify the alignment of axis labels by using the `labelAlign` property on the AxisRenderer. For horizontal axis labels, you can specify `center`, `left`, and `right`. For example, in a ColumnChart control, if you set the value of the `labelAlign` property to `left`, Flex renders the labels at the `left` of the bottoms of the columns. For vertical axis labels, you can specify `center`, `top`, and `bottom`.

How different the locations of the labels are depends on the available space (for example, the width of the columns) and the font size of the labels.

The following example lets you change the label alignment for the vertical and horizontal axes.

```
<?xml version="1.0"?>
<!-- charts/ToggleLabelAlignment.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600" width="750">

     </s:Form>
  </s:Panel>
</s:Application>
```

Formatting tick marks

There are two types of tick marks on a Flex chart: major and minor. Major tick marks are the indications along an axis that correspond to an axis label. The text for the axis labels is often derived from the chart's data provider. Minor tick marks are those tick marks that appear between the major tick marks. Minor tick marks help the user to visualize the distance between the major tick marks.

You use the `tickPlacement` and `minorTickPlacement` properties of the AxisRenderer object to determine whether or not Flex displays tick marks and where Flex displays tick marks.

The following table describes valid values of the `tickPlacement` and `minorTickPlacement` properties:

Value	Description
`cross`	Places tick marks across the axis.
`inside`	Places tick marks on the inside of the axis line.
`none`	Hides tick marks.
`outside`	Places tick marks on the outside of the axis line.

Flex also lets you set the length of tick marks and the number of minor tick marks that appear along the axis. The following table describes the properties that define the length of tick marks on the chart's axes:

Property	Description
`tickLength`	The length, in pixels, of the major tick mark from the axis.
`minorTickLength`	The length, in pixels, of the minor tick mark from the axis.

The minor tick marks overlap the placement of major tick marks. So, if you hide major tick marks but still show minor tick marks, the minor tick marks appear at the regular tick-mark intervals.

The following example sets tick marks to the inside of the axis line, sets the tick mark's length to 12 pixels, and hides minor tick marks:

```
<?xml version="1.0"?>
<!-- charts/TickStyles.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600" width="700">
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/stocks-
xml.aspx"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/stocks.aspx -->
    </fx:Declarations>
  <fx:Style>
     .myAxisStyle {
        placement:bottom;
        minorTickPlacement:none;
        tickLength:12;
        tickPlacement:inside;
        tickStroke: myStroke;
     }
  </fx:Style>

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Tick Styles">
     <s:layout>
         <s:HorizontalLayout/>
     </s:layout>
    <mx:HLOCChart id="mychart"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true">
    <mx:horizontalAxisRenderers>
        <mx:AxisRenderer axis="{a2}" styleName="myAxisStyle">
               <mx:tickStroke>
                    <mx:SolidColorStroke color="#999966" weight="1"/>
                </mx:tickStroke>
        </mx:AxisRenderer>
    </mx:horizontalAxisRenderers>
    <mx:verticalAxis>
        <mx:LinearAxis id="a1" minimum="30" maximum="50"/>
    </mx:verticalAxis>
    <mx:horizontalAxis>
        <mx:LinearAxis id="a2"/>
    </mx:horizontalAxis>
    <mx:series>
        <mx:HLOCSeries openField="open" highField="high"
            lowField="low" closeField="close"
            displayName="Ticker Symbol: FRED"/>
     </mx:series>
  </mx:HLOCChart>
  <mx:Legend dataProvider="{mychart}"/>
  </s:Panel>
</s:Application>
```

Formatting axis lines

Axes have lines to which the tick marks are attached. You can use style properties to hide these lines or change the width of the lines.

To hide the axis line, set the value of the `showLine` property on the AxisRenderer object to `false`. The default value is `true`. The following example sets `showLine` to `false`:

```
<?xml version="1.0"?>
<!-- charts/DisableAxisLines.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
        <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
          <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
          <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:Panel title="Line Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <mx:LineChart id="myChart"
            dataProvider="{srv.lastResult.data.result}"
            showDataTips="true">
            <mx:horizontalAxis>
                <mx:CategoryAxis id="a1" categoryField="month"/>
            </mx:horizontalAxis>
               <mx:verticalAxis>
                    <mx:LinearAxis id="a2"/>
               </mx:verticalAxis>
            <mx:horizontalAxisRenderers>
                <mx:AxisRenderer
                    axis="{a1}"
                    showLine="false"/>
            </mx:horizontalAxisRenderers>
            <mx:verticalAxisRenderers>
                <mx:AxisRenderer axis="{a2}" showLine="false"/>
            </mx:verticalAxisRenderers>
            <mx:series>
                <mx:LineSeries yField="profit" displayName="Profit"/>
                <mx:LineSeries yField="expenses" displayName="Expenses"/>
            </mx:series>
        </mx:LineChart>
        <mx:Legend dataProvider="{myChart}"/>
    </s:Panel>
</s:Application>
```

You can also apply the `showLine` property as a CSS style property.

You can change the `width`, `color`, and `alpha` of the axis line with the `<mx:axisStroke>` tag. You use an `<mx:SolidColorStroke>` child tag to define these properties or define a stroke and then bind it to the `axisStroke` object, as the following example shows:

```
<?xml version="1.0"?>
<!-- charts/StyleAxisLines.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
        <!-- View source of the following page to see the structure of the data that Flex uses 
in this example. -->
         <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
         <!-- To see data in an HTML table, go to 
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
        <mx:SolidColorStroke id="axisStroke" color="#884422"
            weight="8" alpha=".75" caps="square"/>
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:Panel title="Line Chart">
         <s:layout>
             <s:HorizontalLayout/>
         </s:layout>
        <mx:LineChart id="myChart"
            dataProvider="{srv.lastResult.data.result}"
            showDataTips="true">
            <mx:horizontalAxis>
                <mx:CategoryAxis id="a1" categoryField="month"/>
            </mx:horizontalAxis>
            <mx:verticalAxis>
                <mx:LinearAxis id="a2"/>
            </mx:verticalAxis>
            <mx:horizontalAxisRenderers>
                <mx:AxisRenderer axis="{a1}">
                    <mx:axisStroke>{axisStroke}</mx:axisStroke>
                </mx:AxisRenderer>
            </mx:horizontalAxisRenderers>
            <mx:verticalAxisRenderers>
                <mx:AxisRenderer axis="{a2}">
                    <mx:axisStroke>
                        <mx:SolidColorStroke color="#884422"
                            weight="8" alpha=".75" caps="square"/>
                    </mx:axisStroke>
                </mx:AxisRenderer>
            </mx:verticalAxisRenderers>
            <mx:series>
                <mx:LineSeries yField="profit" displayName="Profit"/>
                <mx:LineSeries yField="expenses" displayName="Expenses"/>
            </mx:series>
        </mx:LineChart>
        <mx:Legend dataProvider="{myChart}"/>
    </s:Panel>
</s:Application>
```

For more information about strokes, see “Using strokes with chart controls” on page 1192.

You can change the placement of the axis lines (for example, move the axis line from the bottom of the chart control to the top) by using the `placement` property of the AxisRenderer. For more information, see “Positioning chart axes” on page 1226.

You can also apply filters to axis lines to further customize their appearance. For more information, see “Using filters with chart controls” on page 1213.

Using strokes with chart controls

You use the SolidColorStroke class with the chart series and grid lines to control the properties of the lines that Flex uses to draw chart elements.

You can define strokes in MXML inside the `<fx:Declarations>` block so that you can reuse the stroke. You can also define an individual stroke inside an MXML tag.

The following table describes the properties that you use to control the appearance of strokes:

Property	Description
`color`	Specifies the color of the line as a hexadecimal value. The default value is `0x000000`, which corresponds to black.
`weight`	Specifies the width of the line, in pixels. The default value is 0, which corresponds to a hairline.
`alpha`	Specifies the transparency of a line. Valid values are 0 (invisible) through 100 (opaque). The default value is 100.

The following example defines a line width of 2 pixels, one with a dark gray border (0x808080) and the other with a light gray border (0xC0C0C0) for the borders of chart items in a BarChart control’s BarSeries:

```
<?xml version="1.0"?>
<!-- charts/BasicBarStroke.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">

    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Bar Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:BarChart id="myChart" dataProvider="{srv.lastResult.data.result}"
showDataTips="true">
        <mx:verticalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:verticalAxis>
        <mx:series>
           <mx:BarSeries
                yField="month"
                xField="profit"
                displayName="Profit">
            <mx:stroke>
                <mx:SolidColorStroke
                    color="0x808080"
                    weight="2" alpha=".8"/>
            </mx:stroke>
           </mx:BarSeries>
           <mx:BarSeries
                yField="month"
                xField="expenses"
                displayName="Expenses">
            <mx:stroke>
                <mx:SolidColorStroke
                    color="0xC0C0C0"
                    weight="2" alpha=".8"/>
            </mx:stroke>
           </mx:BarSeries>
        </mx:series>
     </mx:BarChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

Defining AxisRenderer properties with strokes

You can use strokes to define tick marks and other properties of an AxisRenderer, as the following example shows:

```
<?xml version="1.0"?>
<!-- charts/AxisRendererStrokes.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
  <fx:Declarations>
      <!-- View source of the following page to see the structure of the data that Flex uses 
in this example. -->
      <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/stocks-
xml.aspx"/>
      <!-- To see data in an HTML table, go to 
http://aspexamples.adobe.com/chart_examples/stocks.aspx -->
  </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="HighLowOpenClose Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
    <mx:HLOCChart id="myChart"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true">
        <mx:horizontalAxisRenderers>
            <mx:AxisRenderer
                placement="bottom"
                canDropLabels="true"
                tickPlacement="inside"
                tickLength="10"
                minorTickPlacement="inside"
                minorTickLength="5"
                axis="{a1}">
                <mx:axisStroke>
                    <mx:SolidColorStroke color="#000080" weight="1"/>
                </mx:axisStroke>
                <mx:tickStroke>
                    <mx:SolidColorStroke color="#000060" weight="1"/>
                </mx:tickStroke>
                <mx:minorTickStroke>
                    <mx:SolidColorStroke color="#100040" weight="1"/>
                </mx:minorTickStroke>
            </mx:AxisRenderer>
        </mx:horizontalAxisRenderers>
        <mx:verticalAxis>
            <mx:LinearAxis id="a1" minimum="30"  maximum="50"/>
        </mx:verticalAxis>
        <mx:series>
            <mx:HLOCSeries
                openField="open"
                highField="high"
                lowField="low"
                closeField="close"
                displayName="FRED">
            </mx:HLOCSeries>
        </mx:series>
    </mx:HLOCChart>
    <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

Notice that any time you use an AxisRenderer, you must explicitly set the axis to which it is applied with the renderer's `axis` property.

You can define a SolidColorStroke object using an MXML tag, and then bind that SolidColorStroke to the chart's renderer properties. For an example, see "Applying styles by binding tag definitions" on page 1177.

Using strokes in ActionScript

You can instantiate and manipulate a SolidColorStroke object in ActionScript by using the mx.graphics.SolidColorStroke class. You can then use the setStyle() method to apply the SolidColorStroke object to the chart, as the following example shows:

```
<?xml version="1.0"?>
<!-- charts/ActionScriptStroke.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns="*"
    creationComplete="srv.send()"
    height="600">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <fx:Script><![CDATA[
     import mx.graphics.SolidColorStroke;
     public function changeStroke(e:Event):void {
        var s:SolidColorStroke = new SolidColorStroke(0x001100,2);
        s.alpha = .5;
        s.color = 0x0000FF;
        har1.setStyle("axisStroke",s);
        var1.setStyle("axisStroke",s);
     }
  ]]></fx:Script>
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses 
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to 
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
        <mx:SolidColorStroke id="baseAxisStroke"
            color="0x884422"
            weight="10"
            alpha=".25"
            caps="square"/>
    </fx:Declarations>
  <s:Panel title="Column Chart">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
     <mx:ColumnChart id="myChart" dataProvider="{srv.lastResult.data.result}" 
showDataTips="true">
        <mx:horizontalAxis>
           <mx:CategoryAxis id="a1" categoryField="month"/>
        </mx:horizontalAxis>
        <mx:verticalAxis>
          <mx:LinearAxis id="a2"/>
        </mx:verticalAxis>
        <mx:horizontalAxisRenderers>
           <mx:AxisRenderer id="har1" axis="{a1}">
                <mx:axisStroke>{baseAxisStroke}</mx:axisStroke>
           </mx:AxisRenderer>
        </mx:horizontalAxisRenderers>
        <mx:verticalAxisRenderers>
           <mx:AxisRenderer id="var1" axis="{a2}">
```

```
                <mx:axisStroke>{baseAxisStroke}</mx:axisStroke>
           </mx:AxisRenderer>
        </mx:verticalAxisRenderers>
        <mx:series>
           <mx:ColumnSeries
                xField="month"
                yField="profit"
                displayName="Profit"/>
           <mx:ColumnSeries
                xField="month"
                yField="expenses"
                displayName="Expenses"/>
        </mx:series>
     </mx:ColumnChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
  <s:Button id="b1"
    click="changeStroke(event)"
    label="Change SolidColorStroke"/>
</s:Application>
```

Defining strokes for LineSeries and AreaSeries

Some chart series have more than one stroke-related style property. For LineSeries, you use the `stroke` style property to define a style for the chart item's renderer. You use the `lineStroke` property to define the stroke of the actual line segments.

The following example creates a thick blue line for the LineChart control's line segments, with large red boxes at each data point, which use the CrossItemRenderer object as their renderer:

```
<?xml version="1.0"?>
<!-- charts/LineSeriesStrokes.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Line Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:LineChart id="myChart"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true">
        <mx:horizontalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:LineSeries
            yField="profit"
            displayName="Profit">
            <mx:itemRenderer>
                <fx:Component>
                    <mx:CrossItemRenderer scaleX="1.5" scaleY="1.5"/>
                </fx:Component>
            </mx:itemRenderer>
            <mx:fill>
                <mx:SolidColor color="0x0000FF"/>
            </mx:fill>
            <mx:stroke>
                <mx:SolidColorStroke color="0xFF0066" alpha="1"/>
            </mx:stroke>
            <mx:lineStroke>
                <mx:SolidColorStroke color="0x33FFFF" weight="5" alpha=".8"/>
            </mx:lineStroke>
           </mx:LineSeries>
           <mx:LineSeries yField="expenses" displayName="Expenses"/>
        </mx:series>
     </mx:LineChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

Similarly, with the AreaSeries class, you use the `stroke` property to set a style for the chart item's renderer. You use the `areaStroke` style property to define the stroke of the line that defines the area.

Using fills with chart controls

When charting multiple data series, or just to improve the appearance of your charts, you can control the fill for each series in the chart or each item in a series. The fill lets you specify a pattern that defines how Flex draws the chart element. You also use fills to specify the background colors of the chart or bands of background colors defined by the grid lines. Fills can be solid or can use linear and radial gradients. A *gradient* specifies a gradual color transition in the fill color.

You use fills in the following ways:

- `fill` Set the value of the `fill` property on a series to a single fill. This applies that fill to all chart items in that series. For example, all columns in a single series will have the same fill.
- `fills` Set the value of the `fills` property on a series to an Array of fills. This applies a different fill from the Array to each chart item in the series. For example, each column in a series will have a different fill. The LineSeries and LineRenderer objects are not affected by the `fill` property's settings.
- `fillFunction` Set the value of the `fillFunction` property on a series to point to a custom method. This method returns a fill based on the values of the chart item in the series. The return value of this function takes precedence over fills specified as styles. For information on using the `fillFunction` property, see "Using per-item fills" on page 1299.

All series except the HLOCSeries class support setting the fill-related properties.

If you use the `fills` property or the `fillFunction` to define the fills of chart items, and you want a legend, you must manually create the Legend object for that chart. For more information on creating Legend objects, see “Using Legend controls” on page 1316.

One of the most common uses of a fill is to control the color of the chart when you have multiple data series in a chart. The following example uses the `fill` property to set the color for each ColumnSeries object in a ColumnChart control:

```
<?xml version="1.0"?>
<!-- charts/ColumnFills.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
        <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
         <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
         <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Column Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:ColumnChart id="myChart" dataProvider="{srv.lastResult.data.result}"
showDataTips="true">
        <mx:horizontalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:ColumnSeries
                xField="month"
                yField="profit"
                displayName="Profit">
               <mx:fill>
                    <mx:SolidColor color="0x336699"/>
               </mx:fill>
           </mx:ColumnSeries>
           <mx:ColumnSeries
                xField="month"
                yField="expenses"
                displayName="Expenses">
            <mx:fill>
                <mx:SolidColor color="0xFF99FF"/>
            </mx:fill>
           </mx:ColumnSeries>
        </mx:series>
     </mx:ColumnChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

If you do not explicitly define different fills for multiple data series, Flex chooses solid colors for you.

You can also specify an array of colors using the `fills` property of the series. This property takes an Array of objects that define the fills. You can use this property to define a different color for each item in the series. If you do not define as many colors in the Array as there are items in the series, the chart starts with the first item in the Array on the next item.

The following example defines two Arrays of SolidColor objects. The first Array defines the colors of the items in the first series in the chart and the second Array defines the colors of the items in the second series. All of the fills in this example are partially transparent (the alpha value in the SolidColor constructor is .5).

```
<?xml version="1.0"?>
<!-- charts/SimpleFillsExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses 
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to 
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
  <fx:Script>
    <![CDATA[
     import mx.graphics.SolidColor;

     // Make all fills partially transparent by
     // setting the alpha to .5.
     [Bindable]
     private var warmColorsArray:Array = new Array(
        new SolidColor(0xFF0033, .5),
        new SolidColor(0xFF0066, .5),
        new SolidColor(0xFF0099, .5)
     );
     [Bindable]
     private var coolColorsArray:Array = new Array(
        new SolidColor(0x3333CC, .5),
        new SolidColor(0x3366CC, .5),
        new SolidColor(0x3399CC, .5)
     );

    ]]>
  </fx:Script>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Column Chart">
     <s:layout>
         <s:VerticalLayout/>
     </s:layout>
     <mx:ColumnChart id="myChart" 
        dataProvider="{srv.lastResult.data.result}" 
        showDataTips="true">
        <mx:horizontalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:ColumnSeries
                xField="month"
                yField="profit"
                displayName="Profit"
                fills="{warmColorsArray}">
           </mx:ColumnSeries>
           <mx:ColumnSeries
                xField="month"
                yField="expenses"
                displayName="Expenses"
                fills="{coolColorsArray}">
           </mx:ColumnSeries>
        </mx:series>
     </mx:ColumnChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

This example does not have a legend. If you use the `fills` property or the `fillFunction` to define the fills of chart items, and you want a legend, you must manually create the Legend object for that chart. For more information on creating Legend objects, see “Using Legend controls” on page 1316.

With the PieSeries, you typically use a single Array of fills to specify how Flex should draw the individual wedges. For example, you can give each wedge that represents a PieSeries its own color, as the following example shows:

```
<?xml version="1.0"?>
<!-- charts/PieFills.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">

    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses 
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/budget-
xml.aspx"/>
        <!-- To see data in an HTML table, go to 
http://aspexamples.adobe.com/chart_examples/budget.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Pie Chart">
     <s:layout>
         <s:VerticalLayout/>
     </s:layout>
     <mx:PieChart id="myChart"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true">
        <mx:series>
           <mx:PieSeries
                field="amount"
                nameField="item"
                labelPosition="callout">
                <mx:fills>
                    <mx:SolidColor color="0xCC66FF" alpha=".8"/>
                    <mx:SolidColor color="0x9966CC" alpha=".8"/>
                    <mx:SolidColor color="0x9999CC" alpha=".8"/>
                    <mx:SolidColor color="0x6699CC" alpha=".8"/>
                    <mx:SolidColor color="0x669999" alpha=".8"/>
                    <mx:SolidColor color="0x99CC99" alpha=".8"/>
                </mx:fills>
            </mx:PieSeries>
        </mx:series>
     </mx:PieChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

This example also shows how you use the `<mx:fills>` tag inside a series to define an Array of fills for that series.

You can also use fills to set the background of the charts. You do this by adding an `<mx:fill>` child tag to the chart tag, as the following example shows:

```
<?xml version="1.0"?>
<!-- charts/BackgroundFills.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
  <fx:Declarations>
     <!-- View source of the following page to see the structure of the data that Flex uses in
this example. -->
     <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
     <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
  </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Background Fill">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:BarChart id="myChart"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true">
        <mx:verticalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:verticalAxis>
        <mx:fill>
           <mx:SolidColor color="0x66CCFF" alpha=".5"/>
        </mx:fill>
        <mx:series>
           <mx:BarSeries xField="expenses" displayName="Expenses"/>
        </mx:series>
     </mx:BarChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

Setting fills with CSS

You can use the `fill` or `fills` style properties in an `<fx:Style>` declaration by using CSS syntax. You can use a type or a class selector. The following example sets the fill of the custom `myBarChartStyle` class selector to `#FF0000`:

```
<?xml version="1.0"?>
<!-- charts/BackgroundFillsCSS.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
  <fx:Declarations>
     <!-- View source of the following page to see the structure of the data that Flex uses in
this example. -->
     <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
     <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
  </fx:Declarations>
  <fx:Style>
     .myBarChartStyle {
        fill:#FF0000;
     }
  </fx:Style>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Background Fill">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:BarChart id="myChart"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true"
        styleName="myBarChartStyle">
        <mx:verticalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:verticalAxis>
        <mx:series>
           <mx:BarSeries xField="expenses" displayName="Expenses"/>
        </mx:series>
     </mx:BarChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

Flex converts the fill style in the class selector to a SolidColor object.

The following example defines colors for each of the series by setting the value of the `fill` style property in the custom class selectors:

```
<?xml version="1.0"?>
<!-- charts/SimpleCSSFillsExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses 
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to 
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
  <fx:Style>
        .myRedColumnSeries {
            fill:#FF0033;
        }
        .myGreenColumnSeries {
            fill:#33FF00;
        }
  </fx:Style>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Column Chart">
     <s:layout>
         <s:VerticalLayout/>
     </s:layout>
     <mx:ColumnChart id="myChart" 
        dataProvider="{srv.lastResult.data.result}" 
        showDataTips="true">
        <mx:horizontalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:ColumnSeries 
                xField="month" 
                yField="profit" 
                displayName="Profit"
                styleName="myRedColumnSeries">
           </mx:ColumnSeries>
           <mx:ColumnSeries 
                xField="month" 
                yField="expenses" 
                displayName="Expenses"
                styleName="myGreenColumnSeries">
           </mx:ColumnSeries>
        </mx:series>
     </mx:ColumnChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

To specify an Array for the `fills` property in CSS, you use a comma-separated list, as the following example shows:

```
<?xml version="1.0"?>
<!-- charts/CSSFillsArrayExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
        <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
         <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
         <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
  <fx:Style>
        .myRedColumnSeries {
            fills: #FF0033, #FF3333, #FF6633;
        }
        .myGreenColumnSeries {
            fills: #33FF00, #33FF33, #33FF66;
        }
  </fx:Style>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Column Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:ColumnChart id="myChart"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true">
        <mx:horizontalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:ColumnSeries
                xField="month"
                yField="profit"
                displayName="Profit"
                styleName="myRedColumnSeries">
           </mx:ColumnSeries>
           <mx:ColumnSeries
                xField="month"
                yField="expenses"
                displayName="Expenses"
                styleName="myGreenColumnSeries">
           </mx:ColumnSeries>
        </mx:series>
     </mx:ColumnChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

Using gradient fills with chart controls

Flex provides several classes that let you specify gradient fills. You use either the LinearGradient class or the RadialGradient class, along with the GradientEntry class to specify a gradient fill. The following table describes these classes:

Class	Description
LinearGradient	Defines a gradient fill that starts at a boundary of the chart element. You specify an array of GradientEntry objects to control gradient transitions with the LinearGradient object.
RadialGradient	Defines a gradient fill that radiates from the center of a chart element. You specify an array of GradientEntry objects to control gradient transitions with the RadialGradient object.
GradientEntry	Defines the objects that control the gradient transition. Each GradientEntry object contains the following properties: • `color` Specifies a color value. • `alpha` Specifies the transparency. Valid values are 0 (invisible) through 1 (opaque). The default value is 1. • `ratio` Specifies where in the chart, as a percentage, Flex starts the transition to the next `color`. For example, if you set the `ratio` property to .33, Flex begins the transition 33% of the way through the chart. If you do not set the `ratio` property, Flex tries to evenly apply values based on the `ratio` properties for the other GradientEntry objects. Valid values range from 0 to 1.

The following example uses a LinearGradient class with gradient fills for the chart's background:

```
<?xml version="1.0"?>
<!-- charts/GradientFills.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">

    <fx:Declarations>
        <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
         <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
         <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Gradient Background Fill">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:BarChart id="myChart"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true">
        <mx:verticalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:verticalAxis>
        <mx:fill>
           <mx:LinearGradient>
```

```
            <mx:entries>
                <mx:GradientEntry
                    color="0xC5C551"
                    ratio="0"
                    alpha="1"/>
                <mx:GradientEntry
                    color="0xFEFE24"
                    ratio=".33"
                    alpha="1"/>
                <mx:GradientEntry
                    color="0xECEC21"
                    ratio=".66"
                    alpha="1"/>
            </mx:entries>
           </mx:LinearGradient>
        </mx:fill>
        <mx:series>
           <mx:BarSeries xField="expenses"
                displayName="Expenses"/>
        </mx:series>
     </mx:BarChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

The LinearGradient object takes a single attribute, `angle`. By default, it defines a transition from left to right across the chart. Use the `angle` property to control the direction of the transition. For example, a value of 180 causes the transition to occur from right to left, rather than from left to right.

To add gradient fills to a chart in ActionScript, you define GradientEntry objects, assign values to their properties (such as `ratio` and `color`), and add them as entries to a gradient's entries Array. You then apply the gradient to the chart's fill by using the `setStyle()` method. The following example shows how to do this in ActionScript:

```
<?xml version="1.0"?>
<!-- charts/GradientFillsInActionScript.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">

    <fx:Declarations>
        <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
         <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
         <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
  <fx:Script><![CDATA[
     import mx.graphics.LinearGradient;
     import mx.graphics.GradientEntry;
     import mx.collections.ArrayCollection;

     private function styleChart():void {
          var ge1:GradientEntry = new GradientEntry(0xCCFF99, 0);
          var ge2:GradientEntry = new GradientEntry(0x99FF00, .33);
          var ge3:GradientEntry = new GradientEntry(0x669900, .66);

          var lg1:LinearGradient = new LinearGradient();
          lg1.entries = [ge1, ge2, ge3];

          myChart.setStyle("fill", lg1);
     }
  ]]></fx:Script>

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Gradient Entries in ActionScript Fill">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:BarChart id="myChart"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true"
        creationComplete="styleChart()">
        <mx:verticalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:verticalAxis>
        <mx:series>
           <mx:BarSeries xField="expenses"
                displayName="Expenses"/>
        </mx:series>
     </mx:BarChart>
  </s:Panel>
</s:Application>
```

You can set other properties on gradients, such as `angle`, to change the appearance of chart fills. The following example sets the `angle` property to 90, which specifies that the transition occurs from the top of the chart to the bottom.

```
<?xml version="1.0"?>
<!-- charts/GradientFillsAngled.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
        <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
         <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
         <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Angled Gradient Background Fill">
        <s:layout>
```

```
            <s:VerticalLayout/>
        </s:layout>
     <mx:BarChart id="myChart"
          dataProvider="{srv.lastResult.data.result}"
          showDataTips="true">
        <mx:verticalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:verticalAxis>
        <mx:fill>
           <mx:LinearGradient rotation="90">
            <mx:entries>
                <mx:GradientEntry
                    color="0xC5C551"
                    ratio="0"
                    alpha="1"/>
                <mx:GradientEntry
                    color="0xFEFE24"
                    ratio=".33"
                    alpha="1"/>
                <mx:GradientEntry
                    color="0xECEC21"
                    ratio=".66"
                    alpha="1"/>
            </mx:entries>
           </mx:LinearGradient>
        </mx:fill>
        <mx:series>
           <mx:BarSeries xField="expenses"
                displayName="Expenses"/>
        </mx:series>
     </mx:BarChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

Using different alpha values with fills

When charting multiple data series, you can define the series to overlap. For example, the column chart lets you display the columns next to each other or overlap them for multiple data series. To overlap series, you set the `type` property of the chart to `overlaid`. The same is true for an area series.

When you have multiple data series that overlap, you can specify that the fill for each series has an alpha value less than 100%, so that the series have a level of transparency. The valid values for the `alpha` property are 0 (invisible) through 1 (opaque).

You cannot specify alpha values for fills if you apply the fills using CSS.

The following example defines an area chart in which each series in the chart uses a solid fill with the same level of transparency:

```
<?xml version="1.0"?>
<!-- charts/AlphaFills.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">

    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Area Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:AreaChart id="myChart"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true">
        <mx:horizontalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:AreaSeries
                yField="profit"
                displayName="Profit">
                <mx:areaStroke>
                    <mx:SolidColorStroke
                        color="0x9A9A00"
                        weight="2"/>
                </mx:areaStroke>
                <mx:areaFill>
                    <mx:SolidColor
                        color="0x7EAEFF"
                        alpha=".3"/>
                </mx:areaFill>
           </mx:AreaSeries>
           <mx:AreaSeries
                yField="expenses"
                displayName="Expenses">
                <mx:areaStroke>
                    <mx:SolidColorStroke
                        color="0x9A9A00"
                        weight="2"/>
                </mx:areaStroke>
                <mx:areaFill>
                    <mx:SolidColor
                        color="0xAA0000"
                        alpha=".3"/>
                </mx:areaFill>
           </mx:AreaSeries>
        </mx:series>
     </mx:AreaChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

If you define a gradient fill, you can set the `alpha` property on each entry in the Array of `<mx:GradientEntry>` tags, as the following example shows:

```
<?xml version="1.0"?>
<!-- charts/GradientAlphaFills.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
        <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
         <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
         <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Area Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:AreaChart id="myChart"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true">
        <mx:horizontalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:horizontalAxis>
        <mx:series>
            <mx:AreaSeries yField="profit" displayName="Profit">
                <mx:areaStroke>
                    <mx:SolidColorStroke color="0x9A9A00" weight="2"/>
                </mx:areaStroke>
                <mx:areaFill>
                    <mx:LinearGradient rotation="90">
                        <mx:entries>
                            <mx:GradientEntry
                                color="0xC5C551"
                                ratio="0"
                                alpha="1"/>
                            <mx:GradientEntry
                                color="0xFEFE24"
                                ratio=".33"
                                alpha="1"/>
                            <mx:GradientEntry
                                color="0xECEC21"
                                ratio=".66"
                                alpha=".2"/>
                        </mx:entries>
                    </mx:LinearGradient>
                </mx:areaFill>
           </mx:AreaSeries>
           <mx:AreaSeries
                yField="expenses"
                displayName="Expenses">
                <mx:areaStroke>
                    <mx:SolidColorStroke color="0x9A9A00" weight="2"/>
                </mx:areaStroke>
                <mx:areaFill>
                    <mx:LinearGradient rotation="90">
                        <mx:entries>
                            <mx:GradientEntry
                                color="0xAA0000"
                                ratio="0"
                                alpha="1"/>
                            <mx:GradientEntry
                                color="0xCC0000"
                                ratio=".33"
                                alpha="1"/>
                            <mx:GradientEntry
                                color="0xFF0000"
                                ratio=".66"
                                alpha=".2"/>
                        </mx:entries>
                    </mx:LinearGradient>
                </mx:areaFill>
           </mx:AreaSeries>
        </mx:series>
     </mx:AreaChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

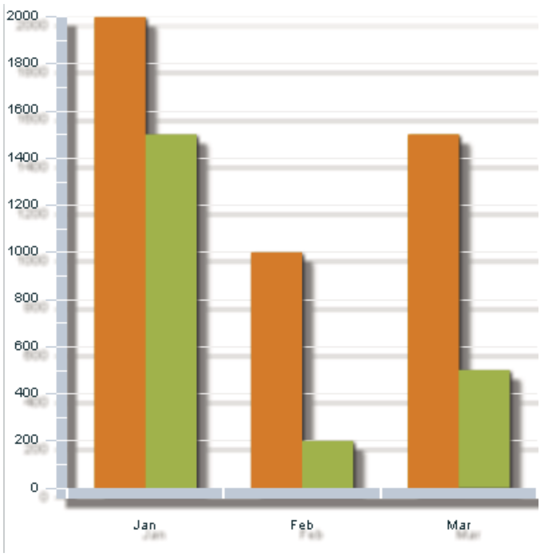
In this example, you make the last gradient color in the series partially transparent by setting its `alpha` property to .2.

Using filters with chart controls

You can add filters such as drop shadows to your chart elements by using the classes in the spark.filters.* package. These filters include:

- BevelFilter
- BitmapFilter
- BlurFilter
- ColorMatrixFilter
- ConvolutionFilter
- DisplacementMapFilter
- DropShadowFilter
- GlowFilter
- GradientBevelFilter
- GradientGlowFilter
- ShaderFilter

You can apply filters to the chart control itself, or to each chart series. When you apply a filter to a chart control, the filter is applied to all aspects of that chart control, including gridlines, axis labels, and each data point in the series. The following image shows a drop shadow filter applied to a ColumnChart control:



You wrap the filter class in an `<mx:filters>` or `<s:filters>` tag to define the array of filters applied to that control. If the control is an MX control, you use the `<mx:filters>` tag. If the control is a Spark control, you use the `<s:filters>` tag. In the case of charting components, you use the `<mx:filters>` tag because the charts are in the MX component set. At compile time, the MX filters are mapped to the Spark filters.

The following example applies a custom drop shadow filter to a ColumnChart control. The result is that every element, including the grid lines, axis labels, and columns, has a background shadow.

```
<?xml version="1.0"?>
<!-- charts/ColumnWithDropShadow.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">

    <fx:Declarations>
        <!-- View source of the following page to see the structure of the data that Flex uses 
in this example. -->
         <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
         <!-- To see data in an HTML table, go to 
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="ColumnChart with drop shadow example">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:ColumnChart id="column" dataProvider="{srv.lastResult.data.result}" 
showDataTips="true">
        <!-- Add a custom drop shadow filter to the ColumnChart control. -->
        <mx:filters>
           <s:DropShadowFilter 
                distance="10" 
                color="0x666666" 
                alpha=".8"/>
        </mx:filters>
        <mx:horizontalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:ColumnSeries 
                xField="month" 
                yField="profit" 
                displayName="Profit"/>
           <mx:ColumnSeries 
                xField="month" 
                yField="expenses" 
                displayName="Expenses"/>
        </mx:series>
     </mx:ColumnChart>
     <mx:Legend dataProvider="{column}"/>
  </s:Panel>
</s:Application>
```

For more information on filters, see “Using filters” on page 1556.

Adding a drop shadow filter to some chart controls can have unexpected consequences. For example, if you add a drop shadow filter to a PieChart control, Flex renders that drop shadow filter in addition to the default drop shadow filter on the PieSeries.

You can remove filters by setting the filters Array to an empty Array, as the following example shows:

```
<?xml version="1.0"?>
<!-- charts/ClearFilters.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    height="600">

  <fx:Script><![CDATA[
      import mx.collections.ArrayCollection;
      [Bindable]
      public var expenses:ArrayCollection = new ArrayCollection([
         {Month:"Jan", Profit:2000, Expenses:1500, Amount:450},
         {Month:"Feb", Profit:1000, Expenses:200, Amount:600},
         {Month:"Mar", Profit:1500, Expenses:500, Amount:300}
      ]);
  ]]></fx:Script>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel id="p1" title="Line chart with no filters">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
      <mx:LineChart id="myChart"
        dataProvider="{expenses}"
        showDataTips="true">

         <!-- Clear the filters array. -->
         <mx:seriesFilters>
            <fx:Array/>
         </mx:seriesFilters>
         <mx:horizontalAxis>
            <mx:CategoryAxis
                dataProvider="{expenses}"
                categoryField="Month"/>
         </mx:horizontalAxis>
         <mx:series>
            <mx:LineSeries
                yField="Profit"
                displayName="Profit"/>
            <mx:LineSeries
                yField="Expenses"
                displayName="Expenses"/>
            <mx:LineSeries
                yField="Amount"
                displayName="Amount"/>
         </mx:series>
      </mx:LineChart>
  </s:Panel>
</s:Application>
```

The following example creates a PieChart control and applies a drop shadow to it; it also removes the default drop shadow filter from the PieSeries so that there is a single drop shadow:

```
<?xml version="1.0"?>
<!-- charts/PieChartShadow.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses 
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/budget-
xml.aspx"/>
        <!-- To see data in an HTML table, go to 
http://aspexamples.adobe.com/chart_examples/budget.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Pie Chart">
     <s:layout>
         <s:VerticalLayout/>
     </s:layout>
     <mx:PieChart id="pie" 
        dataProvider="{srv.lastResult.data.result}" 
        showDataTips="true">
        <!-- Add a custom drop shadow to the PieChart control -->
        <mx:filters>
           <s:DropShadowFilter 
                distance="10" 
                color="0x666666" 
                alpha=".8"/>
        </mx:filters>
        <mx:series>
           <fx:Array>
                <mx:PieSeries field="amount" nameField="item" 
                labelPosition="callout" explodeRadius=".2">
                    <!-- Clear default shadow on the PieSeries -->
                    <mx:filters>
                        <fx:Array/>
                    </mx:filters>
                </mx:PieSeries>
           </fx:Array>
        </mx:series>
     </mx:PieChart>
     <mx:Legend dataProvider="{pie}"/>
  </s:Panel>
</s:Application>
```

You can add filters to individual chart elements that are display objects, such as series, grid lines, legend items, and axes. The following example defines set of filters, and then applies them to various chart elements:

```
<?xml version="1.0"?>
<!-- charts/MultipleFilters.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send();createFilters();"
    height="600">

    <fx:Declarations>
        <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
         <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
         <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
  <fx:Script><![CDATA[
     import spark.filters.*;
     import flash.filters.BitmapFilterType;
     import flash.filters.BitmapFilterQuality;

     private var myBlurFilter:BlurFilter;
     private var myGlowFilter:GlowFilter;
     private var myBevelFilter:BevelFilter;
     private var myDropShadowFilter:DropShadowFilter;
     private var color:Number = 0xFF33FF;
     public function applyFilters():void {
        // Apply filters to series, grid lines, legend, and axis.
        myGridlines.filters = [myBlurFilter];
        myLegend.filters = [myGlowFilter];
        myAxisRenderer.filters = [myBevelFilter];
        s1.filters = [myDropShadowFilter];
        s2.filters = [myDropShadowFilter];
     }
     public function createFilters():void {
        // Define filters.
        myBlurFilter = new BlurFilter(4,4,1);
        myGlowFilter = new GlowFilter(color, .8, 6, 6,
            2, 1, false, false);
        myDropShadowFilter = new DropShadowFilter(15, 45,
            color, 0.8, 8, 8, 0.65, 1, false, false);
        myBevelFilter = new BevelFilter(5, 45, color, 0.8,
            0x333333, 0.8, 5, 5, 1, BitmapFilterQuality.HIGH,
            BitmapFilterType.INNER, false);
        applyFilters();
     }
  ]]></fx:Script>

                id="myAxisRenderer"
                placement="bottom"
                canDropLabels="true"
                axis="{a1}">
                <mx:axisStroke>
                    <mx:SolidColorStroke color="#000080" weight="10"/>
                </mx:axisStroke>
                <mx:tickStroke>
                    <mx:SolidColorStroke color="#000060" weight="5"/>
                </mx:tickStroke>
                <mx:minorTickStroke>
                    <mx:SolidColorStroke color="#100040" weight="5"/>
                </mx:minorTickStroke>
            </mx:AxisRenderer>
        </mx:horizontalAxisRenderers>
        <mx:series>
           <mx:ColumnSeries id="s1"
                xField="month"
                yField="profit"
                displayName="Profit"/>
           <mx:ColumnSeries id="s2"
                xField="month"
                yField="expenses"
                displayName="Expenses"/>
        </mx:series>
     </mx:ColumnChart>
     <mx:Legend id="myLegend" dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

Using chart grid lines

All charts except the PieChart control have grid lines by default. You can control those grid lines with the CSS `gridLinesStyleName` property, and with the chart series' `backgroundElements` and `annotationElements` properties.

You can include horizontal, vertical, or both grid lines in your chart with the GridLines object. You can set these behind the data series by using the chart's `backgroundElements` property or in front of the data series by using the `annotationElements` property.

The following example turns on grid lines in both directions and applies them to the chart:

```
<?xml version="1.0"?>
<!-- charts/GridLinesBoth.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
        <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
         <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
         <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
        <fx:Array id="bge">
            <mx:GridLines gridDirection="both"/>
        </fx:Array>
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Column Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:ColumnChart id="myChart"
        showDataTips="true"
        dataProvider="{srv.lastResult.data.result}"
        backgroundElements="{bge}">
        <mx:horizontalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:ColumnSeries
                xField="month"
                yField="profit"
                displayName="Profit"/>
           <mx:ColumnSeries
                xField="month"
                yField="expenses"
                displayName="Expenses"/>
        </mx:series>
     </mx:ColumnChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

Note: *The* `annotationElements` *property refers to any chart elements that appear in the foreground of your chart, and the* `backgroundElements` *property refers to any chart elements that appear behind the chart's data series.*

You can also define the grid lines inside each chart control's definition, as the following example shows:

```
<?xml version="1.0"?>
<!-- charts/GridLinesBothInternal.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">

    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Column Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:ColumnChart id="myChart"
            dataProvider="{srv.lastResult.data.result}"
            showDataTips="true">
        <mx:backgroundElements>
           <mx:GridLines gridDirection="both"/>
        </mx:backgroundElements>
        <mx:horizontalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:ColumnSeries
                xField="month"
                yField="profit"
                displayName="Profit"/>
           <mx:ColumnSeries
                xField="month"
                yField="expenses"
                displayName="Expenses"/>
        </mx:series>
     </mx:ColumnChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

To define the fills and strokes for grid lines, you use the `horizontalStroke`, `verticalStroke`, `horizontalFill`, and `verticalFill` properties. The following properties also define the appearance of grid lines:

- `horizontalAlternateFill`
- `horizontalChangeCount`
- `horizontalOriginCount`
- `horizontalShowOrigin`

- `horiztontalTickAligned`
- `verticalAlternateFill`
- `verticalChangeCount`
- `verticalOriginCount`
- `verticalShowOrigin`
- `verticalTickAligned`

For information on working with strokes, see “Using strokes with chart controls” on page 1192. For more information on using the `backgroundElements` and `annotationElements` properties, see “Using ChartElement objects” on page 1179.

You can manipulate the appearance of the grid lines directly in MXML, with ActionScript, or with CSS. The following sections describe techniques for formatting grid lines for chart objects.

Formatting chart grid lines with MXML

To control the appearance of the grid lines, you can specify an array of GridLines objects as MXML tags, as the following example shows:

```
<?xml version="1.0"?>
<!-- charts/GridLinesFormatMXML.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
        <fx:Array id="bge">
            <mx:GridLines
                horizontalChangeCount="1"
                verticalChangeCount="1"
                gridDirection="both"
            >
                <mx:horizontalStroke>
                    <mx:SolidColorStroke weight="3"/>
                </mx:horizontalStroke>
                <mx:verticalStroke>
                    <mx:SolidColorStroke weight="3"/>
                </mx:verticalStroke>
                <mx:horizontalFill>
                    <mx:SolidColor color="0x99033" alpha=".66"/>
                </mx:horizontalFill>
            </mx:GridLines>
        </fx:Array>
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
```

```
  <s:Panel title="Column Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:ColumnChart id="myChart"
        showDataTips="true"
        dataProvider="{srv.lastResult.data.result}"
        backgroundElements="{bge}">
        <mx:horizontalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:ColumnSeries
                xField="month"
                yField="profit"
                displayName="Profit"/>
           <mx:ColumnSeries
                xField="month"
                yField="expenses"
                displayName="Expenses"/>
        </mx:series>
     </mx:ColumnChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

This example uses the `changeCount` property to specify that Flex draws grid lines at every tick mark along the axis, and sets the `gridDirection` property to `both`. This causes Flex to draw grid lines both horizontally and vertically. You could also specify `horizontal` or `vertical` as values for the `gridDirection` property.

To remove grid lines entirely, you can set the `backgroundElements` property to an empty Array, as the following example shows:

```
<?xml version="1.0"?>
<!-- charts/NoGridLines.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses 
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to 
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
        <fx:Array id="bge">
        </fx:Array>
    </fx:Declarations>

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="BubbleChart control with no grid lines">
     <s:layout>
         <s:VerticalLayout/>
     </s:layout>
    <mx:BubbleChart id="bc"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true"
        backgroundElements="{bge}">
        <mx:series>
            <mx:BubbleSeries
                xField="profit"
                yField="expenses"
                radiusField="amount"
                displayName="Profit"/>
        </mx:series>
    </mx:BubbleChart>
    <mx:Legend dataProvider="{bc}"/>
  </s:Panel>
</s:Application>
```

You can also change the appearance of grid lines by using filters such as a drop shadow, glow, or bevel. For more information, see "Using filters with chart controls" on page 1213.

Formatting chart grid lines with CSS

You can set the style of grid lines by applying a CSS style to the GridLines object. The following example applies the `myStyle` style to the grid lines:

```
<?xml version="1.0"?>
<!-- charts/GridLinesFormatCSS.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses 
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to 
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->

        <!-- Background element array. -->
        <fx:Array id="bge">
            <mx:GridLines styleName="myStyle">
                <mx:horizontalStroke>
                    <mx:SolidColorStroke weight="3"/>
                </mx:horizontalStroke>
                <mx:verticalStroke>
                    <mx:SolidColorStroke weight="3"/>
                </mx:verticalStroke>
            </mx:GridLines>
        </fx:Array>
    </fx:Declarations>
```

```
  <fx:Style>
     .myStyle {
        gridDirection:"both";
        horizontalShowOrigin:true;
        horizontalTickAligned:false;
        horizontalChangeCount:1;
        verticalShowOrigin:false;
        verticalTickAligned:true;
        verticalChangeCount:1;
        horizontalFill:#990033;
        horizontalAlternateFill:#00CCFF;
     }
  </fx:Style>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Column Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:ColumnChart id="myChart"
        showDataTips="true"
        dataProvider="{srv.lastResult.data.result}"
        backgroundElements="{bge}">
        <mx:horizontalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:ColumnSeries
                xField="month"
                yField="profit"
                displayName="Profit"/>
           <mx:ColumnSeries
                xField="month"
                yField="expenses"
                displayName="Expenses"/>
        </mx:series>
     </mx:ColumnChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

Formatting chart grid lines with ActionScript

You can manipulate the GridLines at run time with ActionScript. The following example adds filled grid lines in front of and behind the chart's series:

```
<?xml version="1.0"?>
<!-- charts/GridLinesFormatActionScript.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
  <fx:Script><![CDATA[
     import mx.graphics.SolidColor;
     import mx.graphics.SolidColorStroke;
     import mx.charts.GridLines;
     [Bindable]
     public var bge:GridLines;
     public function addGridLines():void {
        bge = new GridLines();
        var s:SolidColorStroke = new SolidColorStroke(0xff00ff, 2);
        bge.setStyle("horizontalStroke", s);
        var f:SolidColor = new SolidColor(0x990033, .3);
        bge.setStyle("horizontalFill",f);
        var f2:SolidColor = new SolidColor(0x336699, .3);
        bge.setStyle("horizontalAlternateFill",f2);
        myChart.backgroundElements = [bge];
     }
  ]]></fx:Script>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Column Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:ColumnChart id="myChart"
```

```
        showDataTips="true"
        dataProvider="{srv.lastResult.data.result}"
        creationComplete="addGridLines()">
        <mx:horizontalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:ColumnSeries
                xField="month"
                yField="profit"
                displayName="Profit"/>
           <mx:ColumnSeries
                xField="month"
                yField="expenses"
                displayName="Expenses"/>
        </mx:series>
     </mx:ColumnChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

Positioning chart axes

You can place axes on the left, right, top, or bottom of the chart control. This includes the axis line as well as labels and any tick marks you added. You can place horizontal axes at the top or bottom of the chart (or both, if you have multiple vertical axes). You can place vertical axes at the left or right of the chart (or both, if you have multiple horizontal axes).

To change the location of axes, you use the `placement` property of the AxisRenderer. Valid values for this property for a vertical axis are `top` and `bottom`. Valid values for this property for a horizontal axis are `left` and `right`.

The following example creates a ColumnChart control with the default axis locations (bottom and left). You can select new locations by using the ComboBox controls at the bottom of the panel.

```
<?xml version="1.0"?>
<!-- charts/AxisPlacementExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"

    </s:Form>

  </s:Panel>
</s:Application>
```

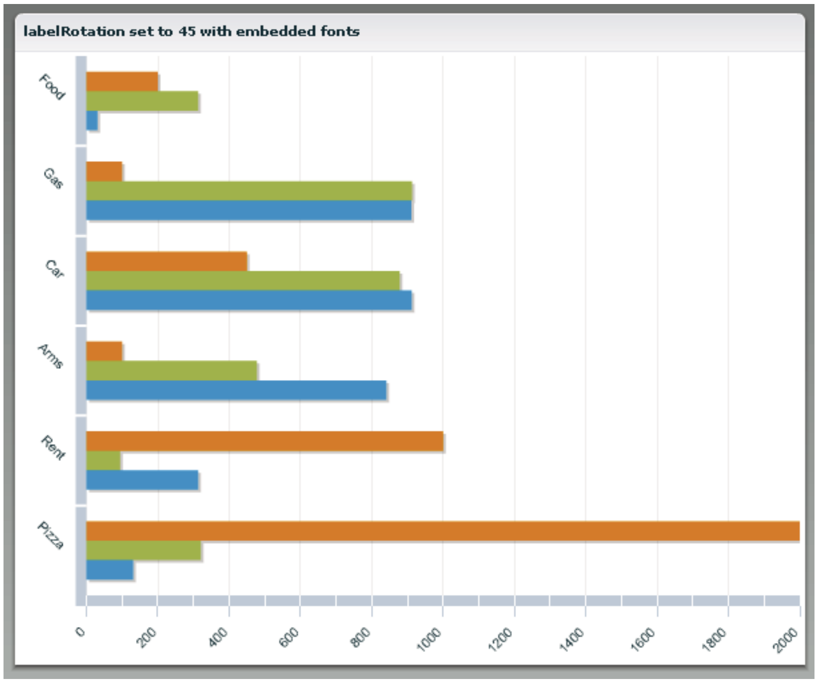
Formatting axis labels with the AxisRenderer class

The appearance of chart axis labels is defined by the AxisRenderer class.

Rotating chart axis labels

You can rotate axis labels by using the `labelRotation` property of the AxisRenderer object. You specify a number from -90 to 90, in degrees. If you set the `labelRotation` property to `null`, Flex determines an optimal angle and renders the axis labels.

The following example shows both sets of axis labels rotated 45 degrees:



To rotate axis labels, you must embed the font in the Flex application. If you rotate the the axis labels without embedding a font, they are rendered horizontally. You must also be sure to set the `embedAsCFF` CSS property to `false` because chart controls are MX controls and do not use the Spark text rendering engine. The default value of this property is `true`.

The following `<fx:Style>` block embeds a font in the Flex application, and then applies that font to the chart control that rotates its horizontal and vertical axis labels 45 degrees:

```
<?xml version="1.0"?>
<!-- charts/RotateAxisLabels.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
  <fx:Style>
     @namespace mx "library://ns.adobe.com/flex/mx";
     @font-face{
        src: url("../assets/MyriadWebPro.ttf");
        fontFamily: myMyriad;
        embedAsCFF: false;
     }
     mx|ColumnChart {
        fontFamily: myMyriad;
        fontSize: 20;
     }
  </fx:Style>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Rotated Axis Labels">
     <s:layout>
         <s:VerticalLayout/>
     </s:layout>
     <mx:ColumnChart id="column"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true">
        <mx:horizontalAxis>
           <mx:CategoryAxis id="a1"
                categoryField="month"
                title="FY 2010"/>
        </mx:horizontalAxis>
        <mx:verticalAxis>
```

```
            <mx:LinearAxis id="a2"/>
         </mx:verticalAxis>
         <mx:horizontalAxisRenderers>
            <mx:AxisRenderer labelRotation="-90" axis="{a1}"/>
         </mx:horizontalAxisRenderers>
         <mx:verticalAxisRenderers>
            <mx:AxisRenderer labelRotation="45" axis="{a2}"/>
         </mx:verticalAxisRenderers>
         <mx:series>
            <mx:ColumnSeries displayName="Profit"
                 xField="month"
                 yField="profit"/>
            <mx:ColumnSeries displayName="Expenses"
                 xField="month"
                 yField="expenses"/>
         </mx:series>
      </mx:ColumnChart>
      <mx:Legend dataProvider="{column}"/>
   </s:Panel>
</s:Application>
```

Using a custom AxisRenderer object

To change the appearance of the axis labels, you can use the `labelRenderer` property of the AxisRenderer class. This lets you specify a class that defines the appearance of the label. The class must extend UIComponent and implement the IDataRenderer and IFlexDisplayObject interfaces. Its `data` property will be the label used in the chart. Typically, you write an ActionScript class that extends the ChartLabel class for the label renderer.

The following example defines a custom component inline by using the `<fx:Component>` tag. It adds ToolTip objects to the labels along the chart's horizontal axis so that the values of the longer labels are not truncated.

```
<?xml version="1.0"?>
<!-- charts/LabelRendererWithToolTips.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    initialize="setupDP()"
    width="550" height="600">

    <fx:Script>
     <![CDATA[
        import mx.collections.ArrayCollection;
        import mx.charts.ColumnChart;

        [Bindable]
        private var ac:ArrayCollection;

        public function setupDP():void{
            ac =  new ArrayCollection([
              [ "Label 1 is short.", 200000],
              [ "Label 2 is a fairly long label.", 150000],
              [ "Label 3 is an extremely long label. It contains 95 characters " +
                "and will likely be truncated.", 40000]
            ]);
        }
     ]]>
    </fx:Script>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:Panel title="Column Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <mx:ColumnChart id="bc1"
            showDataTips="true"
            dataProvider="{ac}">
            <mx:series>
                <mx:ColumnSeries xField="0" yField="1"/>
            </mx:series>
            <mx:verticalAxis>
                <mx:LinearAxis id="va1"/>
            </mx:verticalAxis>
            <mx:horizontalAxis >
                <mx:CategoryAxis id="ha1"
                    dataProvider="{ac}"
                    categoryField="0"/>
            </mx:horizontalAxis>
            <mx:horizontalAxisRenderers>
                <mx:AxisRenderer axis="{ha1}" canDropLabels="false">
                    <mx:labelRenderer>
                        <fx:Component>
                            <mx:Label toolTip="{this.myTip}">
                                <fx:Script><![CDATA[
                                    [Bindable]
                                    private var myTip:String;
                                    override public function set data(value:Object):void{
                                        if(value == null)
                                            return;
                                        myTip = value.text;
                                        var length:int = value.text.toString().length;
                                        if (length > 20) {
                                          text = value.text.toString().substr(0, 20) + "...";
                                        } else {
                                            text = value.text;
                                        }
                                    }
                                ]]></fx:Script>
                            </mx:Label>
                        </fx:Component>
                    </mx:labelRenderer>
                </mx:AxisRenderer>
            </mx:horizontalAxisRenderers>
            <mx:verticalAxisRenderers>
                <mx:AxisRenderer axis="{va1}" canDropLabels="false"/>
            </mx:verticalAxisRenderers>
        </mx:ColumnChart>
        <s:Label id="l1"
            color="white"
           text="Hover over the horizontal axis's labels to see the entire title rendered as
a ToolTip."/>
    </s:Panel>
</s:Application>
```

For an example of an ActionScript class that extends ChartLabel, see "Adding axis titles" on page 1262.

Skinning ChartItem objects

A ChartItem object represents a data point in a series. There is one ChartItem instance for each item in the series' data provider. ChartItem objects contain details about the data for the data point as well as the renderer (or *skin*) to use when rendering that data point in the series. The ChartItem renderers define objects such as the icon that represents a data point in a PlotChart control or the box that makes up a bar in a BarChart control.

Each series has a default renderer that Flex uses to draw that series' ChartItem objects. You can specify a new renderer to use with the series' `itemRenderer` style property. This property points to a class that defines the appearance of the ChartItem object.

The following table lists the available renderer classes for the ChartItem objects of each chart type:

Chart type	Available renderer classes
AreaChart	AreaRenderer
BarChart BubbleChart ColumnChart PlotChart	BoxItemRenderer CircleItemRenderer CrossItemRenderer DiamondItemRenderer ShadowBoxItemRenderer TriangleItemRenderer
CandlestickChart HLOCChart	CandlestickItemRenderer HLOCItemRenderer
LineChart	LineRenderer ShadowLineRenderer
PieChart	WedgeItemRenderer

The appearance of most renderers is self-explanatory. The BoxItemRenderer class draws ChartItem objects in the shape of boxes. The DiamondItemRenderer class draws ChartItem objects in the shape of diamonds. The ShadowBoxItemRenderer and ShadowLineRenderer classes add shadows to the ChartItem objects that they draw.

You can use existing classes to change the default renderers of chart items. The DiamondItemRenderer class is the default renderer for ChartItem objects in a data series in a PlotChart control. The following example uses the default DiamondItemRenderer class for the first data series. The second series uses the CircleItemRenderer class, which draws a circle to represent the data points in that series. The third series uses the CrossItemRenderer class, which draws a cross shape to represent the data points in that series.

```
<?xml version="1.0"?>
<!-- charts/PlotRenderers.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"

    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Plot Chart">
     <s:layout>
         <s:VerticalLayout/>
     </s:layout>
     <mx:PlotChart id="myChart"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true">
        <mx:series>
           <!-- First series uses default renderer. -->
           <mx:PlotSeries
                xField="expenses"
                yField="profit"
                displayName="Plot 1"/>
           <!-- Second series uses CircleItemRenderer. -->
           <mx:PlotSeries
                xField="amount"
                yField="expenses"
                displayName="Plot 2"
                itemRenderer="mx.charts.renderers.CircleItemRenderer"/>
           <!-- Third series uses CrossItemRenderer. -->
           <mx:PlotSeries
                xField="profit"
                yField="amount"
                displayName="Plot 3"
                itemRenderer="mx.charts.renderers.CrossItemRenderer"/>
        </mx:series>
     </mx:PlotChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

To apply a renderer to a series in ActionScript, you use the `setStyle()` method. In that method, you create a new ClassFactory and pass the renderer to its constructor. Flex generates an instance of this class to be the renderer. Be sure to import the appropriate classes when using renderer classes.

The following example sets the renderer for the second series to the CircleItemRenderer and the renderer for the third series to the CrossItemRenderer in ActionScript.

```
<?xml version="1.0"?>
<!-- charts/PlotRenderersAS.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"

    creationComplete="srv.send();initSeriesStyles();"
    height="600">
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
  <fx:Script><![CDATA[
     import mx.charts.renderers.*;
    private function initSeriesStyles():void {
        // Second series uses CircleItemRenderer.
        series2.setStyle("itemRenderer", new
ClassFactory(mx.charts.renderers.CircleItemRenderer));
        // Third series uses CrossItemRenderer.
        series3.setStyle("itemRenderer", new
ClassFactory(mx.charts.renderers.CrossItemRenderer));
    }
  ]]></fx:Script>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Plot Chart">
     <s:layout>
         <s:VerticalLayout/>
     </s:layout>
     <mx:PlotChart id="myChart"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true">
        <mx:series>
```

```
                <mx:PlotSeries
                     id="series1"
                     xField="expenses"
                     yField="profit"
                     displayName="Plot 1"/>
                <mx:PlotSeries
                     id="series2"
                     xField="amount"
                     yField="expenses"
                     displayName="Plot 2"/>
                <mx:PlotSeries
                     id="series3"
                     xField="profit"
                     yField="amount"
                     displayName="Plot 3"/>
             </mx:series>
          </mx:PlotChart>
          <mx:Legend dataProvider="{myChart}"/>
     </s:Panel>
</s:Application>
```

Using multiple renderer classes

You can sometimes choose from more than one renderer for a chart series, depending on the series. These renderers let you change the appearance of your charts by adding shadows or graphics to the chart items.

Some series types require multiple renderers to completely render their data. For example, a LineSeries object has both an `itemRenderer` style property and a `lineSegmentRenderer` style property. The `itemRenderer` property specifies the renderer for the data items. The `lineSegmentRenderer` specifies the appearance of the line segments between items.

The other series type that requires two renderers is the AreaSeries. The `areaRenderer` property specifies the appearance of the area, and the `itemRenderer` specifies the appearance of the data items.

You can also specify the renderer to use for legends. The default is the class that the series' `itemRenderer` property specifies. For more information, see "Formatting Legend controls" on page 1241.

You can use multiple types of data series in a single chart. For example, you can use a ColumnSeries and a LineSeries to show something like a moving average over a stock price. In this case, you can use all the renderers supported by those series in the same chart. For more information on using multiple series, see "Using multiple data series" on page 1163.

Creating custom renderers

You can replace the `itemRenderer` property of a chart series with a custom renderer. You define the renderer on the `itemRenderer` style property for the chart series. This renderer can be a graphical renderer or a class that programmatically defines the renderer.

Creating graphical renderers

You can use a graphic file such as a GIF or JPEG to be used as a renderer on the chart series. You do this by setting the value of the `itemRenderer` style property to be an embedded image. This method of graphically rendering chart items is similar to the graphical skimming method used for other components, as described in "Creating graphical skins for MX components" on page 1671.

The following example uses the graphic file to represent data points on a PlotChart control:

```
<?xml version="1.0"?>
<!-- charts/CustomPlotRenderer.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
        <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
         <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
         <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Plot Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:PlotChart id="myChart"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true">
        <mx:series>
           <!-- First series uses embedded image for renderer. -->
           <mx:PlotSeries
                xField="expenses"
                yField="profit"
                displayName="Plot 1"
                itemRenderer="@Embed(source='../assets/butterfly.gif')"
                radius="20"
                legendMarkerRenderer="@Embed(source='../assets/butterfly.gif')"/>
           <!-- Second series uses CircleItemRenderer. -->
           <mx:PlotSeries
                xField="amount"
                yField="expenses"
                displayName="Plot 2"
                itemRenderer="mx.charts.renderers.CircleItemRenderer"/>
           <!-- Third series uses CrossItemRenderer. -->
           <mx:PlotSeries
                xField="profit"
                yField="amount"
                displayName="Plot 3"
                itemRenderer="mx.charts.renderers.CrossItemRenderer"/>
        </mx:series>
     </mx:PlotChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

This example uses the butterfly.gif graphic to represent each data point on the plot chart. It controls the size of the embedded image by using the `radius` style property.

You are not required to set the value of the `itemRenderer` property inline. You can also embed a graphic file in ActionScript as a Class, pass it to the ClassFactory class's constructor, and then reference it inline, as the following example shows:

```
<?xml version="1.0"?>
<!-- charts/CustomPlotRendererAS.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
        <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
         <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
         <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
  <fx:Script><![CDATA[
     import mx.core.BitmapAsset;

     [Bindable]
     [Embed(source="../assets/butterfly.gif")]
     public var myButterfly:Class;
     [Bindable]
     public var myButterflyFactory:ClassFactory = new ClassFactory(myButterfly);
  ]]></fx:Script>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Plot Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:PlotChart id="myChart"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true">
        <mx:series>
           <!-- First series uses custom class renderer. -->
           <mx:PlotSeries
                id="series1"
                xField="expenses"
                yField="profit"
                displayName="Plot 1"
                itemRenderer="{myButterflyFactory}"
                legendMarkerRenderer="{myButterflyFactory}"
                radius="20"/>
           <!-- Second series uses CircleItemRenderer. -->
           <mx:PlotSeries
                id="series2"
                xField="amount"
                yField="expenses"
                displayName="Plot 2"
                itemRenderer="mx.charts.renderers.CircleItemRenderer"/>
           <!-- Third series uses CrossItemRenderer. -->
           <mx:PlotSeries
                id="series3"
                xField="profit"
                yField="amount"
                displayName="Plot 3"
                itemRenderer="mx.charts.renderers.CrossItemRenderer"/>
        </mx:series>
     </mx:PlotChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

You can also use the `setStyle()` method to apply the custom class to the item renderer. The following example sets the `itemRenderer` and `legendMarkerRenderer` style properties to the embedded image:

```
<?xml version="1.0"?>
<!-- charts/CustomPlotRendererStyles.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send();setStylesInit();"
    height="600">
    <fx:Declarations>
        <!-- View source of the following page to see the structure of the data that Flex uses 
in this example. -->
         <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
         <!-- To see data in an HTML table, go to 
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
  <fx:Script><![CDATA[
     import mx.core.BitmapAsset;

     [Bindable]
     [Embed(source="../assets/butterfly.gif")]
     public var myButterfly:Class;
    private function setStylesInit():void {
        series1.setStyle("itemRenderer", new ClassFactory(myButterfly));
        series1.setStyle("legendMarkerRenderer", new ClassFactory(myButterfly));
    }
  ]]></fx:Script>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Plot Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:PlotChart id="myChart"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true">
        <mx:series>
           <!-- First series uses custom class renderer. -->
           <mx:PlotSeries
                id="series1"
                xField="expenses"
                yField="profit"
                displayName="Plot 1"
                radius="20"/>
           <!-- Second series uses CircleItemRenderer. -->
           <mx:PlotSeries
                id="series2"
                xField="amount"
                yField="expenses"
                displayName="Plot 2"
                itemRenderer="mx.charts.renderers.CircleItemRenderer"/>
           <!-- Third series uses CrossItemRenderer. -->
           <mx:PlotSeries
                id="series3"
                xField="profit"
                yField="amount"
                displayName="Plot 3"
                itemRenderer="mx.charts.renderers.CrossItemRenderer"/>
        </mx:series>
     </mx:PlotChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

Creating programmatic renderers

Creating a custom renderer class for your chart items can give you more control than creating simple graphical renderers. Using class-based renderers is very similar to using programmatic skins, as described in "Creating programmatic skins for MX components" on page 1674.

One approach to is to extend the ProgrammaticSkin class and implement the IDataRenderer interface. In this approach, you can provide all of the logic for drawing chart items in your custom class, and maintain the greatest control over its appearance. For example, you use methods in the Graphics class to draw and fill the rectangles of the bars in a BarChart control.

When you implement the IDataRenderer interface, you must define a setter and getter method to implement the `data` property. This `data` property is of the type of the series item. In the case of a ColumnSeries, it is a ColumnSeriesItem. Other item types include BarSeriesItem, BubbleSeriesItem, LineSeriesItem, and PlotSeriesItem.

In your class, you override the updateDisplayList() method with the logic for drawing the chart item as well as setting any custom properties. You should also call the `super.updateDisplayList()` method.

The following example renders the chart items and uses an Array of colors to color each column in the ColumnChart control differently:

```
// charts/CycleColorRenderer.as
package { // Empty package.

  import mx.charts.series.items.ColumnSeriesItem;
  import mx.skins.ProgrammaticSkin;
  import mx.core.IDataRenderer;
  import flash.display.Graphics;

  public class CycleColorRenderer extends mx.skins.ProgrammaticSkin
     implements IDataRenderer {

     private var colors:Array = [0xCCCC99,0x999933,0x999966];
     private var _chartItem:ColumnSeriesItem;

     public function CycleColorRenderer() {
        // Empty constructor.
     }

     public function get data():Object {
        return _chartItem;
     }
     public function set data(value:Object):void {
        _chartItem = value as ColumnSeriesItem;
        invalidateDisplayList();
     }
     override protected function
        updateDisplayList(unscaledWidth:Number,unscaledHeight:Number):void {
           super.updateDisplayList(unscaledWidth, unscaledHeight);
           var g:Graphics = graphics;
           g.clear();
           g.beginFill(colors[(_chartItem == null)? 0:_chartItem.index]);
           g.drawRect(0, 0, unscaledWidth, unscaledHeight);
           g.endFill();
     }
  } // Close class.
} // Close package.
```

In your Flex application, you use this class as the renderer by using the `itemRenderer` property of the ColumnSeries, as the following example shows:

```
<?xml version="1.0"?>
<!-- charts/ProgrammaticRenderer.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="ColumnChart control with a programmatic ItemRenderer">
     <s:layout>
         <s:VerticalLayout/>
     </s:layout>
     <mx:ColumnChart id="myChart"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true">
        <mx:horizontalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:horizontalAxis>
        <mx:series>
           <fx:Array>
            <mx:ColumnSeries
                xField="month"
                yField="expenses"
                displayName="Expenses"
                itemRenderer="CycleColorRenderer"/>
           </fx:Array>
        </mx:series>
     </mx:ColumnChart>
  </s:Panel>
</s:Application>
```

For more information on overriding the `updateDisplayList()` method, see “Implementing the updateDisplayList() method” on page 1677.

Formatting Legend controls

The Legend control is a subclass of UIComponent. You can use all the standard style properties to format the Legend control. Also, the Legend control has properties (such as `labelPlacement`, `markerHeight`, and `markerWidth)` that you can use to format its appearance. For information on creating Legend controls, see “Using Legend controls” on page 1316.

The following example sets styles by using CSS on the Legend control:

```
<?xml version="1.0"?>
<!-- charts/FormattedLegend.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
  <fx:Style>
    @namespace mx "library://ns.adobe.com/flex/mx";
     mx|Legend {
        labelPlacement:left;
        markerHeight:30;
        markerWidth:30;
     }
  </fx:Style>
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Bar Chart with Legend">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:BarChart id="myChart"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true">
        <mx:verticalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:verticalAxis>
        <mx:series>
           <mx:BarSeries
                yField="month"
                xField="profit"
                displayName="Profit"/>
           <mx:BarSeries
                yField="month"
                xField="expenses"
                displayName="Expenses"/>
        </mx:series>
     </mx:BarChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

You can also change the appearance of the lines on the LegendItem object’s marker. You do this with the `stroke` property or the `legendMarkerRenderer` property. For more information, see “Using strokes with chart controls” on page 1192.

You can place a Legend control anywhere in your application, as long as the control has access to the scope of the chart's data. You can place the Legend control in your application without a container, inside the same container as the chart, or in its own container, such as a Panel container. The latter technique gives the Legend control a border and title bar, and lets you use the `title` attribute of the Panel to create a title for the Legend control, as the following example shows:

```
<?xml version="1.0"?>
<!-- charts/LegendInPanel.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses 
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to 
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Bar Chart with Legend in Panel">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:BarChart id="myChart" 
        dataProvider="{srv.lastResult.data.result}" 
        showDataTips="true">
        <mx:verticalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:verticalAxis>
        <mx:series>
           <mx:BarSeries 
                xField="amount" 
                displayName="Amount (in $USD)"/>
           <mx:BarSeries 
                xField="expenses" 
                displayName="Expenses (in $USD)"/>
           <mx:BarSeries 
                xField="profit" 
                displayName="Profit (in $USD)"/>
        </mx:series>
     </mx:BarChart>
     <s:Panel title="Legend">
        <mx:Legend dataProvider="{myChart}"/>
     </s:Panel>
  </s:Panel>
</s:Application>
```

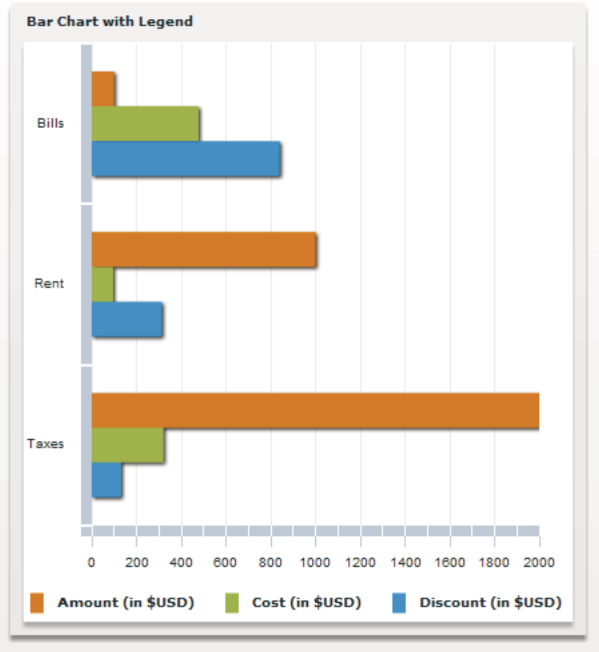
Setting the direction of legends

The `direction` property is a commonly used property to set on the Legend Control. This property of the `<mx:Legend>` tag causes the LegendItem objects to line up horizontally or vertically. The default value of `direction` is `vertical`; when you use this value, Flex stacks the LegendItem objects one on top of the other.

The following example sets the `direction` property to `horizontal`:

```
<?xml version="1.0"?>
<!-- charts/HorizontalLegend.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses 
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to 
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Bar Chart with Legend">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:BarChart id="myChart" 
        dataProvider="{srv.lastResult.data.result}" 
        showDataTips="true">
        <mx:verticalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:verticalAxis>
        <mx:series>
           <mx:BarSeries 
                xField="amount" 
                displayName="Amount (in $USD)"/>
           <mx:BarSeries 
                xField="expenses" 
                displayName="Expenses (in $USD)"/>
           <mx:BarSeries 
                xField="profit" 
                displayName="Profit (in $USD)"/>
        </mx:series>
     </mx:BarChart>
     <mx:Legend dataProvider="{myChart}" direction="horizontal"/>
  </s:Panel>
</s:Application>
```

The following example shows the Legend with the `direction` property set to `horizontal`:



Formatting the legend markers

You can define the appearance of the legend markers by using a programmatic renderer class. Flex includes several default renderer classes that you can use for legend markers.

You can change the renderer of the LegendItem object from the default to one of the ChartItem renderers by using the series' `legendMarkerRenderer` style property. This property specifies the class to use when rendering the marker in all associated legends.

The following example overrides the default renderers and sets the legend markers of all three series to the DiamondItemRenderer class:

```
<?xml version="1.0"?>
<!-- charts/CustomLegendRenderer.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">

    <fx:Declarations>
        <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
         <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
         <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
```

```
  <s:Panel title="Plot Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:PlotChart id="myChart"
          dataProvider="{srv.lastResult.data.result}"
          showDataTips="true">
        <mx:series>
           <!--
                Each series uses the default renderer for
                the ChartItems, but uses the DiamondItemRenderer
                for legend markers.
           -->
           <mx:PlotSeries
                xField="expenses"
                yField="profit"
                displayName="Plot 1"
                legendMarkerRenderer=
                "mx.charts.renderers.DiamondItemRenderer"/>
           <mx:PlotSeries
                xField="amount"
                yField="expenses"
                displayName="Plot 2"
                legendMarkerRenderer=
                "mx.charts.renderers.DiamondItemRenderer"/>
           <mx:PlotSeries
                xField="profit"
                yField="amount"
                displayName="Plot 3"
                legendMarkerRenderer=
                "mx.charts.renderers.DiamondItemRenderer"/>
        </mx:series>
     </mx:PlotChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

If you do not explicitly set the `legendMarkerRenderer` property, the property uses the default class that the series' `itemRenderer` style property specifies. Each series has a default renderer that is used if neither of these style properties is specified.

You can create your own custom legend marker class. Classes used as legend marker renderers must implement the IFlexDisplayObject interface and, optionally, the ISimpleStyleClient and IDataRenderer interfaces.

For more information on available renderer classes, see "Skinning ChartItem objects" on page 1232.

Displaying data and labels in charts

Adobe® Flex® provides some techniques for displaying data and labels in your charts.

Working with axes

Each chart, except for a pie chart, has horizontal and vertical axes. There are two axis types: category and numeric. A *category axis* typically defines strings that represent groupings of items in the chart; for example, types of expenses (such as rent, utilities, and insurance) or names of employees. A *numeric axis* typically defines continuous data such as the amount of an expense or the productivity gains of the employee. These data define the height of a column, for example. Numeric axes include the LinearAxis, LogAxis, and DateTimeAxis.

You work with the axes objects to define their appearance, but also to define what data is displayed in the chart.

The following sections describe the CategoryAxis and NumericAxis classes.

About the CategoryAxis class

The CategoryAxis class maps discrete categorical data (such as states, product names, or department names) to an axis and spaces them evenly along it. This axis accepts any data type that can be represented by a String.

The `dataProvider` property of the CategoryAxis object defines the data provider that contains the text for the labels. In most cases, this can be the same data provider as the chart's data provider. A CategoryAxis object used in a chart inherits its `dataProvider` property from the containing chart, so you are not required to explicitly set the `dataProvider` property on a CategoryAxis object.

The `dataProvider` property of a CategoryAxis object can contain an Array of labels or an Array of objects. If the data provider contains objects, you use the `categoryField` property to point to the field in the data provider that contains the labels for the axis, as the following example shows:

```
<?xml version="1.0"?>
<!-- charts/BasicColumn.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">

    <fx:Declarations>
        <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
         <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
         <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Column Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:ColumnChart id="myChart" dataProvider="{srv.lastResult.data.result}"
showDataTips="true">
        <mx:horizontalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:ColumnSeries
                xField="month"
                yField="profit"
                displayName="Profit"/>
           <mx:ColumnSeries
                xField="month"
                yField="expenses"
                displayName="Expenses"/>
        </mx:series>
     </mx:ColumnChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

If the data provider contains an Array of labels only, you do not specify the `categoryField` property.

You can customize the labels of the CategoryAxis object rather than use the axis labels in the data provider. You do this by providing a custom data provider. To provide a custom data provider, set the value of the CategoryAxis object's `dataProvider` property to a custom Array of labels, as the following example shows:

```
<?xml version="1.0"?>
<!-- charts/CategoryAxisLabels.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">

    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
  <fx:Script><![CDATA[
     [Bindable]
     public var months:Array = [
        {Month:"January", monthAbbrev:"Jan"},
        {Month:"February", monthAbbrev:"Feb"},
        {Month:"March", monthAbbrev:"Mar"}
     ];
  ]]></fx:Script>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Line Chart">
        <s:layout>
```

```
            <s:VerticalLayout/>
        </s:layout>
     <mx:AreaChart id="myChart"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true">
        <mx:horizontalAxis>
           <mx:CategoryAxis
                dataProvider="{months}"
                categoryField="Month"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:AreaSeries
                yField="profit"
                displayName="Profit"/>
           <mx:AreaSeries
                yField="expenses"
                displayName="Expenses"/>
        </mx:series>
     </mx:AreaChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

For more information about chart data providers, see “Defining chart data” on page 1090.

You can also customize the labels using the `labelFunction` property of the CategoryAxis and NumericAxis classes. This property points to a callback function that refines the labels based on the existing data provider. For more information, see “Defining axis labels” on page 1269.

About the NumericAxis class

The NumericAxis class maps a set of continuous numerical values (such as sales volume, revenue, or profit) to coordinates on the screen. You do not typically use the NumericAxis base class directly. Instead, you use the following subclasses when you define your axis:

- LinearAxis
- LogAxis
- DateTimeAxis

These classes give you significant control over how to set the appearance and values of elements such as labels and tick marks along the axis.

You can use the `parseFunction` property to specify a custom method that formats the data points in your chart. This property is supported by all subclasses of the NumericAxis class. For a detailed description of using this property with the DateTimeAxis, see “Using the parseFunction property” on page 1253.

If you want to change the values of the labels, use the `labelFunction` property of the NumericAxis class. For more information, see “Defining axis labels” on page 1269.

About the LinearAxis subclass

The LinearAxis subclass is the simplest of the three NumericAxis subclasses. It maps numeric values evenly between minimum and maximum values along a chart axis. By default, Flex determines the minimum, maximum, and interval values from the charting data to fit all of the chart elements on the screen. You can also explicitly set specific values for these properties. The following example sets the minimum and maximum values to 40 and 50, respectively:

```
<?xml version="1.0"?>
<!-- charts/LinearAxisSample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses

        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/stocks-
xml.aspx"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/stocks.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:Panel title="LineChart control with a linear axis">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <mx:LineChart id="myChart"
            dataProvider="{srv.lastResult.data.result}"
            showDataTips="true"
            height="300" width="400">
            <mx:verticalAxis>
                <mx:LinearAxis
                    title="linear axis"
                    minimum="40"
                    maximum="50"
                    interval="1"/>
            </mx:verticalAxis>
            <mx:horizontalAxis>
                <mx:CategoryAxis categoryField="date"/>
            </mx:horizontalAxis>
            <mx:series>
                <mx:LineSeries
                    yField="close"
                    displayName="FRED close"/>
            </mx:series>
        </mx:LineChart>
        <mx:Legend dataProvider="{myChart}"/>
    </s:Panel>
</s:Application>
```

About the LogAxis subclass

The LogAxis subclass is similar to the LinearAxis subclass, but it maps values to the axis logarithmically rather than linearly. You use a LogAxis object when the data in your chart has such a wide range that clusters of data points are lost to scale. LogAxis data also cannot be rendered if it is negative. For example, if you track the stock price of a successful company since 1929, it is useful to represent the data logarithmically rather than linearly so that the chart is readable.

When you use a LogAxis object, you set a multiplier that defines the values of the labels along the axis. You set the multiplier with the `interval` property. Values must be even powers of 10, and must be greater than or equal to 0. A value of 10 generates labels at 1, 10, 100, and 1000. A value of 100 generates labels at 1, 100, and 10,000. The default value of the `interval` property is 10. The LogAxis object rounds the interval to an even power of 10, if necessary.

As with the vertical and horizontal axes, you can also set the minimum and maximum values of a LogAxis object, as the following example shows:

```
<?xml version="1.0"?>
<!-- charts/LogAxisSample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv_fe.send();srv_big.send()"
    height="600">
     <!-- To see data in an HTML table, go to

                    displayName="FE close"/>
                <mx:LineSeries dataProvider="{srv_big.lastResult.data.result}"
                    yField="close"
                    displayName="BIG close"/>
            </mx:series>
        </mx:LineChart>
        <mx:Legend dataProvider="{myChart}"/>
    </s:Panel>
</s:Application>
```

About the DateTimeAxis subclass

The DateTimeAxis subclass maps time-based values to a chart axis. The DateTimeAxis subclass calculates the minimum and maximum values to align with logical date and time units (for example, the nearest hour or the nearest week). The DateTimeAxis subclass also selects a time unit for the interval so that the chart renders a reasonable number of labels.

The `dataUnits` property of the DateTimeAxis subclass specifies how Flex should interpret the Date objects. Flex determines this property by default, but you can override it. To display data in terms of days, set the `dataUnits` property to *days*, as the following example shows:

```
<mx:DateTimeAxis dataUnits="days"/>
```

Valid values for the `dataUnits` property are `milliseconds`, `seconds`, `minutes`, `hours`, `days`, `weeks`, `months`, and `years`.

When assigning appropriate label units, a DateTimeAxis object does not assign any unit smaller than the units represented by the data. If the `dataUnits` property is set to `days`, the chart does not render labels for every hour, no matter what the minimum or maximum range is. To achieve this, you must set the value explicitly.

When using the DateTimeAxis class, you can filter out units when you set the `dataUnits` property to `days`. This lets you create a chart that shows a "work week" or some other configuration that omits certain days of the week. For more information, see “Omitting days on a DateTimeAxis object” on page 1257.

Some series use the value of the `dataUnits` property to affect their rendering. Specifically, most columnar series (such as Column, Bar, Candlestick, and HLOC controls) use the value of `dataUnits` to determine how wide to render their columns. If, for example, the ColumnChart control’s horizontal axis has its labels set to weeks and `dataUnits` set to days, the ColumnChart control renders each column at one-seventh the distance between labels.

About supported types

Data points on the DateTimeAxis object support the Date, String, and Number data types.

- Date: If the value of the data point is an instance of a Date object, it already represents an absolute date-time value and needs no interpretation. To pass a Date object as a data value, use the `parseFunction` property of the DateTimeAxis subclass. The `parseFunction` property returns a Date object. For more information, see “Using the parseFunction property” on page 1253.
- String: You can use any format that the `Date.parse()` method supports. The supported formats are:
  - *MM/YYYY* (for example, 02/2005)
  - *Day Month DD Hours:Minutes:Seconds GMT Year* (for example, Tue Feb 1 12:00:00 GMT-0800 2005)
  - *Day Month DD YYYY Hours:Minutes:Seconds AM|PM* (for example, Tue Feb 1 2005 12:00:00 AM)
  - *Day Month DD YYYY* (for example, Tue Feb 1 2005)
  - *MM/DD/YYYY* (for example, 02/01/2005)

  You can also write custom logic that uses the `parseFunction` property of the DateTimeAxis to take any data type and return a Date. For more information, see “Using the parseFunction property” on page 1253.
- Number: If you use a number, it is assumed to be the number of milliseconds since Midnight, 1/1/1970; for example, 543387600000. To get this value on an existing Date object, use the Date object’s `getTime()` method.

The following example specifies that the dates are displayed in units of days:

```
<?xml version="1.0"?>
<!-- charts/DateTimeAxisSample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    height="600">

  <fx:Script><![CDATA[
     import mx.collections.ArrayCollection
     [Bindable]
     public var deck:ArrayCollection = new ArrayCollection([
        {date:"08/01/2005", close:42.71},
        {date:"08/02/2005", close:42.99},
        {date:"08/03/2005", close:42.65}
     ]);
  ]]></fx:Script>

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Sample DateTimeAxis">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:LineChart id="myChart"
        dataProvider="{deck}"
        showDataTips="true">
        <mx:horizontalAxis>
           <mx:DateTimeAxis dataUnits="days"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:LineSeries
                yField="close"
                xField="date"
                displayName="DECK"/>
        </mx:series>
     </mx:LineChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

Using the parseFunction property

You use the `parseFunction` property of the DateTimeAxis object to specify a method that customizes the value of the data points. With this property, you specify a method that accepts a value and returns a Date object. The Date object is then used in the DateTimeAxis object of the chart. This lets you provide customizable input strings and convert them to Date objects, which Flex can then interpret for use in the DateTimeAxis.

The parsing method specified by the `parseFunction` property is called every time a value for the DateTimeAxis must be calculated. It is called each time a data point is encountered when the user interacts with the chart. Consequently, Flex might call the parsing method often, which can degrade an application's performance. Therefore, you should try to keep the amount of code in the parsing method to a minimum.

Flex passes only one parameter to the parsing method. This parameter is the value of the data point that you specified for the series. Typically, it is a String representing some form of a date. You cannot override this parameter or add additional parameters.

The following example shows a parsing method that creates a Date object from String values in the data provider that match the “YYYY, MM, DD” pattern:

```
<?xml version="1.0"?>
<!-- charts/DateTimeAxisParseFunction.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    height="600">
  <fx:Script>
    <![CDATA[
     import mx.collections.ArrayCollection;
     [Bindable]
     public var ABC:ArrayCollection = new ArrayCollection([
        {date:"2005, 8, 1", close:42.71},
        {date:"2005, 8, 2", close:42.99},
        {date:"2005, 8, 3", close:44}
     ]);
     public function myParseFunction(s:String):Date {
        // Get an array of Strings from the
        // comma-separated String passed in.
        var a:Array = s.split(",");
        // Trace out year, month, and day values.
        trace("y:" + a[0]);
        trace("m:" + a[1]);
        trace("d:" + a[2]);
        // To create a Date object, you pass "YYYY,MM,DD",
        // where MM is zero-based, to the Date() constructor.
        var newDate:Date = new Date(a[0],a[1]-1,a[2]);
        return newDate;
     }
    ]]>
  </fx:Script>

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="DateTimeAxis with parseFunction">
        <s:layout>
```

```
            <s:VerticalLayout/>
        </s:layout>
    <mx:LineChart id="myChart"
        dataProvider="{ABC}"
        showDataTips="true">
     <mx:horizontalAxis>
        <mx:DateTimeAxis
            dataUnits="days"
            parseFunction="myParseFunction"/>
     </mx:horizontalAxis>
     <mx:series>
        <mx:LineSeries
            yField="close"
            xField="date"
            displayName="ABC"/>
     </mx:series>
    </mx:LineChart>
    <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

Formatting DateTimeAxis labels

When assigning the units to display along the axis, the DateTimeAxis object uses the largest unit allowed to render a reasonable number of labels. The following table describes the default label format and the minimum range for each unit type:

Unit	Label format	Minimum range
Years	YYYY	If the minimum and maximum values span at least 2 years.
Months	MM/YY	Spans at least 2 months.
Weeks	DD/MM/YY	Spans at least 2 weeks.
Days	DD/MM/YY	Spans at least 1 day.
Hours	HH:MM	Spans at least 1 hour.
Minutes	HH:MM	Spans at least 1 minute.
Seconds	HH:MM:SS	Spans at least 1 second.
Milliseconds	HH:MM:SS:mmmm	Spans at least 1 millisecond.

You can restrict the list of valid units for a particular chart instance to a subset that makes sense for the use case. As with a LinearAxis object, you can specify minimum, maximum, and interval values for a DateTimeAxis object.

When rounding off values, the DateTimeAxis object determines if values passed to it should be displayed in the local time zone or UTC. You can set the `displayLocalTime` property to `true` to instruct the DateTimeAxis object to treat values as local time values. The default value is `false`.

To change the values of the labels, use the `labelFunction` property of the DateTimeAxis object. This property is inherited from the NumericAxis class and is described in “Defining axis labels” on page 1269.

Setting minimum and maximum values on a DateTimeAxis

You can define the range of values that any axis uses by setting the values of the `minimum` and `maximum` properties on that axis. For the DateTimeAxis class, however, you must use Date objects and not Numbers or Strings to define that range. To do this, you create bindable Date objects and bind the values of the `minimum` and `maximum` properties to those objects.

When creating Date objects, remember that the month parameter in the constructor is zero-based. The following example sets the minimum date for the axis to the first day of December 2006, and the maximum date for the axis to the first day of February 2007. The result is that Flex excludes the first and last data points in the ArrayCollection because those dates fall outside of the range set on the axis:

```
<?xml version="1.0"?>
<!-- charts/DateTimeAxisRange.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    height="600">

  <fx:Script><![CDATA[
     import mx.collections.ArrayCollection;
     // To create a Date object, you pass "YYYY,MM,DD",
     // where MM is zero-based, to the Date() constructor.
     [Bindable]
     public var minDate:Date = new Date(2006, 11, 1);
     [Bindable]
     public var maxDate:Date = new Date(2007, 1, 1);
     [Bindable] public var myData:ArrayCollection = new
     ArrayCollection([
        {date: "11/03/2006", amt: 12345},
        {date: "12/02/2006", amt: 54331},
        {date: "1/03/2007", amt: 34343},
        {date: "2/05/2007", amt: 40299}
     ]);
  ]]></fx:Script>

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="DateTimeAxis with range">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:ColumnChart id="myChart"
        dataProvider="{myData}"
        showDataTips="true">
        <mx:horizontalAxis>
           <mx:DateTimeAxis
                dataUnits="months"
                minimum="{minDate}"
                maximum="{maxDate}"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:ColumnSeries
                yField="amt"
                xField="date"
                displayName="My Data"/>
        </mx:series>
     </mx:ColumnChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

You can also represent the range of dates in MXML by using the following syntax:

```
<mx:horizontalAxis>
    <mx:DateTimeAxis dataUnits="months">
        <mx:minimum>
            <mx:Date fullYear="2005" month="11" date="1"/>
        </mx:minimum>
        <mx:maximum>
            <mx:Date fullYear="2007" month="1" date="1"/>
        </mx:maximum>
    </mx:DateTimeAxis>
</mx:horizontalAxis>
```

Omitting days on a DateTimeAxis object

You can exclude particular days or ranges of days from a chart. This lets you create charts that show only the days of the work week or that exclude other days of the week for other reasons.

For example, if you create a LineChart control that shows a stock price over the course of an entire month, the source data typically includes pricing data only for Monday through Friday. Values for the weekend days are typically not in the data. So, the chart control extrapolates values by extending the line through the weekend days on the chart, which makes it appear as though there is data for those days. If you *disable* the weekend days, the chart control removes those days from the chart and the line draws only the days that are not disabled. There is no breakage or other indicator that there are omitted days.

To disable days of the week or ranges of days in your charts, you must set the `dataUnits` property of the DateTimeAxis object to `days`. You then use the `disabledDays` or `disabledRanges` properties of the DateTimeAxis object.

The value of the `disabledDays` property of DateTimeAxis is an Array of numbers. These numbers correspond to days of the week, with 0 being Sunday, 1 being Monday, and so on, up until 6 being Saturday.

The following example excludes Saturdays and Sundays from the chart by setting the value of the `disabledDays` property to an Array that contains 0 and 6:

```
<?xml version="1.0"?>
<!-- charts/WorkWeekAxis.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/stocks.aspx -->
       <!-- View source of the following pages to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/stocks-
xml.aspx"/>
    </fx:Declarations>
  <fx:Script><![CDATA[
     /* Create an Array that specifies which days to exclude.
        0 is Sunday and 6 is Saturday. */
     [Bindable]
     private var offDays:Array = [0,6];

  ]]></fx:Script>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="WorkWeekAxis Example">
     <s:layout>
         <s:HorizontalLayout/>
     </s:layout>
     <mx:LineChart id="myChart"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true">
        <mx:horizontalAxis>
           <mx:DateTimeAxis dataUnits="days"
            disabledDays="{offDays}"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:LineSeries
                yField="close" xField="date"
                displayName="FRED"/>
        </mx:series>
     </mx:LineChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

To exclude a range of dates from the DateTimeAxis object, you use the `disabledRanges` property. This property takes an of objects. Each object specifies two dates: a `rangeStart` and `rangeEnd` property. The following example excludes August 13, and then the range of days between August 27 and August 31:

```
<?xml version="1.0"?>
<!-- charts/DisabledDateRanges.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="init()"
    height="600">

  <fx:Script><![CDATA[
     import mx.collections.ArrayCollection
     [Bindable]
     public var deck:ArrayCollection = new ArrayCollection([
        {date:"08/01/2007", close:42},
        {date:"08/02/2007", close:43},
        {date:"08/03/2007", close:43},
        {date:"08/06/2007", close:42},
        {date:"08/07/2007", close:38},
        {date:"08/08/2007", close:37},
        {date:"08/09/2007", close:39},
        {date:"08/10/2007", close:41},
        {date:"08/13/2007", close:45},
        {date:"08/14/2007", close:47},
        {date:"08/15/2007", close:48},
        {date:"08/16/2007", close:42},
        {date:"08/17/2007", close:43},
        {date:"08/20/2007", close:45},
        {date:"08/21/2007", close:50},
        {date:"08/22/2007", close:51},
        {date:"08/23/2007", close:55},
        {date:"08/24/2007", close:51},
        {date:"08/27/2007", close:49},
        {date:"08/28/2007", close:51},
        {date:"08/29/2007", close:50},
        {date:"08/30/2007", close:49},
        {date:"08/31/2007", close:54}
     ]);

     private function myParseFunction(s:String):Date {
        var a:Array = s.split("/");
        var newDate:Date = new Date(a[2],a[0]-1,a[1]);
        return newDate;
     }
     private var d1:Date, d2:Date, d3:Date;
     [Bindable]
     private var offRanges:Array = new Array ([]);
     private function init():void {
        d1 = new Date("08/13/2007");
        d2 = new Date("08/27/2007");
        d3 = new Date("08/31/2007");
        offRanges = [ {rangeStart:d1, rangeEnd:d1},{rangeStart:d2, rangeEnd:d3} ];
     }

     private var series1:LineSeries;
  ]]></fx:Script>

    <s:layout>
```

```
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Disabled Date Ranges">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:LineChart id="myChart"
        dataProvider="{deck}"
        showDataTips="true">
        <mx:horizontalAxis>
           <mx:DateTimeAxis
            dataUnits="days"
            parseFunction="myParseFunction"
            disabledRanges="{offRanges}"/>
        </mx:horizontalAxis>

        <mx:series>
           <mx:LineSeries id="mySeries"
                yField="close"
                xField="date"
                displayName="DECK"/>
        </mx:series>
    </mx:LineChart>
    <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

The following example expands on the previous example, except it adds a DateChooser control. You can select days on the DateChooser that are then removed from the chart.

```
<?xml version="1.0"?>
<!-- charts/DisabledDateRangesWithDateChooser.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="init()"
    height="600">

  <fx:Script><![CDATA[
     import mx.collections.ArrayCollection;
     [Bindable]
     public var deck:ArrayCollection = new ArrayCollection([
        {date:"08/01/2007", close:42},
        {date:"08/02/2007", close:43},
        {date:"08/03/2007", close:43},
        {date:"08/06/2007", close:42},
        {date:"08/07/2007", close:38},
        {date:"08/08/2007", close:37},
        {date:"08/09/2007", close:39},
        {date:"08/10/2007", close:41},
        {date:"08/13/2007", close:45},
        {date:"08/14/2007", close:47},
        {date:"08/15/2007", close:48},

  </s:Panel>
</s:Application>
```

Adding axis titles

Each axis in a chart control can include a title that describes the purpose of the axis to the users. Flex does not add titles to the chart's axes unless you explicitly set them. To add titles to the axes of a chart, you use the `title` property of the axis object. This is CategoryAxis or one of the NumericAxis subclasses such as DateTimeAxis, LinearAxis, or LogAxis. To set a style for the axis title, use the `axisTitleStyleName` property of the chart control.

The following example sets the titles of the horizontal and vertical axes (in MXML and ActionScript), and applies the styles to those titles:

```
<?xml version="1.0"?>
<!-- charts/AxisTitles.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send();setTitles();"
    height="600">
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses 
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to 
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
    <fx:Script><![CDATA[
        private function setTitles():void {
            la1.title="Dollars";
        }
    ]]></fx:Script>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Style>
        .myStyle {
            fontFamily:Verdana;
            fontSize:12;
            color:#4691E1;
            fontWeight:bold;
            fontStyle:italic;
        }
    </fx:Style>
    <s:Panel title="Axis with title">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <mx:ColumnChart id="myChart" 
            showDataTips="true"
            axisTitleStyleName="myStyle"
            dataProvider="{srv.lastResult.data.result}">
            <mx:verticalAxis>
                <mx:LinearAxis id="la1"/>
            </mx:verticalAxis>
            <mx:horizontalAxis>
                <mx:CategoryAxis title="FY 2009" categoryField="month"/>
            </mx:horizontalAxis>
            <mx:series>
                <mx:ColumnSeries
                    xField="month"
                    yField="profit"
                    displayName="Profit"/>
                <mx:ColumnSeries
                    xField="month"
                    yField="expenses"
                    displayName="Expenses"/>
            </mx:series>
        </mx:ColumnChart>
        <mx:Legend dataProvider="{myChart}"/>
    </s:Panel>
</s:Application>
```

You can also use embedded fonts for your axis titles. The following example embeds the font and sets the style for the vertical axis title:

```
<?xml version="1.0"?>
<!-- charts/AxisTitleEmbedFont.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
  <fx:Declarations>
     <!-- View source of the following page to see the structure of the data that Flex uses in
this example. -->
     <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
     <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
  </fx:Declarations>
  <fx:Style>
     @font-face{
        src:url("../assets/MyriadWebPro.ttf");
        fontFamily:myMyriad;
     }

     .myEmbeddedStyle {
        fontFamily:myMyriad;
        fontSize:20;
     }
  </fx:Style>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Axis title with embedded font">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:ColumnChart id="column"
        showDataTips="true"
        dataProvider="{srv.lastResult.data.result}"
        axisTitleStyleName="myEmbeddedStyle">
        <mx:horizontalAxis>
           <mx:CategoryAxis categoryField="month"
                title="FY 2009"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:ColumnSeries
                xField="month"
                yField="profit"
                displayName="Profit"/>
           <mx:ColumnSeries
                xField="month"
                yField="expenses"
                displayName="Expenses"/>
        </mx:series>
     </mx:ColumnChart>
     <mx:Legend dataProvider="{column}"/>
  </s:Panel>
</s:Application>
```

For information on embedding fonts, see “Embed fonts” on page 1571.

You can take advantage of the fact that the chart applies the `axisTitleStyleName` property without explicitly specifying it, as the following example shows:

```
<?xml version="1.0"?>
<!-- charts/CSSAxisTitle.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
        <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
         <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
         <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
  <fx:Style>
     @namespace mx "library://ns.adobe.com/flex/mx";
     .axisTitles {
        color:red;
        fontWeight:bold;
        fontFamily:Arial;
        fontSize:20;
     }
     mx|ColumnChart {
        axisTitleStyleName:axisTitles;
     }
  </fx:Style>
```

```
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Styling Axis Titles with CSS">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:ColumnChart id="column"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true">
        <mx:horizontalAxis>
           <mx:CategoryAxis categoryField="month" title="FY 2009"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:ColumnSeries
                xField="month"
                yField="profit"
                displayName="Profit"/>
           <mx:ColumnSeries
                xField="month"
                yField="expenses"
                displayName="Expenses"/>
        </mx:series>
     </mx:ColumnChart>
     <mx:Legend dataProvider="{column}"/>
  </s:Panel>
</s:Application>
```

You can also apply the title style to the axis, as the following example shows:

```
<mx:CategoryAxis title="State" styleName="myEmbeddedStyle"/>
```

To change the appearance of the title on a chart, you can also use the `titleRenderer` property of the AxisRenderer class. This lets you specify a class that defines the appearance of the title. The class must extend UIComponent and implement the IDataRenderer and IFlexDisplayObject interfaces. Its `data` property will be the title used in the chart.

Typically, you extend the ChartLabel class to create a custom title renderer. In that class, you override the `updateDisplayList()` method. In the `updateDisplayList()` method, you define the appearance of the box surrounding the title as well as the appearance of the title's text.

The following example is a custom title renderer. It creates a gradient fill background for each of the axis titles.

```
// charts/MyTextRenderer.as
package {
    import mx.charts.chartClasses.ChartLabel;
    import mx.charts.*;
    import flash.display.*;
    import flash.geom.Matrix;

    public class MyTextRenderer extends ChartLabel {
        public function MyTextRenderer() {
            super();
        }

        override protected function updateDisplayList(w:Number, h:Number):void {
            super.updateDisplayList(w, h);

            this.setStyle("textAlign","center");
            var g:Graphics = graphics;
            g.clear();
            var m:Matrix = new Matrix();
            m.createGradientBox(w+100,h,0,0,0);
            g.beginGradientFill(GradientType.LINEAR,[0xFF0000,0xFFFFFF],
                [.1,1],[0,255],m,null,null,0);
            g.drawRect(-50,0,w+100,h);
            g.endFill();
        }
    }
}
```

To use this class in your application, you point the `titleRenderer` property to it. This assumes that the class is in your source path. In this case, store both the MyTextRenderer.as and RendererSample.mxml files in the same directory.

The following example applies the custom title renderer to all axis titles.

```
<?xml version="1.0"?>
<!-- charts/RendererSample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"

            </mx:verticalAxisRenderers>
        </mx:BarChart>
    </s:Panel>

</s:Application>
```

Defining axis labels

You define the values of axis labels on the horizontal axis or vertical axis. You can customize these values by using the available data in the series or you can disable these values altogether.

Disabling axis labels

You can disable labels by setting the value of the `showLabels` property to `false` on the AxisRenderer object, as the following example shows:

```
<?xml version="1.0"?>
<!-- charts/DisabledAxisLabels.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">

    <fx:Declarations>
        <!-- View source of the following page to see the structure of the data that Flex uses 
in this example. -->
         <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
         <!-- To see data in an HTML table, go to 
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:Panel title="Disabled Axis Labels">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <mx:ColumnChart id="column"
            dataProvider="{srv.lastResult.data.result}"
            showDataTips="true">
            <mx:horizontalAxis>
                <mx:CategoryAxis id="a1" categoryField="month"/>
            </mx:horizontalAxis>
            <mx:horizontalAxisRenderers>
                <mx:AxisRenderer
                    axis="{a1}"
                    showLabels="false"/>
            </mx:horizontalAxisRenderers>
            <mx:verticalAxisRenderers>
                <mx:AxisRenderer axis="{a1}" showLabels="false"/>
            </mx:verticalAxisRenderers>
            <mx:series>
                <mx:ColumnSeries
                    xField="month"
                    yField="profit"
                    displayName="Profit"/>
                <mx:ColumnSeries
                    xField="month"
                    yField="expenses"
                    displayName="Expenses"/>
            </mx:series>
        </mx:ColumnChart>
        <mx:Legend dataProvider="{column}"/>
    </s:Panel>
</s:Application>
```

Note that any time you want to use an AxisRenderer, you must explicitly set the axis to which it is applied with the renderer’s `axis` property.

Customizing axis labels

You can customize the value of axis labels by using the `labelFunction` callback function of the axis. The function specified in `labelFunction` returns a String, Number, or Date object that Flex displays as the axis label.

The callback function signature for a NumericAxis object (including the DateTimeAxis, LinearAxis, and LogAxis classes) is:

```
function_name(labelValue:Object, previousLabelValue:Object, axis:IAxis):return_type
```

The callback function signature for a CategoryAxis object is:

```
function_name(labelValue:Object, previousLabelValue:Object, axis:axis_type,
labelItem:Object):return_type
```

The following table describes the parameters of the callback function:

Parameter	Description
labelValue	The value of the current label.
previousLabelValue	The value of the label preceding this label. If this is the first label, the value of ***previousLabelValue*** is `null`.

Parameter	Description
axis	The axis object, such as CategoryAxis or NumericAxis.

labelItem	A reference to the label object. This argument is only passed in for a CategoryAxis object. For NumericAxis subclasses such as LogAxis, DateTimeAxis, and LinearAxis objects, you omit this argument.
	This object contains a name/value pair for the chart data. For example, if the data provider defines the Month, Profit, and Expenses fields, this object might look like the following:
	`Profit:1500`
	`Month:Mar`
	`Expenses:500`
	You can access the values in this object by using dot-notation for dynamic objects, as the following example shows:
	`return "$" + labelItem.Profit;`

return_type	The type of object that the callback function returns. This can be any object type, but is most commonly a String for CategoryAxis axes, a Number for NumericAxis objects, or a Date object for DateTimeAxis objects.

When you use the `labelFunction`, you must be sure to import the class of the axis or the entire charts package; for example:

```
import mx.charts.*;
```

The following example defines a `labelFunction` for the horizontal CategoryAxis object. In that function, Flex appends ’10 to the axis labels, and displays the labels as Jan ’10, Feb ’10, and Mar ‘10. For the vertical axis, this example specifies that it is a LinearAxis, and formats the values to include a dollar sign and a thousands separator (by setting the `useGrouping` property to `true` on the NumberFormatter). The NumberFormatter also removes decimal values by setting the `fractionalDigits` property to 0. The return types of the label formatting functions are Strings.

```
<?xml version="1.0"?>
<!-- charts/CustomLabelFunction.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
        <!-- View source of the following page to see the structure of the data that Flex uses 
in this example. -->
         <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
         <!-- To see data in an HTML table, go to 
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
         <s:NumberFormatter id="numForm" useGrouping="true" fractionalDigits="0"/>
    </fx:Declarations>
  <fx:Script><![CDATA[
    import mx.charts.*;
    // This method customizes the values of the axis labels.
    // This signature (with 4 arguments) is for a CategoryAxis.
    public function defineLabel(cat:Object, 
                                pcat:Object,
                                ax:CategoryAxis,
                                labelItem:Object):String
    {
        // Show contents of the labelItem:
```

```
        for (var s:String in labelItem) {
            trace(s + ":" + labelItem[s]);
        }
        // Return the customized categoryField value:
        return cat + " '10";
        // Note that if you did not specify a categoryField,
        // cat would refer to the entire object and not the
        // value of a single field. You could then access
        // fields by using cat.field_name.
    }
    // For a NumericAxis, you do not use the labelItem argument.
    // This example uses a NumberFormatter to add a thousands
    // separator (by setting useGrouping to true) and removes decimal values
    // (by setting fractionalDigits to 0).
    public function defineVerticalLabel(
                                        cat:Object,
                                        pcat:Object,
                                        ax:LinearAxis):String
    {
        return "$" + numForm.format(cat);
    }
  ]]></fx:Script>

        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Custom Label Function">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:ColumnChart id="column"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true">
        <mx:horizontalAxis>
           <mx:CategoryAxis
                categoryField="month"
                title="Expenses"
                labelFunction="defineLabel"/>
        </mx:horizontalAxis>
        <mx:verticalAxis>
            <mx:LinearAxis title="Income"
                minimum="0" maximum="2500"
                labelFunction="defineVerticalLabel"/>
        </mx:verticalAxis>
        <mx:series>
           <mx:ColumnSeries
                xField="month"
                yField="profit"
                displayName="Profit"/>
           <mx:ColumnSeries
                xField="month"
                yField="expenses"
                displayName="Expenses"/>
        </mx:series>
     </mx:ColumnChart>
  </s:Panel>
</s:Application>
```

In the previous example, if you use a CategoryAxis but do not specify the value of the `categoryField` property on the axis, the label format function receives an object rather than a value for the first argument. In that case, you must drill down into the object to return a formatted String.

You can also customize labels by using the `labelFunction` property of the AxisRenderer class. This lets you control the labels if you use multiple axes. The callback function signature for the AxisRenderer's label function is:

```
function_name(axisRenderer:IAxisRenderer, label:String):String
```

Because this particular callback function takes an argument of type IAxisRenderer, you must import that class when you use this function:

```
import mx.charts.chartClasses.IAxisRenderer;
```

The following example specifies the value of the `labelFunction` property for one of the vertical axis renderers. The resulting function, `CMstoInches()`, converts centimeters to inches for the axis' labels.

```
<?xml version="1.0"?>
<!-- charts/CustomLabelsOnAxisRenderer.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"

                <mx:AxisRenderer axis="{h1}" placement="bottom"/>
                <mx:AxisRenderer axis="{h1}" placement="top"/>
            </mx:horizontalAxisRenderers>
            <mx:series>
                <mx:LineSeries yField="5"  form="curve" displayName="5%"/>
                <mx:LineSeries yField="10" form="curve" displayName="10%"/>
                <mx:LineSeries yField="25" form="curve" displayName="25%"/>
                <mx:LineSeries yField="50" form="curve" displayName="50%"/>
                <mx:LineSeries yField="75" form="curve" displayName="75%"/>
                <mx:LineSeries yField="90" form="curve" displayName="90%"/>
                <mx:LineSeries yField="95" form="curve" displayName="95%"/>
                <mx:ColumnSeries displayName="Height of Child X"
                    dataProvider="{SampleHeightData}"
                    yField="height"
                    fills="{[0xCC6600]}"/>
            </mx:series>
        </mx:ColumnChart>
        <mx:Legend dataProvider="{linechart}"/>
    </s:Panel>
</s:Application>
```

Another way to customize the labels on an axis is to set a custom data provider for the labels. This can be done if you are using the CategoryAxis and not the NumericAxis class for the axis values. For more information, see "About the CategoryAxis class" on page 1247.

For the PieChart control, you can customize labels with the label function defined on the PieSeries class. For more information, see "Using data labels with PieChart controls" on page 1153.

Setting ranges on a NumericAxis

Flex determines the minimum and maximum values along an axis and sets the interval based on the settings of the NumericAxis object. You can override the values that Flex calculates. By changing the range of the data displayed in the chart, you also change the range of the tick marks.

The following table describes the properties of the axis that define the ranges along the axes:

Property	Description
`minimum`	The lowest value of the axis.
`maximum`	The highest value of the axis.
`interval`	The number of units between values along the axis.

The following example defines the range of the y-axis:

```
<?xml version="1.0"?>
<!-- charts/LinearAxisSample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/stocks-
xml.aspx"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/stocks.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:Panel title="LineChart control with a linear axis">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <mx:LineChart id="myChart"
            dataProvider="{srv.lastResult.data.result}"
            showDataTips="true"
            height="300" width="400">
            <mx:verticalAxis>
                <mx:LinearAxis
                    title="linear axis"
                    minimum="40"
                    maximum="50"
                    interval="1"/>
            </mx:verticalAxis>
            <mx:horizontalAxis>
                <mx:CategoryAxis categoryField="date"/>
            </mx:horizontalAxis>
            <mx:series>
                <mx:LineSeries
                    yField="close"
                    displayName="FRED close"/>
            </mx:series>
        </mx:LineChart>
        <mx:Legend dataProvider="{myChart}"/>
    </s:Panel>
</s:Application>
```

In this example, the minimum value displayed along the y-axis is 10, the maximum value is 100, and the interval is 10. Therefore, the label text is 10, 20, 30, 40, and so on.

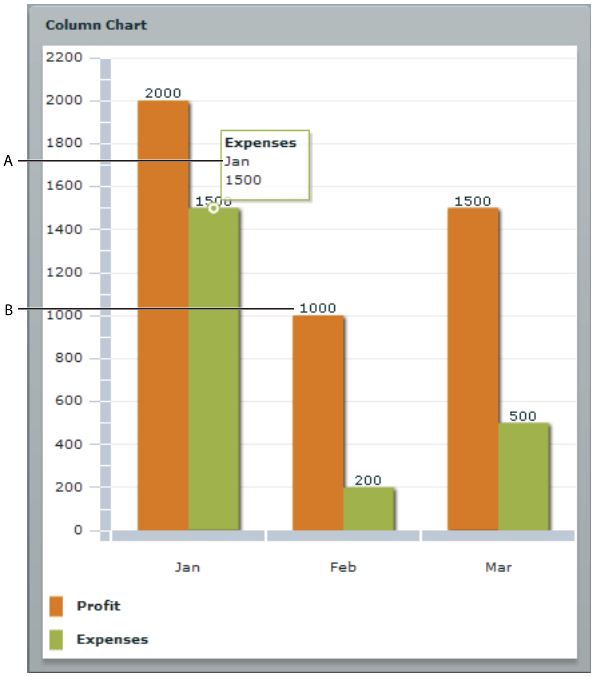
To set the minimum and maximum values on a DateTimeAxis, you must use Date objects rather than Strings or Numbers in the axis's tag. For more information, see "Setting minimum and maximum values on a DateTimeAxis" on page 1256.

For information about setting the length and location of tick marks, see "Formatting tick marks" on page 1187.

Using data labels

Data labels show static data on the chart control. They typically appear on the chart for each chart element (such as all pie wedges or all bars) for the entire time the chart is active. They are different from DataTip objects in that they typically show only the simple value of a chart element in a series (for example, a column's height or a pie wedge's percentage) and do not include other information such as the series name or complex formatting. DataTip controls are more interactive, since they appear and disappear as the user moves the mouse over chart elements. For more information about DataTip objects, see "Using DataTip objects" on page 1287.

The following example shows a column chart with an active DataTip object and visible data labels:



A. *DataTip* ***B.*** *Data label*

The following chart series support data labels:

- BarSeries
- ColumnSeries
- PieSeries

Just like DataTip controls, data labels are not enabled by default. You can add data labels by setting the value of the series' `labelPosition` property to `inside` or `outside` (for BarSeries and ColumnSeries) or `inside`, `outside`, `callout`, or `insideWithCallout` (for PieSeries). For more information, see "Adding data labels" on page 1279. The default value of the series's `labelPosition` property is `none`.

The following example enables data labels on the columns by setting the value of the `labelPosition` style property to `inside`. You can click the button to change the position of the labels to `outside`.

```
<?xml version="1.0"?>
<!-- charts/BasicDataLabel.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send();setStartLabelLocation();"
    height="600">
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
  <fx:Script><![CDATA[

        </mx:series>
     </mx:ColumnChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
  <s:Button id="b1" label="Change Label Location"
    click="changeLabelLocation()"/>
</s:Application>
```

Adding data labels

By default, BarSeries, ColumnSeries, and PieSeries objects do not display data labels. To enable data labels on BarSeries and ColumnSeries objects, set the value of the `labelPosition` property to `inside` or `outside`. To enabled data labels on PieSeries, set the value of the `labelPosition` property to `inside`, `outside`, `callout`, or `insideWithCallout`.

The default value of the `labelPosition` property is `none`.

Because `labelPosition` property is a style property, you can set it either inline in the series' tag or by using the `setStyle()` method, as the following example shows:

```
mySeries.setStyle("labelPosition", "outside");
```

The contents of the data label are determined by several factors, in order of precedence:

- `labelField`—Specifies a field in the data provider that sets the contents of the data label. This overrides any method specified by the `labelFunction` property.
- `labelFunction`—Specifies a method that takes several arguments and returns a String that the chart series uses for the data label's contents. For more information, see "Customizing data label values" on page 1283.
- Default—If neither the `labelField` nor the `labelFunction` are specified, the default content of the data label is the value that the series uses to draw the chart element. This is the `xField` value for a ColumnSeries and the `yField` value for a BarSeries. For a PieSeries, the default content of the data labels is the value of the `field` property.

Setting the `labelPosition` property to `inside` restricts the amount of styling you can perform on the data labels. If the data labels are inside the chart elements (for example, inside the column in a ColumnSeries), their size is restricted by the available space within that element. A data label cannot be bigger than the chart element that contains it. If you try to set a data label to be larger than its underlying chart element, Flex scales and possibly truncates the contents of the data label. As a result, you should usually set the value of the `labelPosition` property to `outside`. For information about styling your data labels, see "Styling data labels" on page 1280.

For 100%, stacked, and overlaid charts, the values of the series's `labelPosition` property can only be `inside`. If you set the `labelPosition` property to `outside` for these types of bar and column series, the value is ignored and the labels are rendered as if the `labelPosition` was `inside`.

If you set the `labelPosition` property to `inside`, you cannot rotate data labels.

Styling data labels

You can style the data labels so that their appearance fits into the style of your application. You can apply the following styles to data labels:

- `fontFamily`
- `fontSize`
- `fontStyle`
- `fontWeight`
- `labelAlign` (when the `labelPosition` property is set to `inside` only)
- `labelPosition`
- `labelSizeLimit`

You can apply these styles by using type or class selectors in CSS or by using the `setStyle()` method. You can also set these properties inline in the series's MXML tag.

The following example shows how to use CSS class selectors to set the `labelPosition` and other properties that affect the appearance of data labels in a chart:

```
<?xml version="1.0"?>
<!-- charts/StylingDataLabels.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
      <!-- Style properties on series that affect data labels:
        fontFamily; fontSize; fontStyle; fontWeight;
        labelPosition; labelRotation; labelSizeLimit -->
       <fx:Style>
         .incomeSeries {
             fontSize:9;
             fontWeight:bold;
             labelPosition:inside;
             labelAlign:top;
         }

         .expensesSeries {
             fontSize:8;
             labelPosition:inside;
             labelAlign:middle;
         }

       </fx:Style>

    <s:layout>
```

```
        <s:VerticalLayout/>
    </s:layout>
       <s:Panel title="Column Chart">
             <s:layout>
                 <s:HorizontalLayout/>
             </s:layout>
          <mx:ColumnChart id="myChart"
             dataProvider="{srv.lastResult.data.result}"
             showDataTips="true">
             <mx:horizontalAxis>
                <mx:CategoryAxis categoryField="month"/>
             </mx:horizontalAxis>

             <mx:verticalAxis>
                 <mx:LinearAxis minimum="0" maximum="2500"/>
             </mx:verticalAxis>

             <mx:series>
                <mx:ColumnSeries
                     xField="month"
                     yField="profit"
                     displayName="Profit"
                     styleName="incomeSeries"/>
                <mx:ColumnSeries xField="month" yField="expenses"
                     displayName="Expenses" styleName="expensesSeries"/>
             </mx:series>
          </mx:ColumnChart>
          <mx:Legend dataProvider="{myChart}"/>
       </s:Panel>
</s:Application>
```

Labels are scaled and possibly truncated if they are too big for the area. Labels will never overlap each other or other chart elements.

For PieSeries objects, you can also specify the gap and stroke of callout lines that associate a data label with a particular wedge in the pie. For more information, see “Using data labels with PieChart controls” on page 1153.

Aligning data labels

You can align data labels so that they are positioned, either vertically or horizontally, relative to the underlying chart element. For example, you can center a data label over a column in a ColumnChart control, or align it to the left of all bars in a BarChart control.

To align data labels, you use the series’ `labelAlign` style property. For ColumnSeries objects, valid values are `middle`, `top`, and `bottom`. For BarSeries objects, valid values are `left`, `center`, and `right`. The defaults are `middle` and `center`, respectively.

You can only set the `labelAlign` style if the `labelPosition` property is set to `inside`. Label alignment is ignored if the `labelPosition` is `outside`.

You cannot change the alignment of data labels on a PieSeries object.

ColumnChart controls have two additional properties that you can use to control the way data labels are rendered: showLabelVertically and extendLabelToEnd. These properties are important when the available space for labels is not sufficient to render the entire label. If you set showLabelVertically to true, Flex can render the label vertically rather than horizontally if the columns are not wide enough to render them normally. If you set extendLabelToEnd to true, then Flex can use the space between the data item's edge and the outer boundary of the chart to render the label in, rather than truncate the label at the end of the data item's column.

Rotating data labels

You can rotate data labels on a series by setting the value of the labelRotation style property on the data label's axis renderer. You must embed a font to rotate them. You must also set the embedAsCFF property in CSS to false because the chart is an MX control and not a Spark control. If you rotate the data labels without embedding a font, they are rendered horizontally.

The following example embeds a font and rotates the data labels 45 degrees:

```
<?xml version="1.0"?>
<!-- charts/RotatingDataLabels.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
    <fx:Style>
        @font-face{
            src: url("../assets/MyriadWebPro.ttf");
            fontFamily: myMyriad;
            embedAsCFF: false;
        }
        @namespace mx "library://ns.adobe.com/flex/mx";
        mx|ColumnSeries {
            labelPosition:outside;
            labelRotation:45;
        }
        mx|ColumnChart {
            fontFamily: myMyriad;
        }
    </fx:Style>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:Panel title="Rotating Data Labels in a Column Chart">
         <s:layout>
             <s:VerticalLayout/>
         </s:layout>
        <mx:ColumnChart id="myChart"
```

```
            dataProvider="{srv.lastResult.data.result}"
            showDataTips="true">

            <mx:horizontalAxis>
                <mx:CategoryAxis id="a1" categoryField="month"/>
            </mx:horizontalAxis>
            <mx:verticalAxis>
                <mx:LinearAxis id="a2" minimum="0" maximum="2500"/>
            </mx:verticalAxis>
            <mx:series>
                <mx:ColumnSeries displayName="Profit"
                    xField="month"
                    yField="profit"/>
                <mx:ColumnSeries displayName="Expenses"
                    xField="month"
                    yField="expenses"/>
            </mx:series>
        </mx:ColumnChart>
    </s:Panel>
</s:Application>
```

You can only rotate data labels if the series's `labelPosition` property is set to `outside`. You cannot rotate data labels if the `labelPosition` property of the series is set to `inside`.

If by rotating labels, you cause them to overlap each other or overlap chart elements, Flex repositions them. If there is not enough space to reposition the labels, Flex scales and ultimately truncates the labels. Data labels will never overlap each other or the underlying chart elements.

For more information on embedding fonts, see "Embed fonts" on page 1571.

Customizing data label values

You can customize the value of your data labels. For example, you can prepend a dollar sign ($) or apply numeric formatters to the data labels to make your chart more readable. You can change the value of the data label altogther if you want.

To customize the contents of a data label, you use the `labelFunction` property of the series to specify a callback function. The function specified in `labelFunction` returns a String that Flex displays as the data label. Flex calls this callback function for each chart element in the series when the data labels are first rendered, and calls this method any time the labels are rendered again (for example, if the data changes).

The exact signature of the custom label callback function depends on the series that you are using it with. For BarSeries and ColumnSeries objects, the function takes two arguments (see "Customizing data labels for ColumnSeries and BarSeries objects" on page 1283); for PieSeries objects, the function takes four arguments (see "Customizing data labels for PieSeries objects" on page 1285).

Customizing data labels for ColumnSeries and BarSeries objects

For a ColumnSeries or BarSeries object, the signature for the custom label callback function is:

```
function_name(element:ChartItem, series:Series):String { ... }
```

The following table describes the parameters of the `labelFunction` callback function for a ColumnSeries or BarSeries object:

Parameter	Description
element	A reference to the ChartItem that this data label applies to. The ChartItem represents a single data point in a series.
series	A reference to the series that this data label is used on.

When you customize the value of the data label, you typically get a reference to the series item. You do this by casting the `element` argument to a specific chart item type (BarSeriesItem or ColumnSeriesItem). You then point to either the `yNumber` or `xNumber` property to get the underlying data.

You can also get a reference to the current series by casting the `series` argument to the specific series type (ColumnSeries or BarSeries). This lets you access properties such as the `yField` or `xField`.

The following example creates data labels for each of the columns in the ColumnChart control:

```
<?xml version="1.0"?>
<!-- charts/DataLabelFunctionColumn.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">

        <mx:series>
           <mx:ColumnSeries
                labelPosition="outside"
                xField="month"
                yField="profit"
                displayName="Profit"
                labelFunction="setCustomLabel"/>
           <mx:ColumnSeries
                labelPosition="outside"
                xField="month"
                yField="expenses"
                displayName="Expenses"
                labelFunction="setCustomLabel"/>
        </mx:series>
     </mx:ColumnChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

You can also access the specific field in the data provider that provides the data. For example, in the previous example, you could get the value of the data item (in this case, the value of the Income field) by using code similar to the following:

```
var item:ColumnSeriesItem = ColumnSeriesItem(element);
var s:String = item.item.Income;
return s;
```

This is not a recommended practice, however, because it makes the callback function less reusable and can force you to use additional code to detect which column you are providing data labels for.

Customizing data labels for PieSeries objects

For a PieSeries object, the signature for the custom label callback function is:

```
function_name(data:Object, field:String, index:Number, percentValue:Number):String { ... }
```

The following table describes the parameters of the `labelFunction` callback function for a PieSeries:

Parameter	Description
data	A reference to the data point that chart element represents; type Object.
field	The field name from the data provider; type String.
index	The number of the data point in the data provider; type Number.
percentValue	The size of the pie wedge relative to the pie; type Number. If the pie wedge is a quarter of the size of the pie, this value is 25.

The following example generates data labels for a PieSeries object that include data and formatting. It defines the `display()` method as the `labelFunction` callback function to handle formatting of the label text.

```
<?xml version="1.0"?>
<!-- charts/PieLabelFunction.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses 
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/budget-
xml.aspx"/>
        <!-- To see data in an HTML table, go to 
http://aspexamples.adobe.com/chart_examples/budget.aspx -->
    </fx:Declarations>
  <fx:Script><![CDATA[
     import spark.formatters.*;
     public function display(
        data:Object,
        field:String,
        index:Number,
        percentValue:Number):String
     {
            return data.item + "\n$" + data.amount +
            "\n(" + round(percentValue,2) + "%)";
     }
     // Rounds to 2 places:
     public function round(num:Number, precision:Number):Number {
        var result:String;
        var f:NumberFormatter = new NumberFormatter();
        f.fractionalDigits = precision;
        result = f.format(num);
        return Number(result);
     }
  ]]></fx:Script>
    <s:layout>
```

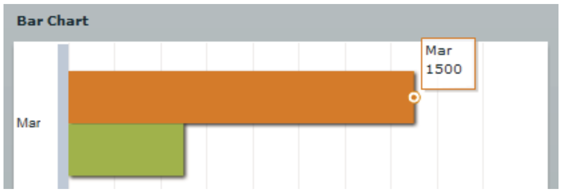
```
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Expenditures for FY '09">
     <s:layout>
         <s:VerticalLayout/>
     </s:layout>
     <mx:PieChart id="chart"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="false">
        <mx:series>
           <mx:PieSeries
                labelPosition="callout"
                field="amount"
                labelFunction="display"
                nameField="item"/>
        </mx:series>
     </mx:PieChart>
     <mx:Legend dataProvider="{chart}"/>
  </s:Panel>
</s:Application>
```

Using DataTip objects

The values displayed in the DataTip depends on the chart type, but typically it displays the names of the fields and the values of the data from the data provider.

***Note:** DataTip controls and data labels are not the same, although they can show the same information. Data labels are always visible regardless of the location of the user's mouse pointer. For more information about data labels, see "Using data labels" on page 1277.*

The following image shows a simple DataTip:



To enable DataTip objects, set the value of the chart control's `showDataTips` property to `true`, as the following example shows:

```
<?xml version="1.0"?>
<!-- charts/EnableDataTips.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
        <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
         <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
         <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Bar Chart with DataTip objects enabled">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:BarChart id="myChart"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true">
        <mx:verticalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:verticalAxis>
        <mx:series>
           <mx:BarSeries
                yField="month"
                xField="profit"
                displayName="Profit"/>
           <mx:BarSeries
                yField="month"
                xField="expenses"
                displayName="Expenses"/>
        </mx:series>
     </mx:BarChart>
      <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

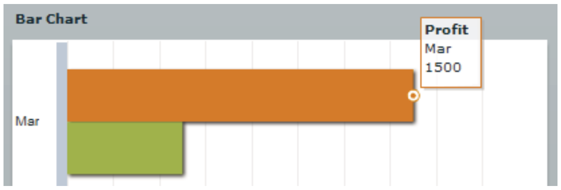
To change the styles of the DataTip, you can use the DataTip type selector in an `<fx:Style>` block or in an external CSS file. You must create a separate style namespace definition for the DataTip package. The following example applies new style properties to the text in the DataTip:

```
<?xml version="1.0"?>
<!-- charts/DataTipStyles.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
        <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
          <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
          <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
    <fx:Style>
        @namespace chartClasses "mx.charts.chartClasses.*";
        chartClasses|DataTip {
            fontFamily: "Arial";
            fontSize: 12;
            fontWeight:bold;
            fontStyle:italic;
        }
    </fx:Style>

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:Panel title="Bar Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <mx:BarChart id="myChart"
            dataProvider="{srv.lastResult.data.result}"
            showDataTips="true">
            <mx:verticalAxis>
                <mx:CategoryAxis categoryField="month"/>
            </mx:verticalAxis>
            <mx:series>
                <mx:BarSeries
                    yField="month"
                    xField="profit"
                    displayName="Profit"/>
                <mx:BarSeries
                    yField="month"
                    xField="expenses"
                    displayName="Expenses"/>
            </mx:series>
        </mx:BarChart>
        <mx:Legend dataProvider="{myChart}"/>
    </s:Panel>
</s:Application>
```

Customizing the text inside a DataTip object

To make the information in the DataTip more understandable to users, you can define the series of your chart with names that are easily understood. Adobe® Flash® Player or Adobe® AIR™ displays this name in the DataTip, as the following image shows:

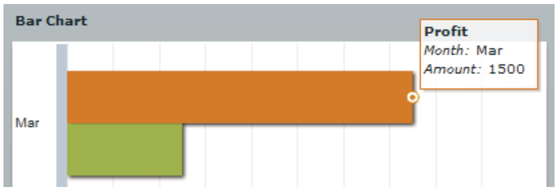


The following example names the data series by using the `displayName` property of the series:

```
<?xml version="1.0"?>
<!-- charts/DataTipsDisplayName.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
        <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
         <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
         <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Bar Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
```

```
     <mx:BarChart id="myChart"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true">
        <mx:verticalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:verticalAxis>
        <mx:series>
           <mx:BarSeries
                yField="month"
                xField="profit"
                displayName="--==Profit==--"/>
           <mx:BarSeries
                yField="month"
                xField="expenses"
                displayName="--==Expenses==--"/>
        </mx:series>
     </mx:BarChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

You can also name the axis to display labels in the DataTip by using the `displayName` property. When the axis has a name, this name appears in the DataTip in italic font before the label data, as the following image shows:



In some cases, you add an axis solely for the purpose of adding the label to the DataTip. The following example names both axes so that both data points are labeled in the DataTip:

```
<?xml version="1.0"?>
<!-- charts/DataTipsAxisNames.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">

    <fx:Declarations>
        <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
         <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
         <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
     <s:Panel title="Bar Chart">
        <s:layout>
```

```
            <s:VerticalLayout/>
        </s:layout>
         <mx:BarChart id="myChart"
            dataProvider="{srv.lastResult.data.result}"
            showDataTips="true">
            <mx:verticalAxis>
               <mx:CategoryAxis categoryField="month"
                    displayName="Month"/>
            </mx:verticalAxis>
            <mx:horizontalAxis>
               <mx:LinearAxis displayName="Amount"/>
            </mx:horizontalAxis>
            <mx:series>
               <mx:BarSeries
                    yField="month"
                    xField="profit"
                    displayName="Profit"/>
               <mx:BarSeries
                    yField="month"
                    xField="expenses"
                    displayName="Expenses"/>
            </mx:series>
         </mx:BarChart>
         <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

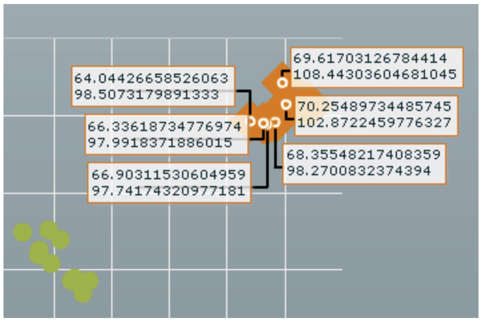
Showing multiple DataTip objects

You can display more than one DataTip by using the `dataTipMode` property on the chart control. The display options are `single` and `multiple`. When `dataTipMode` is set to `multiple`, the chart displays all DataTip objects within range of the cursor. The following example sets the value of a ColumnChart control's `dataTipMode` property to `multiple`:

```
<?xml version="1.0"?>
<!-- charts/DataTipsMultiple.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
        <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
         <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
         <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Bar Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:BarChart id="myChart"
```

```
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true"
        mouseSensitivity="50"
        dataTipMode="multiple">
        <mx:verticalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:verticalAxis>
        <mx:series>
           <mx:BarSeries
                yField="month"
                xField="profit"
                displayName="Profit"/>
           <mx:BarSeries
                yField="month"
                xField="expenses"
                displayName="Expenses"/>
        </mx:series>
     </mx:BarChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

The following example shows DataTip objects when the `dataTipMode` property is set to `multiple`:



The default value of `dataTipMode` depends on the chart type. Its setting is based on the likelihood that there are overlapping DataTip objects in that chart type. The default value of the `dataTipMode` property for the following chart types is `single`:

- BarChart
- CandlestickChart
- ColumnChart
- HLOCChart
- PieChart

The default value is `multiple` for the `dataTipMode` property for all other chart types.

To determine the size of the interactive area around a data point, you set the `mouseSensitivity` property. The `mouseSensitivity` property configures the distance, in pixels, around the data points where Flex reacts to mouse events such as `click` and `mouseOver`. With this property, you can trigger DataTip objects to appear when the user moves the mouse pointer *near* the data point rather than *onto* the data point. For more information, see “Changing mouse sensitivity” on page 1335.

You can also show all the available data tips on a chart at one time by setting the value of the chart control's `showAllDataTips` property to `true`. The result is that all data tips are visible at all times. When you do this, you typically set the value of the `showDataTips` property to `false` so that a second data tip does not appear when you mouse over a chart item.

Customizing DataTip values

You can customize the text displayed in a DataTip by using the `dataTipFunction` callback function. When you specify a `dataTipFunction` callback function, you can access the data of the DataTip before Flex renders it and customizes the text.

The argument to the callback function is a HitData object. As a result, you must import mx.charts.HitData when using a DataTip callback function.

Flex displays whatever the callback function returns in the DataTip box. You must specify a String as the callback function's return type.

The following example defines a new callback function, `dtFunc`, that returns a formatted value for the DataTip:

```
<?xml version="1.0"?>
<!-- charts/CustomDataTips.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">

    <fx:Declarations>
        <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
         <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
         <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
  <fx:Script><![CDATA[
     import mx.charts.HitData;
     public function dtFunc(hd:HitData):String {
        return hd.item.month + ": " +
        "<B>$" + hd.item.profit + "</B>";
     }
  ]]></fx:Script>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Bar Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:BarChart id="myChart"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true"
        dataTipFunction="dtFunc">
        <mx:verticalAxis>
           <mx:CategoryAxis categoryField="month" displayName="Month"/>
        </mx:verticalAxis>
        <mx:horizontalAxis>
           <mx:LinearAxis displayName="Amount"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:BarSeries
                yField="month"
                xField="profit"
                displayName="Profit"/>
           <mx:BarSeries
                yField="month"
                xField="expenses"
                displayName="Expenses"/>
        </mx:series>
     </mx:BarChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

You can also use the HitData object to get information about the series in which that data item appears. To do this, you cast the HitData object to a Series class, as the following example shows:

```
<?xml version="1.0"?>
<!-- charts/HitDataCasting.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">

    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
  <fx:Script><![CDATA[
     import mx.charts.HitData;
     import mx.charts.series.ColumnSeries;
     public var b:Boolean = true;
     public function myDataTipFunction(e:HitData):String {
        var s:String;
        s = ColumnSeries(e.element).displayName + "\n";
        s += "Profit: $" + (e.item.profit - e.item.expenses);
        return s;
     }
  ]]></fx:Script>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Casting HitData Objects">
        <s:layout>
```

```
            <s:VerticalLayout/>
        </s:layout>
     <mx:ColumnChart id="myChart"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true"
        dataTipFunction="myDataTipFunction">
        <mx:horizontalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:ColumnSeries
                yField="profit"
                displayName="Income '09"/>
           <mx:ColumnSeries
                yField="expenses"
                displayName="Expenses '09"/>
        </mx:series>
     </mx:ColumnChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

The series item is also accessible from the HitData object in a custom DataTip function. The `chartItem` property refers to an instance of a subclass of the ChartItem class. The type depends on the series type; for example, the `chartItem` for a ColumnSeries is an instance of the ColumnSeriesItem class.

In the following example, the `yValue` of the ColumnSeriesItem represents the percentage which a series takes up in a 100% chart:

```
<?xml version="1.0"?>

For more information on using the HitData object of chart events, see "Using the HitData object" on page 1327.

The DataTip callback function can render simple HTML for formatted DataTip objects. Flex supports a small subset of HTML tags including `<FONT>`, `<B>`, `<I>`, and `<BR>`.

Creating custom DataTip renderers

You can create a custom class that defines the appearance of the data tip. This class must implement the IFlexDisplayObject and IDataRenderer interfaces.

You typically create a custom ActionScript class that extends DataTip, and override the `updateDisplayList()` method. In the `updateDisplayList()` method, you define the appearance of the box for the data tip and apply styles that apply to the text for the data tip.

The following example class creates a custom data tip:

```
// charts/MyDataTip.as
package {
    import mx.charts.chartClasses.DataTip;
    import mx.charts.*;
    import flash.display.*;
    import flash.geom.Matrix;

    public class MyDataTip extends DataTip {
        public function MyDataTip() {
            super();
        }

        override protected function updateDisplayList(w:Number, h:Number):void {
            super.updateDisplayList(w, h);

            this.setStyle("textAlign","center");
            var g:Graphics = graphics;
            g.clear();
            var m:Matrix = new Matrix();
            m.createGradientBox(w+100,h,0,0,0);
            g.beginGradientFill(GradientType.LINEAR,[0xFF0000,0xFFFFFF],
                [.1,1],[0,255],m,null,null,0);
            g.drawRect(-50,0,w+100,h);
            g.endFill();
        }
    }
}
```

To use the custom data tip, you set the value of the `dataTipRenderer` style property of the chart control to the custom class. The following sample application applies the custom data tip to the chart control.

```
<?xml version="1.0"?>
<!-- charts/CustomDataTipRenderer.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send();applyCustomDataTips();"
    height="600">
    <fx:Declarations>
        <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
          <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
          <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
  <fx:Script><![CDATA[
    private function applyCustomDataTips():void {
        myChart.setStyle("dataTipRenderer",MyDataTip);
    }
  ]]></fx:Script>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Bar Chart">
        <s:layout>
```

```
            <s:VerticalLayout/>
        </s:layout>
     <mx:BarChart id="myChart"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true">
        <mx:verticalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:verticalAxis>
        <mx:series>
           <mx:BarSeries
                yField="month"
                xField="profit"
                displayName="Profit"/>
           <mx:BarSeries
                yField="month"
                xField="expenses"
                displayName="Expenses"/>
        </mx:series>
     </mx:BarChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

If you want to prevent the data tip's box from displaying when you mouse over a chart item, you can set the `dataTipRenderer` style property to a dummy class, such as ProgrammaticSkin; for example:

```
myChart.setStyle("dataTipRenderer",mx.skins.ProgrammaticSkin);
```

If you want to change the text of the data tip, you use the `dataTipFunction` callback function on the chart control, as described in "Customizing DataTip values" on page 1294.

Using per-item fills

You can customize the appearance of chart items in a series by using the `fillFunction` property to define the fill. This function takes the chart item and its index as arguments, so that you can examine the chart item's data values and return a fill based on whatever criteria you choose to use.

Programmatically assigning fills lets you set a threshold for color values, or conditionalize the colors of your chart items. For example, if the size of a pie wedge is greater than 25%, make it red, or if a column's value is greater than 100, make it green.

You set the value of the `fillFunction` property on each series, so if you have multiple series, you can have multiple fill functions, or all series can share the same fill function.

The signature of the `fillFunction` is as follows:

```
function_name(element:ChartItem, index:Number):IFill { ... }
```

The following table describes the arguments:

Argument	Description
element	The chart item for which the fill is created; type ChartItem.
index	The index of the chart item in the RenderData object's cache. This is different from the index of the chart's data provider because it is sorted based on the x, y, and z values; type Number.

The fillFunction property returns a Fill object (an object that implements the IFill interface). This object is typically an instance of the SolidColor class, but it can also be of type BitmapFill, LinearGradient, or RadialGradient. For information on working with gradients, see “Using gradient fills with chart controls” on page 1206.

The returned fill from a fillFunction takes precedence over fills that are set with traditional style methods. For example, if you set the value of the fill or fills property of a series and also specify a fillFunction, the fills are ignored and the fill returned by the fillFunction is used when rendering the chart items in the series.

The following example compares the value of the yField in the data provider when it fills each chart item. If the yField value (corresponding to the CurrentAmount field) is greater than $50,000, the column is green. If it is less than $50,000, the column is red.

           </mx:fill>
           <mx:stroke>
            <mx:SolidColorStroke color="0x000000" weight="1"/>
           </mx:stroke>
         </mx:LegendItem>
     </mx:Legend>
  </s:Panel>
</s:Application>
```

This example defines custom entries in the Legend. If you use the `fillFunction` property to define the fills of chart items, and you want a Legend control in your chart, you must manually create the Legend object and its LegendItem objects. For more information on creating Legend and LegendItem objects, see “Using Legend controls” on page 1316.

The color returned by the fill function is used by the itemRenderer for the series. In the case of the ColumnSeries and BarSeries classes, this is the column or bar in the chart. For LineSeries and AreaSeries classes, however, the renderer is used on the line itself. As a result, the color is applied only if you define a custom itemRenderer (such as a CircleItemRenderer or DiamondItemRenderer), and then it is applied only to the that renderer (such as the color inside the diamond) along the line of those series, not to the fill area below the line as you might expect.

By using the `index` argument that is passed to the fill function, you can also access other items inside the same series.

The following example sets the color of the fill to green for only the columns whose item value is greater than the previous item’s value. Otherwise, it sets the color of the fill to red.

            <mx:SolidColor color="0xFF0000"/>
           </mx:fill>
           <mx:stroke>
            <mx:SolidColorStroke color="0x000000" weight="1"/>
           </mx:stroke>
         </mx:LegendItem>
     </mx:Legend>
  </s:Panel>
</s:Application>
```

This example defines custom entries in the Legend because using a `fillFunction` prevents you from using an automatically generated Legend. For more information on creating Legend objects, see "Using Legend controls" on page 1316.

You can compare the values of data in a chart item to other values in the same or different series. The following example compares the value of the current amount of sales in the currentSalesSeries series against the sales goal in the salesGoalSeries series. If the goal is met or exceeded, the column is green. If the goal is not yet met, the negative difference between the goal and the actual sales is red.

     <mx:ColumnChart id="myChart"
        dataProvider="{sales}"
        type="overlaid"
        showDataTips="true">
        <mx:horizontalAxis>
           <mx:CategoryAxis
                title="Sales Person"
                categoryField="Name"/>
        </mx:horizontalAxis>
        <mx:verticalAxis>
            <mx:LinearAxis title="Sales (in $USD)"/>
        </mx:verticalAxis>

        <mx:series>
           <mx:ColumnSeries id="salesGoalSeries"
                xField="Name"
                yField="SalesGoal"
                fillFunction="myFillFunction"
                displayName="Sales Goal">
           </mx:ColumnSeries>
           <mx:ColumnSeries id="currSalesSeries"
                xField="Name"
                yField="CurrentAmount"
                displayName="Current Sales">
                <mx:fill>
                    <mx:SolidColor color="0x00FF00"/>
                </mx:fill>
           </mx:ColumnSeries>
        </mx:series>
     </mx:ColumnChart>
     <mx:Legend>
```

```
        <mx:LegendItem label="Current Sales" fontWeight="bold">
           <mx:fill>
            <mx:SolidColor color="0x00FF00"/>
           </mx:fill>
           <mx:stroke>
            <mx:SolidColorStroke color="0x000000" weight="1"/>
           </mx:stroke>
        </mx:LegendItem>
        <mx:LegendItem label="Missed Goal" fontWeight="bold">
           <mx:fill>
            <mx:SolidColor color="0xFF0000"/>
           </mx:fill>
           <mx:stroke>
            <mx:SolidColorStroke color="0x000000" weight="1"/>
           </mx:stroke>
         </mx:LegendItem>
     </mx:Legend>
     <s:Button click="showDataPoints()" label="Show Data"/>
  </s:Panel>
</s:Application>
```

You can access data from other series inside a series's fill function, but only if the other series has been rendered. If you were to rearrange the order of the series in the previous example, Flash would throw an error because the second series has not yet been rendered when the fill function is called.

Using the minField property

Some series types let you specify a minimum value for the elements drawn on the screen. For example, in a ColumnChart control, you can specify the base value of the column. To specify a base value (or minimum) for the column, set the value of the series object's `minField` property to the data provider field.

You can specify the `minField` property for the following chart series types:

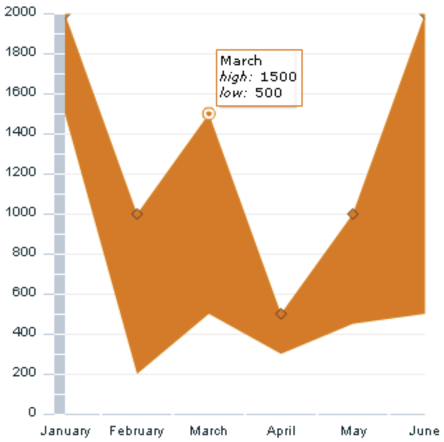
- AreaSeries
- BarSeries
- ColumnSeries

Setting a value for the `minField` property creates two values on the axis for each data point in an area; for example:

```
<?xml version="1.0"?>
<!-- charts/MinField.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">

    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses 
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to 
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Area Chart">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
     <mx:AreaChart id="myChart" 
        dataProvider="{srv.lastResult.data.result}" 
        showDataTips="true">
        <mx:horizontalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:AreaSeries 
                yField="profit" 
                minField="expenses" 
                displayName="Profit"/>
        </mx:series>
     </mx:AreaChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

The resulting DataTip labels the current value “high” and the `minField` value “low.” The following example shows an AreaChart that defines the base of each column:



For an example of using the `minField` property to create a waterfall or cascading ColumnChart control, see “Using column charts” on page 1137.

You can also use the `baseAtZero` property to determine whether or not the axis starts at zero. Set this property to `true` to start the axis at zero; set it to `false` to let Flex determine a reasonable starting value relative to the values along the axis.

Stacking charts

When you use multiple data series in the AreaChart, BarChart, and ColumnChart controls, you can control how Flex displays the series using the `type` property of the controls. The following table describes the values that the `type` property supports:

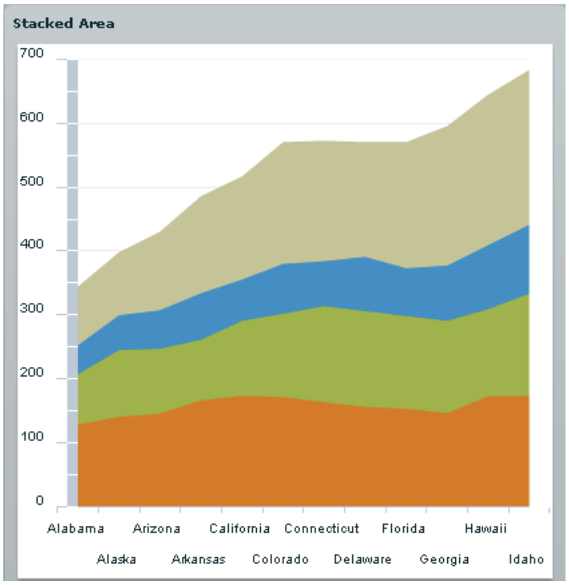
Property	Description
`clustered`	Chart elements for each series are grouped by category. This is the default value for BarChart and ColumnChart controls.
`overlaid`	Chart elements for each series are rendered on top of each other, with the element corresponding to the last series on top. This is the default value for AreaChart controls.
`stacked`	Chart elements for each series are stacked on top of each other. Each element represents the cumulative value of the elements beneath it.
`100%`	Chart elements are stacked on top of each other, adding up to 100%. Each chart element represents the percentage that the value contributes to the sum of the values for that category.

The following example creates an AreaChart control that has four data series, stacked on top of each other:

```
<?xml version="1.0"?>
<!-- charts/AreaStacked.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">

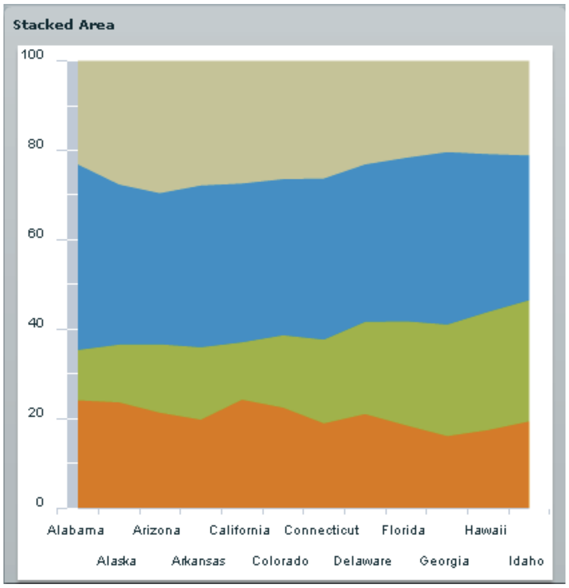
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Stacked AreaChart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:AreaChart id="myChart"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true"
        type="stacked">
        <mx:horizontalAxis>
           <mx:CategoryAxis categoryField="Month"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:AreaSeries yField="profit" displayName="Profit"/>
           <mx:AreaSeries yField="expenses" displayName="Expenses"/>
           <mx:AreaSeries yField="amount" displayName="Amount"/>
        </mx:series>
     </mx:AreaChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

The following example shows a stacked AreaChart control:



With an overlay, the last series appears on top, and can obscure the data series below it unless you use the `alpha` property of the fill to make it transparent. For more information, see "Using fills with chart controls" on page 1197.

If you set the `type` property to 100%, the control draws each series stacked on top of each other, adding up to 100% of the area. Each column represents the percentage that the value contributes to the sum of the values for that category, as the following example shows:



You can use the ColumnSet, BarSet, and AreaSet classes to combine groups of chart series, and thereby use different types of series within the same chart. The following example uses BarSet classes to combine clustered and stacked BarSeries in a single chart. The example shows how to do this in MXML and ActionScript:

```
<?xml version="1.0"?>
<!-- charts/UsingBarSets.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp()"
    height="1050" width="600">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <fx:Script><![CDATA[
     import mx.charts.Legend;
     import mx.charts.BarChart;
     import mx.charts.series.BarSet;
     import mx.charts.series.BarSeries;
     import mx.collections.ArrayCollection;
     [Bindable]
     private var yearlyData:ArrayCollection = new ArrayCollection([
        {month:"January", revenue:120, costs:45,
            overhead:102, oneTime:23},
        {month:"February", revenue:108, costs:42,
            overhead:87, oneTime:47},
        {month:"March", revenue:150, costs:82,
            overhead:32, oneTime:21},
        {month:"April", revenue:170, costs:44,
            overhead:68},
        {month:"May", revenue:250, costs:57,
            overhead:77, oneTime:17},
        {month:"June", revenue:200, costs:33,
            overhead:51, oneTime:30},
        {month:"July", revenue:145, costs:80,
            overhead:62, oneTime:18},
        {month:"August", revenue:166, costs:87,
            overhead:48},
        {month:"September", revenue:103, costs:56,
            overhead:42},
        {month:"October", revenue:140, costs:91,
            overhead:45, oneTime:60},
        {month:"November", revenue:100, costs:42,
            overhead:33, oneTime:67},
        {month:"December", revenue:182, costs:56,
            overhead:25, oneTime:48},
        {month:"May", revenue:120, costs:57,
            overhead:30}
     ]);
     private function initApp():void {
        var c:BarChart = new BarChart();
        c.dataProvider = yearlyData;
        c.showDataTips = true;
        var vAxis:CategoryAxis = new CategoryAxis();
        vAxis.categoryField = "month";
        c.verticalAxis = vAxis;

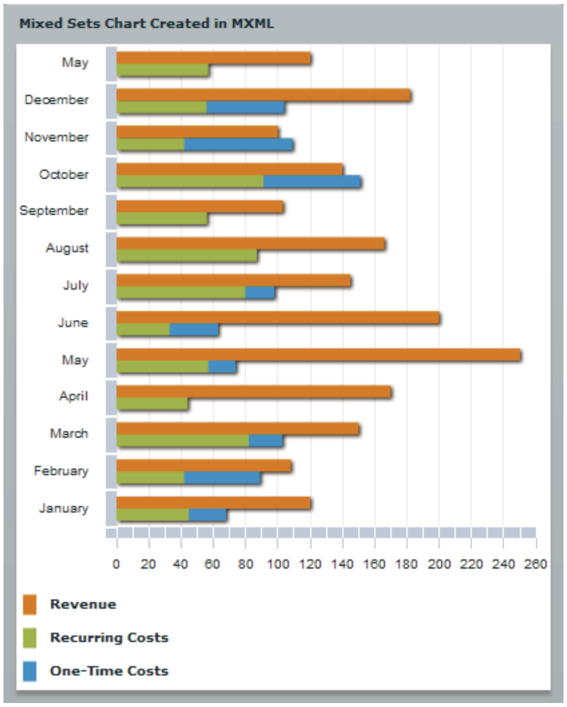
            <mx:BarSet type="clustered">
                <mx:BarSeries xField="revenue"
                    displayName="Revenue"/>
                <mx:BarSet type="stacked">
                    <mx:BarSeries
                        xField="costs"
                        displayName="Recurring Costs"/>
                    <mx:BarSeries
                        xField="oneTime"
                        displayName="One-Time Costs"/>
                </mx:BarSet>
            </mx:BarSet>
        </mx:series>
     </mx:BarChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
  <s:Panel title="Mixed Sets Chart Created in ActionScript" id="panel2">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  </s:Panel>
</s:Application>
```

The resulting chart shows two clustered series; one is a standalone series, and the other is a stacked series, as the following example shows:



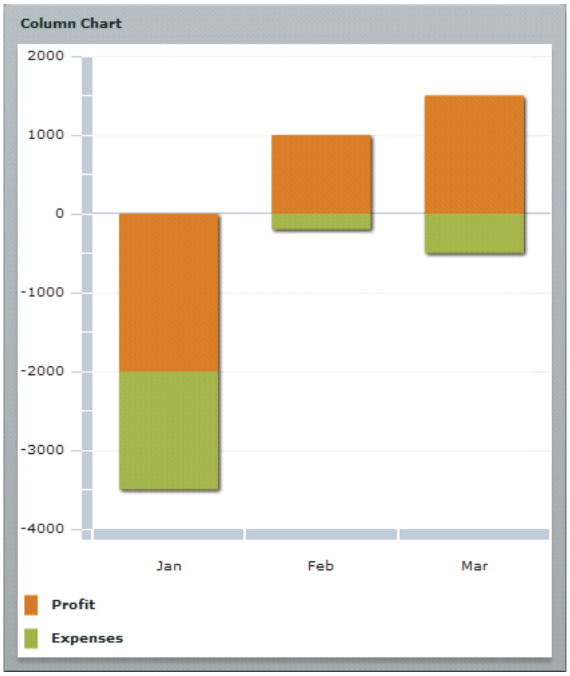
Normally, the values in stacked series are additive, which means that they are all added to one another to create an ever larger data item (column or bar or area). When one or more values is negative, the rendering of the data items can be unpredictable because adding a negative value would normally take away from the data item. You can also use the `allowNegativeForStacked` property of the AreaSet, BarSet, and ColumnSet classes to let a stacked series include data with negative values, and thereby render negative data items that are properly stacked.

The following example stacks the Profit and Expenses fields, in which some of the values are negative.

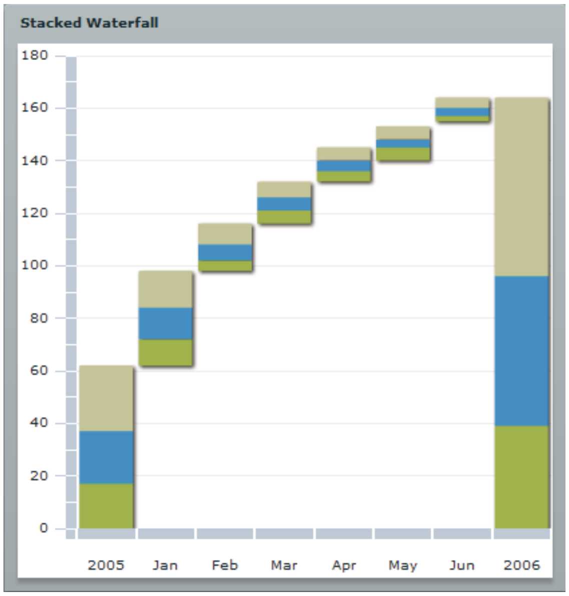
```
<?xml version="1.0"?>
<!-- charts/StackedNegative.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    height="600">
  <fx:Script><![CDATA[
     import mx.collections.ArrayCollection;
     [Bindable]
     public var expenses:ArrayCollection = new ArrayCollection([
        {Month:"Jan", Profit:-2000, Expenses:-1500},
        {Month:"Feb", Profit:1000, Expenses:-200},
        {Month:"Mar", Profit:1500, Expenses:-500}
     ]);
  ]]></fx:Script>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Column Chart">
```

```
     <s:layout>
         <s:HorizontalLayout/>
     </s:layout>
     <mx:ColumnChart id="myChart"
        dataProvider="{expenses}"
        showDataTips="true">
        <mx:horizontalAxis>
           <mx:CategoryAxis
                dataProvider="{expenses}"
                categoryField="Month"/>
        </mx:horizontalAxis>
        <mx:series>
            <mx:ColumnSet type="stacked"
                allowNegativeForStacked="true">
                <mx:series>
                    <mx:ColumnSeries
                        xField="Month"
                        yField="Profit"
                        displayName="Profit"/>
                    <mx:ColumnSeries
                        xField="Month"
                        yField="Expenses"
                        displayName="Expenses"/>
                </mx:series>
            </mx:ColumnSet>
        </mx:series>
     </mx:ColumnChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

The resulting chart shows three months of data, with all expenses and some income data rendering in negative values:



You can create cascading or waterfall column charts by using the ColumnChart control. One way to do this is to create an invisible series and to use that to set the variable height of the other columns, creating the waterfall effect. The following is an example of a waterfall chart:



The following code creates this chart:

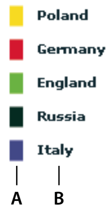
```
<?xml version="1.0"?>
<!-- charts/WaterfallStacked.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    height="600">

  <fx:Script><![CDATA[
     import mx.collections.ArrayCollection;
     [Bindable]
     public var expenses:ArrayCollection = new ArrayCollection([
        {Month:"2005", top:25, middle:20, bottom:17, Invisible:0},
        {Month:"Jan", top:14, middle:12, bottom:10, Invisible:62},
        {Month:"Feb", top:8, middle:6, bottom:4, Invisible:98},
        {Month:"Mar", top:6, middle:5, bottom:5, Invisible:116},
        {Month:"Apr", top:5, middle:4, bottom:4, Invisible:132},
        {Month:"May", top:5, middle:3, bottom:5, Invisible:140},
        {Month:"Jun", top:4, middle:3, bottom:2, Invisible:155},
        {Month:"2006", top:68, middle:57, bottom:39, Invisible:0}
     ]);
  ]]></fx:Script>

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Stacked Waterfall">
     <s:layout>
         <s:HorizontalLayout/>
     </s:layout>
     <mx:ColumnChart id="myChart"
        dataProvider="{expenses}"
        columnWidthRatio=".9"
        showDataTips="true"
        type="stacked">
        <mx:horizontalAxis>
           <mx:CategoryAxis
                dataProvider="{expenses}"
                categoryField="Month"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:ColumnSeries yField="Invisible">
                <mx:fill>
                    <!--Set alpha to 0 to hide invisible column.-->
                    <mx:SolidColor color="0xFFFFFF" alpha="0"/>
                </mx:fill>
           </mx:ColumnSeries>
           <mx:ColumnSeries yField="bottom" displayName="Profit"/>
           <mx:ColumnSeries yField="middle" displayName="Expenses"/>
           <mx:ColumnSeries yField="top" displayName="Profit"/>
        </mx:series>
     </mx:ColumnChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

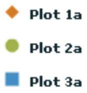
Using Legend controls

Legend controls match the fill patterns on your chart to labels that describe the data series shown with those fill patterns. Each entry in a Legend control is known as a legend item. A legend item contains two basic parts: the marker, and the label. Legend items are of type LegendItem. The following example shows the two parts of a legend item:



***A.** Marker **B.** Label*

In addition to matching fill patterns, legend markers also use the renderer classes of ChartItem objects, such as the points on a PlotChart control. The following example shows a Legend control for a PlotChart control with three series. Each series uses its own renderer class to draw a particular shape, and the Legend control reflects those shapes:



For information on styling Legend controls, see “Formatting Legend controls” on page 1241.

Scrollbars are not supported on Legend controls. If you want to add scrollbars, wrap your Legend control in a container, and add scrollbars to the container.

Adding a Legend control to your chart

You use the Legend class to add a legend to your charts. The Legend control displays the label for each data series in the chart and a key that shows the chart element for the series.

The simplest way to create a Legend control is to bind a chart to it by using the `dataProvider` property, as the following example shows:

```
<?xml version="1.0"?>
<!-- charts/LegendNamedSeries.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">

    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Bar Chart with Legend">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:BarChart id="myChart"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true">
        <mx:verticalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:verticalAxis>
        <mx:series>
           <mx:BarSeries
                xField="amount"
                displayName="Amount (in $USD)"/>
           <mx:BarSeries
                xField="profit"
                displayName="Profit (in $USD)"/>
           <mx:BarSeries
                xField="expenses"
                displayName="Expense (in $USD)"/>
        </mx:series>
     </mx:BarChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

You add a Legend to a chart in ActionScript by instantiating a new object of type Legend, and then calling the container's `addElement()` method to add the Legend to the container, as the following example shows:

```
<?xml version="1.0"?>
<!-- charts/LegendInAS.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">

    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx" result="createLegend()"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
  <fx:Script><![CDATA[
     import mx.charts.Legend;
     private function createLegend():void {
        var myLegend:Legend = new Legend();
        myLegend.dataProvider = myChart;
        panel1.addElement(myLegend);
     }
  ]]></fx:Script>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel id="panel1" title="Bar Chart with Legend (Created in ActionScript)">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:BarChart id="myChart"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true">
        <mx:verticalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:verticalAxis>
        <mx:series>
           <mx:BarSeries
                xField="amount"
                displayName="Amount (in $USD)"/>
           <mx:BarSeries
                xField="profit"
                displayName="Profit (in $USD)"/>
           <mx:BarSeries
                xField="expenses"
                displayName="Expense (in $USD)"/>
        </mx:series>
     </mx:BarChart>
  </s:Panel>
</s:Application>
```

The Legend control creates the legend using information from the chart control. It matches the colors and names of the LegendItem markers to the fills and labels of the chart's data series. In the previous example, Flex uses the BarSeries control's `displayName` property to define the LegendItem label.

Legend controls require that elements of the charts be named. If they are not named, the Legend markers appear, but without labels.

A Legend control for a PieChart control uses the `nameField` property of the data series to find values for the legend. The values that the `nameField` property point to must be Strings.

The following example sets the `nameField` property of a PieChart control's data series to `item`. Flex uses the value of the `item` field in the data provider in the Legend control.

```
<?xml version="1.0"?>
<!-- charts/LegendNameField.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/budget-
xml.aspx"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/budget.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Pie Chart with Legend">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:PieChart id="myChart"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true">
        <mx:series>
           <mx:PieSeries field="amount" nameField="item"/>
        </mx:series>
     </mx:PieChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

The `nameField` property also defines the series for the DataTip objects and labels.

Creating a custom Legend control

You can create a custom Legend control in MXML by defining the `<mx:Legend>` tag and populating it with `<mx:LegendItem>` tags. The following example creates a custom legend for the chart with multiple axes:

```
<?xml version="1.0"?>
<!-- charts/MultipleAxesWithCustomLegend.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv_fe.send();srv_strk.send();"
    height="600">
    <fx:Declarations>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/stocks.aspx -->
       <!-- View source of the following pages to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv_fe" url="http://aspexamples.adobe.com/chart_examples/stocks-
xml.aspx?tickerSymbol=FE"/>
       <mx:HTTPService id="srv_strk" url="http://aspexamples.adobe.com/chart_examples/stocks-
xml.aspx?tickerSymbol=STRK"/>
          <mx:SolidColorStroke id="h1Stroke"
                color="{feColor}"
                weight="8" alpha=".75"
                caps="square"/>
          <mx:SolidColorStroke id="h2Stroke"
                color="{strkColor}"
                weight="8" alpha=".75"
                caps="square"/>
    </fx:Declarations>
  <fx:Script><![CDATA[
    [Bindable]
    public var strkColor:Number = 0x224488;
    [Bindable]
    public var feColor:Number = 0x884422;
  ]]></fx:Script>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Column Chart With Multiple Axes">
     <s:layout>
         <s:VerticalLayout/>
     </s:layout>
     <mx:ColumnChart id="myChart" showDataTips="true">
        <mx:horizontalAxis>
           <mx:DateTimeAxis id="h1" dataUnits="days"/>
        </mx:horizontalAxis>
        <mx:horizontalAxisRenderers>
            <mx:AxisRenderer placement="bottom" axis="{h1}"/>
        </mx:horizontalAxisRenderers>
        <mx:verticalAxisRenderers>
            <mx:AxisRenderer placement="left" axis="{v1}">
                <mx:axisStroke>{h1Stroke}</mx:axisStroke>
            </mx:AxisRenderer>
            <mx:AxisRenderer placement="left" axis="{v2}">
                <mx:axisStroke>{h2Stroke}</mx:axisStroke>
            </mx:AxisRenderer>
        </mx:verticalAxisRenderers>
        <mx:series>
           <mx:ColumnSeries id="cs1"
                horizontalAxis="{h1}"
                dataProvider="{srv_fe.lastResult.data.result}"
                yField="close"
                xField="date"
                displayName="FE">
                <mx:fill>
                    <mx:SolidColor color="{feColor}"/>
                </mx:fill>
                <mx:verticalAxis>
                   <mx:LinearAxis id="v1"/>
                </mx:verticalAxis>
           </mx:ColumnSeries>
           <mx:LineSeries id="cs2"
                horizontalAxis="{h1}"
                dataProvider="{srv_strk.lastResult.data.result}"
                yField="close"
                xField="date"
                displayName="STRK">
                <mx:verticalAxis>
                    <mx:LinearAxis id="v2"/>
                </mx:verticalAxis>
                <mx:lineStroke>
                    <mx:SolidColorStroke
                        color="{strkColor}"
                        weight="4"
                        alpha="1"/>
                </mx:lineStroke>
           </mx:LineSeries>
        </mx:series>
     </mx:ColumnChart>
     <mx:Legend>
        <mx:LegendItem label="FE" fontWeight="bold">
           <mx:fill>
            <mx:SolidColor color="{feColor}"/>
           </mx:fill>
           <mx:stroke>
            <mx:SolidColorStroke color="0xCCCCCC" weight="2"/>
           </mx:stroke>
        </mx:LegendItem>
        <mx:LegendItem label="STRK" fontWeight="bold">
           <mx:fill>
            <mx:SolidColor color="{strkColor}"/>
           </mx:fill>
           <mx:stroke>
            <mx:SolidColorStroke color="0xCCCCCC" weight="2"/>
           </mx:stroke>
         </mx:LegendItem>
     </mx:Legend>
  </s:Panel>
</s:Application>
```

To create a custom Legend control in ActionScript, you create a container and add LegendItem objects to it. You then apply the appropriate styles and properties to the LegendItem objects. You can get each LegendItem's label and fill color from the corresponding series in the chart's series array.

The following example creates a custom legend in ActionScript. It lays the LegendItem objects out in a grid, with GridRows and GridItems. This example lets the user customize the number of LegendItem objects in each GridRow. You can use any layout container you want to get the desired appearance of your custom legend.

```
<?xml version="1.0"?>
<!-- charts/CustomLegendInActionScript.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="drawLegend()"
    height="600">

  <fx:Script><![CDATA[
     import mx.containers.GridItem;
     import mx.containers.GridRow;
     import mx.graphics.SolidColor;
     import mx.charts.LegendItem;
     import mx.collections.ArrayCollection;
     [Bindable]
     public var expenses:ArrayCollection = new ArrayCollection([
      {Expense:"Taxes", April:2000, May:321, June:131, July:1100, August:200, September:1400,
October:42},
        {Expense:"Rent", April:1000, May:95, June:313, July:600, August:400, September:200,
October:52},
        {Expense:"Taxes", April:2000, May:321, June:131, July:90, August:500, September:900,
October:300},
       {Expense:"Bills", April:100, May:478, June:841, July:400, August:600, September:1100,
October:150}
     ]);

     [Bindable]
     private var rowSize:int = 5;

     [Bindable]
     private var rowSizes:ArrayCollection = new ArrayCollection(
          [ {label:"1 Per Row", data:1},
            {label:"2 Per Row", data:2},
            {label:"3 Per Row", data:3},
            {label:"4 Per Row", data:4},
            {label:"5 Per Row", data:5},
            {label:"6 Per Row", data:6},
            {label:"7 Per Row", data:7} ]);

     private function drawLegend():void {
          clearLegend();
          // Use a counter for the series.
          var z:int = 0;
          var numRows:int;
          if (myChart.series.length % rowSize == 0) {
               // The number of series is exactly divisible by the rowSize.
               numRows = Math.floor(myChart.series.length / rowSize);
          } else {
               // One extra row is needed if there is a remainder.
               numRows = Math.floor(myChart.series.length / rowSize) + 1;
          }
          for (var j:int = 0; j < numRows; j++) {
          var gr:GridRow = new GridRow();
          myGrid.addChild(gr);

          for (var k:int = 0; k < rowSize; k++) {
               // As long as the series counter is less than the number of series...
               if (z < myChart.series.length) {
                    var gi:GridItem = new GridItem();
                    gr.addChild(gi);

                    var li:LegendItem = new LegendItem();

                    // Apply the current series' displayName to the LegendItem's label.
                    li.label = myChart.series[z].displayName;

                    // Get the current series' fill.
                    var sc:SolidColor = myChart.series[z].getStyle("fill");

                    // Apply the current series' fill to the corresponding LegendItem.
                    li.setStyle("fill", sc);

                    // Apply other styles to make the LegendItems look uniform.
                    li.setStyle("textIndent", 5);
                    li.setStyle("labelPlacement", "left");
                    li.setStyle("fontSize", 9);

                    gi.setStyle("backgroundAlpha", "1");
                    gi.setStyle("backgroundColor", sc.color);
                    gi.width = 80;

                    // Add the LegendItem to the GridItem.
                    gi.addChild(li);

                    // Increment any time a LegendItem is added.
                    z++;
               }
          }
          }
     }

     private function clearLegend():void {
          myGrid.removeAllChildren();
     }

     private function changeRowSize(e:Event):void {
          rowSize = ComboBox(e.target).selectedItem.data;
          drawLegend();
     }
  ]]></fx:Script>

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Custom Legend in Grid" width="500" height="750">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:BarChart id="myChart" dataProvider="{expenses}" height="400" showDataTips="true">
        <mx:verticalAxis>
           <mx:CategoryAxis dataProvider="{expenses}" categoryField="Expense"/>
        </mx:verticalAxis>
        <mx:series>
```

```
            <mx:BarSeries xField="April" displayName="April"/>
            <mx:BarSeries xField="May" displayName="May"/>
            <mx:BarSeries xField="June" displayName="June"/>
            <mx:BarSeries xField="July" displayName="July"/>
            <mx:BarSeries xField="August" displayName="August"/>
            <mx:BarSeries xField="September" displayName="September"/>
            <mx:BarSeries xField="October" displayName="October"/>
         </mx:series>
      </mx:BarChart>
      <mx:HRule width="100%"/>
      <mx:Grid id="myGrid"/>
      <mx:HRule width="100%"/>
      <s:HGroup>
           <s:Label text="Select the number of rows in the Legend."/>
           <s:ComboBox id="cb1"
                dataProvider="{rowSizes}"
                close="changeRowSize(event)" selectedIndex="4"/>
      </s:HGroup>
   </s:Panel>
</s:Application>
```

Note that in this example, you use the `addChild()` method to add the Legend to the Grid container. MX containers use the `addChild()` method, while Spark containers use the `addElement()` method.

Events and effects in charts

You can use Adobe® Flex® charting controls to make interesting and engaging charts. Important factors to consider are how users' interactions with your applications trigger effects and events.

Handling user interactions with charts

Chart controls accept many kinds of user interactions, from moving the mouse over a data point to clicking or double-clicking on that data point. You can create an event handler for each of these interactions and use the Event object in that handler to access the data related to that interaction. For example, if a user clicks on a column in a ColumnChart control, you can access that column's data in the click event handler of that chart.

The chart controls support the mouse events that are inherited from the UIComponent class: `mouseMove`, `mouseOver`, `mouseUp`, `mouseDown`, and `mouseOut`. These events are of type MouseEvent. In addition, the base class for all chart controls, ChartBase, adds support for the the ChartEvent and ChartItemEvent events.

The ChartItemEvent class defines events that are specific to the chart components, such as when the user clicks a data item in a chart. The ChartEvent class defines events that occur when the user clicks or double-clicks on a chart control, but not on a chart item in that chart control.

The following table describes the ChartEvent event types:

Chart event type	**Description**
`chartClick`	Broadcast when the user clicks the mouse button while the mouse pointer is over a chart but not on a chart item.
`chartDoubleClick`	Broadcast when the user double-clicks the mouse button while the mouse pointer is over a chart but not on a chart item.

The following table describes the ChartItemEvent event types:

Chart data event type	Description
`change`	Dispatched when the selected item or items changes in the chart.
`itemClick`	Broadcast when the user clicks the mouse button while over a data point.
`itemDoubleClick`	Broadcast when the user double-clicks the mouse button while over a data point.
`itemMouseDown`	Broadcast when the mouse button is down while over a data point.
`itemMouseMove`	Broadcast when the user moves the mouse pointer while over a data point.
`itemMouseUp`	Broadcast when the user releases the mouse button while over a data point.
`itemRollOut`	Broadcast when the closest data point under the mouse pointer changes.
`itemRollOver`	Broadcast when the user moves the mouse pointer over a new data point.

In addition to the ChartEvent and ChartItemEvent classes, there is also the LegendMouseEvent. This class defines events that are broadcast when the user clicks on legend items or mouses over them.

About chart events

Chart events are triggered when the user clicks or double-clicks the mouse button while the mouse pointer is over a chart control, but not over a chart item in that chart control. These events are dispatched only if the hit data set is empty.

Chart events are of type ChartEvent. Because ChartEvent events are part of the charts package, and not part of the events package, you must import the appropriate classes in the mx.charts.events package to use a ChartEvent event.

The following example logs a ChartEvent when you click or double-click the chart control, but only if you are not over a chart item or within it’s range, as determined by its `mouseSensitivity` property.

```
<?xml version="1.0"?>
<!-- charts/BasicChartEvent.mxml -->

               <mx:PlotSeries
                    xField="amount"
                    yField="expenses"
                    displayName="Plot 2"/>
               <mx:PlotSeries
                    xField="profit"
                    yField="amount"
                    displayName="Plot 3"/>
            </mx:series>
         </mx:PlotChart>
         <s:TextArea id="ta1" width="150" height="300"/>
       </s:HGroup>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

About chart data events

Chart data events are triggered only when the user moves the mouse pointer over a data point, whereas UIComponent events are triggered by any mouse interaction with a control.

The chart data events are of type ChartItemEvent. Because ChartItemEvent events are part of the charts package, and not part of the events package, you must import the appropriate classes in the mx.charts.events package to use a ChartItemEvent event.

The following example opens an alert when the user clicks a data point (a column) in the chart:

```
<?xml version="1.0"?>
<!-- charts/DataPointAlert.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
      <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
      <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
      <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
  <fx:Script><![CDATA[
     import mx.controls.Alert;
     import mx.charts.events.ChartItemEvent;
     public function myHandler(e:ChartItemEvent):void {
        Alert.show("Chart data was clicked");
     }
  ]]></fx:Script>

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Clickable Column Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:ColumnChart id="myChart"
        itemClick="myHandler(event)"
        dataProvider="{srv.lastResult.data.result}">
        <mx:horizontalAxis>
           <mx:CategoryAxis categoryField="month"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:ColumnSeries yField="expenses" displayName="Expenses"/>
        </mx:series>
     </mx:ColumnChart>
  </s:Panel>
</s:Application>
```

Using the HitData object

Flex dispatches a ChartItemEvent object for each chart data event such as when you click on an item in the series. In addition to the standard `target` and `type` properties that all Event objects have, Flex adds the `hitData` property to the ChartItemEvent object. This property is an object instance of the HitData class. The `hitData` property contains information about the data point that is closest to the mouse pointer at the time of the mouse event.

The item property of the HitData object refers to the data point. You can use that property to access its value by its name, as the previous example shows. The HitData*x* and *y* properties refer to the screen coordinates of the data point.

Only data points within the radius determined by the mouseSensitivity property can trigger an event on that data point. For more information, see “Changing mouse sensitivity” on page 1335.

The following example uses the itemDoubleClick event handler to display HitData information for data points in a column chart when the user clicks on a column. Because each column in the ColumnChart control is associated with a single data point value, clicking the mouse anywhere in a column displays the same information for the x and y coordinates.

```
<?xml version="1.0"?>
<!-- charts/HitDataOnClick.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send();init()"
    height="600">
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
  <fx:Script><![CDATA[
     import mx.charts.events.ChartItemEvent;
     // Define the event handler.
     public function myListener(e:ChartItemEvent):void {
        ti1.text = e.hitData.item.expenses;
        ti2.text = String(e.hitData.x) + ", " + String(e.hitData.y);
     }
     // Define event listeners when the application initializes.
     public function init():void {
        myChart.addEventListener(ChartItemEvent.ITEM_DOUBLE_CLICK, myListener);
     }
  ]]></fx:Script>

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Accessing HitData Object in Event Handlers">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>

        <!--Define a form to display the event information.-->
        <s:FormItem label="Expenses:">
           <s:TextInput id="ti1" width="100%"/>
        </s:FormItem>
        <s:FormItem label="x/y:">
           <s:TextInput id="ti2" width="100%"/>
        </s:FormItem>
     </s:Form>
  </s:Panel>
</s:Application>
```

Getting chart elements

The HitData object accesses the chart's ChartItem objects. These objects represent data points on the screen. In addition to providing access to the data of data points, ChartItem objects provide information about the size and position of graphical elements that make up the chart. For example, you can get the *x* and *y* positions of columns in a ColumnChart.

The following example uses a semitransparent Canvas container to highlight the data point that the user clicks on with the mouse. The application also accesses the ChartItem object to get the current value to display in a ToolTip on that Canvas:

```
<?xml version="1.0"?>
<!-- charts/ChartItemObjectAccess.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send();init()"
    height="600">

            alpha=".5"/>
</s:Application>
```

For information about changing the appearance of ChartItem objects, see “Skinning ChartItem objects” on page 1232.

Getting data with coordinates

When you create charts, you can use the coordinates on the screen to get the nearest data point or data points, or conversely, to pass the data point and get the coordinates.

The `findDataPoints()` and `localToData()` methods take coordinates and return data. The `findDataPoints()` method returns a HitData object. The `localToData()` method returns an Array of the data.

You can also pass the data itself and get the coordinates with the `dataToLocal()` method.

Using the findDataPoints() method

You can use the chart control’s `findDataPoints()` method to get an Array of HitData objects by passing in x and y coordinates. If the coordinates do not correspond to the location of a data point, the `findDataPoints()` method returns `null`. Otherwise, the `findDataPoints()` method returns an Array of HitData objects.

The `findDataPoints()` method has the following signature:

```
findDataPoints(x:Number, y:Number):Array
```

The following example creates a PlotChart control and records the location of the mouse pointer as the user moves the mouse over the chart. It uses the `findDataPoints()` method to get an Array of HitData objects, and then displays some of the first object’s properties.

```
<?xml version="1.0"?>
<!-- charts/FindDataPoints.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
        <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
         <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
         <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
  <fx:Script><![CDATA[
     import mx.charts.HitData;
     public function handleMouseMove(e:MouseEvent):void {
        // Use coordinates to get HitData object of
        // current data point.
        var hda:Array =
            chart.findDataPoints(e.currentTarget.mouseX,
            e.currentTarget.mouseY);
        if (hda[0]) {
           ta.text = "Found data point " +
                hda[0].chartItem.index + " (x/y):" +
                Math.round(hda[0].x) + "," +
                Math.round(hda[0].y) + "\n";
           ta.text += "Expenses:" + hda[0].item.expenses;
        } else {
           ta.text = "No data point found  (x/y):" +
                Math.round(e.currentTarget.mouseX) +
                "/" + Math.round(e.currentTarget.mouseY);
        }
     }
  ]]></fx:Script>
    <s:layout>
```

```
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Plot Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:PlotChart id="chart"
        mouseMove="handleMouseMove(event)"
        dataProvider="{srv.lastResult.data.result}"
        showDataTips="true"
        mouseSensitivity="5">
        <mx:series>
           <mx:PlotSeries
                xField="profit"
                yField="expenses"/>
        </mx:series>
     </mx:PlotChart>
  </s:Panel>
  <s:TextArea id="ta" width="300" height="50"/>
</s:Application>
```

Using the localToData() method

The `localToData()` method takes a Point object that represents the x and y coordinates you want to get the data for and returns an Array of data values, regardless of whether any data items are at or near that point. You call this method on the series.

The following example creates a Point object from the mouse pointer's location on the screen and displays the data values associated with that point:

```
<?xml version="1.0"?>
<!-- charts/LocalToData.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">

    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/stocks-
xml.aspx"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/stocks.aspx -->
    </fx:Declarations>
  <fx:Script><![CDATA[
     import mx.collections.ArrayCollection;
     public var p:Point;
     private function updateDetails(e:MouseEvent):void {
        p = new Point(myChart.mouseX, myChart.mouseY);
        mpos.text = "(" + p.x + "," + p.y + ")";
        var d:Array = series1.localToData(p);
        var da:Date = new Date(d[0]);

        // Round y coordinate value on column to two places.
        var v:Number = int((d[1])*100)/100;

        dval.text = "(" + daxis.formatForScreen(da) + ", " + v + ")";
        p = series1.dataToLocal(d[0], d[1]);
        dpos.text ="(" + Math.floor(p.x) + ", " + Math.floor(p.y) + ")";
     }
  ]]></fx:Script>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Column Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>

           <mx:ColumnSeries id="series1"
                xField="date"
                yField="close"
                displayName="Close"/>
        </mx:series>
     </mx:ColumnChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
  <s:Form width="300">
     <s:FormItem label="Mouse Position:">
        <s:Label id="mpos"/>
     </s:FormItem>
     <s:FormItem label="Data Position:">
        <s:Label id="dpos"/>
     </s:FormItem>
     <s:FormItem label="Data:">
        <s:Label id="dval"/>
     </s:FormItem>
  </s:Form>
</s:Application>
```

The chart type determines how coordinates are mapped, and how many values are returned in the Array. The values returned are typically numeric values.

In a chart that is based on the CartesianChart class (for example, a BarChart or ColumnChart control), the first item in the returned Array is the value of the *x*-coordinate along the horizontal axis, and the second item is the value of the *y*-coordinate along the vertical axis.

In a chart based on the PolarChart class (such as PieChart), the returned Array maps the coordinates to a set of polar coordinates—an angle around the center of the chart, and a distance from the center. Those values are mapped to data values that use the first (angular) and second (radial) axes of the chart.

Using the dataToLocal() method

The `dataToLocal()` method converts a set of values tox and y coordinates on the screen. The values you give the method are in the "data space" of the chart; this method converts these values to coordinates. The *data space* is the collection of all possible combinations of data values that a chart can represent.

The number and meaning of arguments passed to the `dataToLocal()` method depend on the chart type. For CartesianChart controls, such as the BarChart and ColumnChart controls, the first value is used to map along the x axis, and the second value is used to map along the y axis.

For PolarChart controls, such as the PieChart control, the first value maps to the angle around the center of the chart, and the second value maps to the distance from the center of the chart along the radius.

The coordinates returned are based on 0,0 being the upper-left corner of the chart. For a ColumnChart control, for example, the height of the column is inversely related to the x coordinate that is returned.

Changing mouse sensitivity

You use the `mouseSensitivity` property of the chart control to determine when the mouse pointer is considered to be over a data point; for example:

```
<mx:ColumnChart id="chart" dataProvider="{dataSet}" mouseSensitivity="30">
```

The current data point is the nearest data point to the mouse pointer that is less than or equal to the number of pixels that the `mouseSensitivity` property specifies.

The default value of the `mouseSensitivity` property is 3 pixels. If the mouse pointer is 4 or more pixels away from a data point, Flex does not trigger a ChartItemEvent (of types such as `itemRollOver` or `itemClick`). Flex still responds to events such as `mouseOver` and `click` by generating a ChartEvent object of type `chartClick` or `chartDoubleClick`.

The following example initially sets the `mouseSensitivity` property to 20, but lets the user change this value with the HSlider control:

```
<?xml version="1.0"?>
<!-- charts/MouseSensitivity.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">

                tickColor="black"
                snapInterval="1"
                tickInterval="20"
                labels="['0','300']"
                allowTrackClick="true"
                liveDragging="true"/>
        </s:VGroup>
      </s:HGroup>
  </s:Panel>
</s:Application>
```

You can use the `mouseSensitivity` property to increase the area that triggers DataTip events or emits chart-related events. If the mouse pointer is within the range of multiple data points, Flex chooses the closest data point. For DataTip events, if you have multiple DataTip controls enabled, Flex displays all DataTip controls within range. For more information, see “Showing multiple DataTip objects” on page 1292.

Disabling interactivity

You can make the series in a chart ignore all mouse events by setting the `interactive` property to `false` for that series. The default value is `true`. This lets you disable mouse interactions for one series while allowing it for another.

The following example disables interactivity for events on the first and third PlotSeries objects:

```
<?xml version="1.0"?>
<!-- charts/DisableInteractivity.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
        <!-- View source of the following page to see the structure of the data that Flex uses 
in this example. -->
         <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
         <!-- To see data in an HTML table, go to 
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Disable Interactivity">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:PlotChart id="myChart" 
        dataProvider="{srv.lastResult.data.result}" 
        showDataTips="true">
        <mx:series>
           <mx:PlotSeries 
                xField="expenses" 
                yField="profit" 
                displayName="Plot 1" 
                interactive="false"/>
           <mx:PlotSeries 
                xField="amount" 
                yField="expenses" 
                displayName="Plot 2"/>
           <mx:PlotSeries 
                xField="profit" 
                yField="amount" 
                displayName="Plot 3" 
                interactive="false"/>
        </mx:series>
     </mx:PlotChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

Disabling the series interactivity has the following results:

- The series does not show DataTip controls.
- The series does not generate a `hitData` structure on any chart data event.
- The series does not return a `hitData` structure when you call the `findDataPoints()` method on the chart.

Using effects with charts

Chart controls support the standard Flex effects such as Zoom and Fade. You can use these effects to make the entire chart control zoom in or fade out in your applications. In addition, chart data series support the following effect classes that apply to the data in the chart:

- SeriesInterpolate
- SeriesSlide
- SeriesZoom

These effects zoom or slide the chart items inside the chart control. These classes are in the mx.charts.effects.effects.* package. The base class for chart effects is SeriesEffect.

All chart controls and series support the standard Flex triggers and effects that are inherited from UIComponent. These triggers include `focusInEffect`, `focusOutEffect`, `moveEffect`, `showEffect`, and `hideEffect`. The charting controls also include the `showDataEffect` and `hideDataEffect` triggers.

For information on creating complex effects, see "Introduction to effects" on page 1784.

Using standard effect triggers

Chart controls support standard effects triggers, such as `showEffect` and `hideEffect`.

The following example defines a set of wipe effects that Flex executes when the user toggles the chart's visibility by using the Button control. Also, Flex fades in the chart when it is created.

```
<?xml version="1.0"?>
<!-- charts/StandardEffectTriggers.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
          <!-- Define the effects -->
          <mx:Parallel id="showEffects">
             <mx:WipeRight duration="2000"/>
             <mx:Fade alphaFrom="0" alphaTo="1" duration="4000"/>
          </mx:Parallel>
          <mx:Parallel id="hideEffects">
             <mx:Fade alphaFrom="1" alphaTo="0" duration="2500"/>
             <mx:WipeLeft duration="3000"/>
          </mx:Parallel>
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Area Chart with Effects">
     <s:layout>
```

```
            <s:HorizontalLayout/>
        </s:layout>
        <mx:AreaChart id="myChart"
           dataProvider="{srv.lastResult.data.result}"
           creationCompleteEffect="showEffects"
           hideEffect="hideEffects"
           showEffect="showEffects">
           <mx:horizontalAxis>
              <mx:CategoryAxis categoryField="month"/>
           </mx:horizontalAxis>
           <mx:series>
              <mx:AreaSeries yField="profit" displayName="Profit"/>
              <mx:AreaSeries yField="expenses" displayName="Expenses"/>
           </mx:series>
        </mx:AreaChart>
        <mx:Legend dataProvider="{myChart}"/>
    </s:Panel>
    <s:Button label="Toggle visibility"
      click="myChart.visible=!myChart.visible"/>
</s:Application>
```

A negative aspect of using standard effect triggers with charts is that the effects are applied to the entire chart control, and not just the data in the chart control. The result is that an effect such as Fade causes the chart's axes, gridlines, labels, and other chart elements, in addition to the chart's data, to fade in or out during the effect. To solve this, you use special charting effect triggers (see "Using charting effect triggers" on page 1339).

Using charting effect triggers

Charts have two unique effect triggers: `hideDataEffect` and `showDataEffect`. You set these triggers on the data series for the chart. Whenever the data for a chart changes, Flex executes these triggers in succession on the chart's data. The chart control's other elements, such as gridlines, axis lines, and labels are not affected by the effect.

The `hideDataEffect` trigger defines the effect that Flex uses as it hides the current data from view. The `showDataEffect` trigger defines the effect that Flex uses as it moves the current data into its final position on the screen.

Because Flex triggers the effects associated with `hideDataEffect` and `showDataEffect` when the data changes, there is "old" data and "new" data. The effect associated with the `hideDataEffect` trigger is the "old" data that will be replaced by the new data.

The order of events is:

1. Flex first uses the `hideDataEffect` trigger to invoke the effect set for each element of a chart that is about to change. These triggers execute at the same time.
2. Flex then updates the chart with its new data. Any elements (including the grid lines and axes) that do not have effects associated with them are updated immediately with their new values.
3. Flex then invokes the effect set with the `showDataEffect` trigger for each element associated with them. Flex animates the new data in the chart.

Charting effects with data series

Three effects classes are unique to charting: SeriesInterpolate, SeriesSlide, and SeriesZoom. You use these effects on a data series to achieve an effect when the data in that series changes. These effects can have a great deal of visual impact. Data series do not support other Flex effects.

The following example shows the SeriesSlide effect making the data slide in and out of a screen when the data changes. You can trigger changes to data in a chart series in many ways. Most commonly, you trigger an effect when the data provider changes for a chart control. In the following example, when the user clicks the button, the chart control's data provider changes, triggering the effect:

```
<?xml version="1.0"?>
<!-- charts/BasicSeriesSlideEffect.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv_fred.send();srv_strk.send()"
    height="600">
    <fx:Declarations>
         <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/stocks.aspx -->
         <!-- View source of the following pages to see the structure of the data that Flex
uses in this example. -->
       <mx:HTTPService id="srv_fred" url="http://aspexamples.adobe.com/chart_examples/stocks-
xml.aspx?tickerSymbol=FRED"/>
       <mx:HTTPService id="srv_strk" url="http://aspexamples.adobe.com/chart_examples/stocks-
xml.aspx?tickerSymbol=STRK"/>
        <!-- Define chart effects -->
        <mx:SeriesSlide
            id="slideIn"
            duration="1000"
            direction="up"/>
        <mx:SeriesSlide
            id="slideOut"
            duration="1000"
            direction="down"/>
    </fx:Declarations>
    <fx:Script><![CDATA[
        public function changeProvider():void {
            if (series1.displayName == "STRK") {
                myChart.dataProvider = srv_fred.lastResult.data.result;
                series1.displayName = "FRED";
                lbl.text = "Ticker: " + series1.displayName;
            } else {
                myChart.dataProvider = srv_strk.lastResult.data.result;
                series1.displayName = "STRK";
                lbl.text = "Ticker: " + series1.displayName;
            }
        }
    ]]></fx:Script>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:Panel title="Column Chart with Basic Series Slide Effect"
        height="493">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <s:Label id="lbl" text="Ticker: FRED"
            width="233.5" height="44"
            fontSize="24" color="#091D96"
            top="5" right="10"/>
        <mx:ColumnChart id="myChart"
            dataProvider="{srv_fred.lastResult.data.result}">
            <mx:horizontalAxis>
                <mx:DateTimeAxis dataUnits="days"/>
            </mx:horizontalAxis>
            <mx:verticalAxis>
                <mx:LinearAxis minimum="0" maximum="100"/>
            </mx:verticalAxis>
            <mx:series>
                <mx:ColumnSeries id="series1"
                    xField="date" yField="close"
                    displayName="FRED"
                    showDataEffect="slideIn"
                    hideDataEffect="slideOut"/>
            </mx:series>
        </mx:ColumnChart>
        <mx:Legend dataProvider="{myChart}" bottom="0"/>
    </s:Panel>
    <s:Button id="b1" click="changeProvider()" label="Toggle Ticker"/>
</s:Application>
```

This example explicitly defines the minimum and maximum values of the vertical axis. If not, Flex would recalculate these values when the new data provider was applied. The result could be a change in the axis labels during the effect.

Changing a data provider first triggers the `hideDataEffect` effect on the original data provider, which causes that data provider to "slide out," and then triggers the `showDataEffect` effect on the new data provider, which causes that data provider to "slide in."

Note: *If you set the data provider on the series and not the chart control, you must change it on the series and not the chart control.*

Another trigger of data effects is when a new data point is added to a series. The following example triggers the `showDataEffect` when the user clicks the button and adds a new item to the series' data provider:

```
<?xml version="1.0"?>
<!-- charts/AddItemEffect.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">

     <fx:Declarations>
        <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
         <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/widgets-
xml.aspx" result="resultHandler(event)"/>
         <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/widgets.aspx -->
        <!-- Define chart effect -->
        <mx:SeriesSlide id="slideIn"
            duration="1000"
            direction="up"
        />
    </fx:Declarations>
    <s:layout>
```

```
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script><![CDATA[
        import mx.collections.ArrayCollection;
          [Bindable]
          public var items:ArrayCollection;

        public function addDataItem():void {
            // Add a randomly generated value to
            // the data provider.
            var n:Number = Math.random() * 3000;
            var o:Object = {item: n};
            items.addItem(o);
        }

        private function resultHandler(e:Event):void {
          items = ArrayCollection(srv.lastResult.data.result);
        }
    ]]></fx:Script>
    <s:Panel title="Column Chart with Series Effect">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <mx:ColumnChart id="myChart" dataProvider="{items}">
            <mx:series>
                <mx:ColumnSeries yField="item"
                    displayName="Quantity"
                    showDataEffect="slideIn"/>
            </mx:series>
        </mx:ColumnChart>
    </s:Panel>
    <s:Button id="b1" click="addDataItem()" label="Add Data Item"/>
</s:Application>
```

This example casts the results of the HTTPService call to an ArrayCollection, so that you can add new items with the `addItem()` method. The new items are not added to the data on the server, but just in the local application's results ArrayCollection. For more information about changing charting data at run time, see "Changing chart data at run time" on page 1115.

The charting effects have several properties in common that traditional effects do not have. All of these properties are optional. The following table lists the common properties of the charting effects:

Property	**Description**
`duration`	The amount of time, in milliseconds, that Flash Player takes to complete the entire effect. This property defines the speed with which the effect executes. The `duration` property acts as a minimum duration. The effect can take longer based on the settings of other properties. The default value is 500.
`elementOffset`	The amount of time, in milliseconds, that Flash Player delays the effect on each element in the series. Set the `elementOffset` property to 0 to make all elements start at the same time and end at the same time. Set the `elementOffset` property to an integer such as 30 to stagger the effect on each element by that amount of time. For example, with a slide effect, the first element slides in immediately. The next element begins 30 milliseconds later, and so on. The amount of time for the effect to execute is the same for each element, but the overall duration of the effect is longer. Set the `elementOffset` property to a negative value to make the effect display the last element in the series first. The default value is 20.
`minimumElementDuration`	The amount of time, in milliseconds, that an individual element should take to complete the effect. Charts with a variable number of data points in the series cannot reliably create smooth effects with only the `duration` property. For example, an effect with a duration of 1000 and `elementOffset` of 100 takes 900 milliseconds per element to complete if you have two elements in the series. This is because the start of each effect is offset by 100, and each effect finishes in 1000 milliseconds. If there are four elements in the series, each element takes 700 milliseconds to complete (the last effect starts 300 milliseconds after the first and must be completed within 1000 milliseconds). With 10 elements, each element has only 100 milliseconds to complete the effect. The value of the `minimumElementDuration` property sets a minimal duration for each element. No element of the series takes less than this amount of time (in milliseconds) to execute the effect. As a result, it is possible for an effect to take longer than a specified duration if you specify at least two of the following three properties: `duration`, `offset`, and `minimumElementDuration`. The default value is 0, which means that the `duration` property is used to control the total length of time, in milliseconds, that Flex takes to complete the effect.
`offset`	The amount of time, in milliseconds, that Flash Player delays the start of the effect. Use this property to stagger effects on multiple series. The default value is 0.

Using the SeriesSlide effect

The SeriesSlide effect slides a data series into and out of the chart's boundaries. The SeriesSlide effect takes a `direction` property that defines the location from which the series slides. Valid values of `direction` are `left`, `right`, `up`, or `down`.

If you use the SeriesSlide effect with a `hideDataEffect` trigger, the series slides from the current position on the screen to a position off the screen, in the direction indicated by the `direction` property. If you use SeriesSlide with a `showDataEffect` trigger, the series slides from off the screen to a position on the screen, in the indicated direction.

When you use the SeriesSlide effect, the entire data series disappears from the chart when the effect begins. The data then reappears based on the nature of the effect. To keep the data on the screen at all times during the effect, you can use the SeriesInterpolate effect. For more information, see "Using the SeriesInterpolate effect" on page 1347.

The following example creates an effect called `slideDown`. Each element starts its slide 30 milliseconds after the element before it, and takes at least 20 milliseconds to complete its slide. The entire effect takes at least 1 second (1000 milliseconds) to slide the data series down. Flex invokes the effect when it clears old data from the chart and when new data appears.

```

            hideDataEffect="slideDown"/>
        </mx:series>
     </mx:ColumnChart>
  </s:Panel>
  <s:Button id="b1" click="addDataItem()" label="Add Data Item"/>
</s:Application>
```

Using the SeriesZoom effect

The SeriesZoom effect implodes and explodes chart data into and out of the focal point that you specify. As with the SeriesSlide effect, whether the effect is zooming to or from this point depends on whether it's used with a `showDataEffect` or `hideDataEffect` trigger.

The SeriesZoom effect can take several properties that define how the effect acts. The following table describes these properties:

Property	Description
`horizontalFocus` `verticalFocus`	Defines the location of the focal point of the zoom. You combine the `horizontalFocus` and `verticalFocus` properties to define the point from which the data series zooms in and out. For example, set the `horizontalFocus` property to `left` and the `verticalFocus` property to `top` to have the series data zoom to and from the upper-left corner of either element or the chart (depending on the setting of the `relativeTo` property). Valid values of the `horizontalFocus` property are `left`, `center`, `right`, and `undefined`. Valid values of the `verticalFocus` property are `top`, `center`, `bottom`, and `undefined`. If you specify only one of these two properties, the focus is a horizontal or vertical line rather than a point. For example, when you set the `horizontalFocus` property to `left`, the element zooms to and from a vertical line along the left edge of its bounding box. Setting the `verticalFocus` property to `center` causes the element to zoom to and from a horizontal line along the middle of its bounding box. The default value for both properties is `center`.
`relativeTo`	Controls the bounding box used to calculate the focal point of the zooms. Valid values for `relativeTo` are `series` and `chart`. Set the `relativeTo` property to `series` to zoom each element relative to itself. For example, each column of a ColumnChart zooms from the upper-left of the column. Set the `relativeTo` property to `chart` to zoom each element relative to the chart area. For example, each column zooms from the upper-left of the axes, the center of the axes, and so on.

The following example zooms in the data series from the upper-right corner of the chart. While zooming in, Flex displays the last element in the series first because the `elementOffset` value is negative.

```
<?xml version="1.0"?>
<!-- charts/SeriesZoomEffect.mxml -->

            hideDataEffect="zoomOut"/>
        </mx:series>
     </mx:ColumnChart>
  </s:Panel>
  <s:Button id="b1" click="addDataItem()" label="Add Data Item"/>
</s:Application>
```

When you use the SeriesZoom effect, the entire data series disappears from the chart when the effect begins. The data then reappears based on the nature of the effect. To have the data stay on the screen at all times during the effect, you can use the SeriesInterpolate effect. For more information, see “Using the SeriesInterpolate effect” on page 1347.

Using the SeriesInterpolate effect

The SeriesInterpolate effect moves the graphics that represent the existing data in the series to the new points. Instead of clearing the chart and then repopulating it as with SeriesZoom and SeriesSlide, this effect keeps the data on the screen at all times.

You use the SeriesInterpolate effect only with the `showDataEffect` effect trigger. It has no effect if set with a `hideDataEffect` trigger.

The following example sets the `elementOffset` property of the SeriesInterpolate effect to 0. As a result, all elements move to their new locations without disappearing from the screen.

```
<?xml version="1.0"?>
<!-- charts/SeriesInterpolateEffect.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/widgets-
xml.aspx" result="resultHandler(event)"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/widgets.aspx -->
      <!-- Define chart effect. -->
      <mx:SeriesInterpolate id="rearrangeData"
         duration="1000"
         minimumElementDuration="200"
         elementOffset="0"
      />
    </fx:Declarations>
  <fx:Script><![CDATA[
     import mx.collections.ArrayCollection;
     [Bindable]
     public var items:ArrayCollection;
     public function addDataItem():void {
        // Add a randomly generated value to the data provider.
        var n:Number = Math.random() * 3000;
        var o:Object = {item: n};
        items.addItem(o);
     }
     private function resultHandler(e:Event):void {
          items = ArrayCollection(srv.lastResult.data.result);
     }
  ]]></fx:Script>

  <s:Button id="b1" click="addDataItem()" label="Add Data Item"/>
</s:Application>
```

Applying chart series effects with ActionScript

You can define effects and apply them to chart series by using ActionScript. One way to apply an effect is the same as the way you apply style properties. You use the `setStyle()` method and Cascading Style Sheets (CSS) to apply the effect.

For more information on using styles, see “Styles and themes” on page 1492.

The following example defines the `slideIn` effect that plays every time the user adds a data item to the chart control’s ColumnSeries. The effect is applied to the series by using the `setStyle()` method when the application first loads.

```
<?xml version="1.0"?>
<!-- charts/ApplyEffectsAsStyles.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp();srv.send();"
    height="600">

    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/widgets-
xml.aspx" result="resultHandler(event)"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/widgets.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <fx:Script><![CDATA[
     import mx.collections.ArrayCollection;
     import mx.charts.effects.SeriesInterpolate;
     [Bindable]
     public var items:ArrayCollection;
     public var rearrangeData:SeriesInterpolate;
     public function initApp():void {
        rearrangeData = new SeriesInterpolate();
        rearrangeData.duration = 1000;
        rearrangeData.minimumElementDuration = 200;
        rearrangeData.elementOffset = 0;
        // Apply the effect as a style.
        mySeries.setStyle("showDataEffect", rearrangeData);
     }
     public function addDataItem():void {
        // Add a randomly generated value to the data provider.
        var n:Number = Math.random() * 3000;
        var o:Object = {item: n};
        items.addItem(o);
     }
     private function resultHandler(e:Event):void {
          items = ArrayCollection(srv.lastResult.data.result);
     }
  ]]></fx:Script>
  <s:Panel title="Column Chart with Series Interpolate Effect">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:ColumnChart id="myChart" dataProvider="{items}">
        <mx:series>
           <mx:ColumnSeries id="mySeries"
            yField="item" displayName="Quantity"/>
        </mx:series>
     </mx:ColumnChart>
  </s:Panel>
  <s:Button id="b1" click="addDataItem()" label="Add Data Item"/>
</s:Application>
```

When you define an effect in ActionScript, you must import the appropriate classes. If you define an effect by using MXML, the compiler imports the class for you.

Instead of applying effects with the `setStyle()` method, you can apply them with CSS if you predefine them in your MXML application; for example:

```
<?xml version="1.0"?>
<!-- charts/ApplyEffectsWithCSS.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send();"
    height="600">

    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses 
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/widgets-
xml.aspx" result="resultHandler(event)"/>
        <!-- To see data in an HTML table, go to 
http://aspexamples.adobe.com/chart_examples/widgets.aspx -->
        <!-- Define chart effect. -->
        <mx:SeriesSlide
            duration="1000"
            direction="down"
            minimumElementDuration="20"
            elementOffset="30"
            id="slideDown"/>
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <fx:Style>
     @namespace mx "library://ns.adobe.com/flex/mx";
     mx|ColumnSeries {
        showDataEffect:slideDown;
        hideDataEffect:slideDown;
     }
  </fx:Style>
  <fx:Script><![CDATA[
     import mx.collections.ArrayCollection;
     [Bindable]
     public var items:ArrayCollection;
     public function addDataItem():void {
        // Add a randomly generated value to the data provider.
        var n:Number = Math.random() * 3000;
        var o:Object = {item:n};
        items.addItem(o);
     }
     private function resultHandler(e:Event):void {
          items = ArrayCollection(srv.lastResult.data.result);
     }
  ]]></fx:Script>
  <s:Panel title="Column Chart with Custom Series Slide Effect">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
     <mx:ColumnChart id="myChart" dataProvider="{items}">
        <mx:series>
           <mx:ColumnSeries yField="item" displayName="Quantity"/>
        </mx:series>
     </mx:ColumnChart>
  </s:Panel>
  <s:Button id="b1" click="addDataItem()" label="Add Data Item"/>
</s:Application>
```

You can use controls such as a slider to let the user adjust the effect's properties. To bind the properties of an ActionScript object, such as an effect, to a control, you use methods of the BindingUtils class, as the following example shows:

```
<?xml version="1.0"?>
<!-- charts/ApplyEffectsWithActionScriptSlider.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp();srv.send();"
    height="750">

    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/widgets-
xml.aspx" result="resultHandler(event)"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/widgets.aspx -->
    </fx:Declarations>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <fx:Script><![CDATA[
     import mx.collections.ArrayCollection;
     import mx.charts.effects.SeriesInterpolate;
     import mx.binding.utils.BindingUtils;
     public var rearrangeData:SeriesInterpolate;

     [Bindable]
     public var items:ArrayCollection;
     public function initApp():void {
        rearrangeData = new SeriesInterpolate();
        // Bind effect properties to slider controls
        BindingUtils.bindProperty(rearrangeData, "duration", durationSlider, "value");
```

```
            BindingUtils.bindProperty(rearrangeData, "minimumElementDuration",
                minimumElementDurationSlider, "value");
            BindingUtils.bindProperty(rearrangeData, "elementOffset",
                elementOffsetSlider, "value");
        }
        public function addDataItem():void {
            // Add a randomly generated value to the data provider.
            var n:Number = Math.random() * 3000;
            var o:Object = {item: n};
            items.addItem(o);
        }
        public function resetSliders():void {
            durationSlider.value = 1000;
            minimumElementDurationSlider.value = 200;
            elementOffsetSlider.value = 0;
        }
        private function resultHandler(e:Event):void {
              items = ArrayCollection(srv.lastResult.data.result);
        }
    ]]></fx:Script>
    <s:Panel title="Column Chart with Series Interpolate Effect">

             </s:FormItem>
          </s:Form>
       </s:Panel>
       <s:Button id="b2" label="Reset Sliders" click="resetSliders()"/>
     </s:Application>
```

For more information about databinding in ActionScript, see “Defining data bindings in ActionScript” on page 318.

Drilling down into data

One common use of charts is to allow the user to drill down into the data. This usually occurs when the user performs some sort of event on the chart such as clicking on a wedge in a PieChart control or clicking on a column in a ColumnChart control. Clicking on a data item reveals a new chart that describes the make-up of that data item.

For example, you might have a ColumnChart control that shows the month-by-month production of widgets. To initially populate this chart, you might make a database call (through a service or some other adapter). If the user then clicks on the January column, the application could display the number of widgets of each color that were produced that month. To get the individual month’s widget data, you typically make another database call and pass a parameter to the listening service that describes the specific data you want. You can then use the resulting data provider to render the new view.

Typically, when you drill down into chart data, you create new charts in your application with ActionScript. When creating new charts in ActionScript, you must be sure to create a series, add it to the new chart’s series Array, and then call the `addElement()` method (on Spark containers) or `addChild()` method (on MX containers) to add the new chart to the display list. For more information, see “Creating charts in ActionScript” on page 1084.

One way to provide drill-down functionality is to make calls that are external to the application to get the drill-down data. You typically do this by using the chart’s `itemClick` event listener, which gives you access to the HitData object. The HitData object lets you examine what data was underneath the mouse when the event was triggered. This capability lets you perform actions on specific chart data. For more information, see “Using the HitData object” on page 1327.

You can also use a simple Event object to get a reference to the series that was clicked. The following example shows the net worth of a fictional person. When you click on a column in the initial view, the example drills down into a second view that shows the change in value of a particular asset class over time.

The following example uses the Event object to get a reference to the clicked ColumnSeries. It then drills down into the single ColumnSeries by replacing the chart’s series Array with the single ColumnSeries in the chart. When you click a column again, the chart returns to its original configuration with all ColumnSeries.

```

                <mx:ColumnSeries id="s5"
                    displayName="Other"
                    yField="other"
                    xField="date"
                    click="zoomIntoSeries(event)"/>
            </mx:series>
            <mx:horizontalAxis >
                <mx:DateTimeAxis title="Date" dataUnits="months"/>
            </mx:horizontalAxis>
        </mx:ColumnChart>
        <mx:Legend dataProvider="{chart}"/>
    </s:Panel>
</s:Application>
```

Another approach to drilling down into chart data is to use unused data within the existing data provider. You can do this by changing the properties of the series and axes when the chart is clicked.

The following example is similar to the previous example in that it drills down into the assets of a fictional person’s net worth. In this case, though, it shows the value of the asset classes for the clicked-on month in the drill-down view rather than the change over time of a particular asset class.

This example uses the HitData object’s `item` property to access the values of the current data provider. By building an Array of objects with the newly-discovered data, the chart is able to drill down into the series without making calls to any external services.

Drilling down into data is an ideal time to use effects such as SeriesSlide. This example also defines `seriesIn` and `seriesOut` effects to slide the columns in and out when the drilling down (and the return from drilling down) occurs.

```
<?xml version="1.0"?>

    </s:Panel>
</s:Application>
```

Another way to drill down into chart data is to use the selection API. You can select a subset of data points on a chart to create a new data provider. For more information, see “Selecting chart items” on page 1358.

Selecting chart items

As part of interacting with charts, you can select data points (ChartItem objects), examine the underlying data, and then perform actions on those objects. A ChartItem class represents a single entry in the chart series’ data provider. A series is made up of an Array of ChartItem objects.

To enable data point selection, you set the value of the `selectionMode` property on the chart. Possible values of this property are `none`, `single`, and `multiple`. Setting the `selectionMode` property to `none` prevents any data points in the chart from being selected. Setting `selectionMode` to `single` lets you select one data point at a time. Setting `selectionMode` to `multiple` lets you select one or more data points at a time. The default value is `none`.

You also toggle the series’ selectability by setting the value of the `selectable` property. As a result, while you might set the `selectionMode` on the chart to `multiple`, you can make the data points in some series selectable and others not selectable within the same chart by using the series’ `selectable` property.

Methods of chart item selection

You can programmatically select data points or the user can interactively select data points in the following ways:

- Mouse selection—Move the mouse pointer over a data point and click the left mouse button to select data points. For more information, see “Keyboard and mouse selection” on page 1362.
- Keyboard selection—Use the keyboard to select one or more data points, as described in “Keyboard and mouse selection” on page 1362.
- Region selection—Draw a rectangle on the chart. This rectangle defines the range, and selects all data points within that range. For more information, see “Region selection” on page 1362.
- Programmatic selection—Programmatically select one or more data points using the chart selection API. For more information, see “Programmatic selection” on page 1363.

When selecting chart items, you should also understand the following terms:

- *caret*—The current chart item that could be selected or deselected if you press the space bar. If you select multiple items, one at a time, the caret is the last item selected. If you selected multiple items by using a range, the caret is the last item in the last series in the selection. This is not always the item that was selected last.
- *anchor*—The starting chart item for a multiple selection operation.

The following example creates three different types of charts. You can select one or more data points in each chart using the mouse, keyboard, and region selection techniques. The example displays the data points in each series that are currently selected.

             <s:TextArea id="textArea3" height="100" width="213"/>
         </s:VGroup>
    </s:Panel>
</s:Application>
```

You can specify the colors that are used to indicate if an item is selected, disabled, or being rolled over. You do this by using the `itemSelectionColor`, `itemDisabledColor`, and `itemRollOverColor` style properties of the chart controls. The following example specifies different colors for these states for several chart types:

```
BarChart, PieChart, PlotChart {
    itemSelectionColor: red;
    itemDisabledColor: green;
    itemRollOverColor: blue;
}
```

Region selection

Users can select all data points in an area on a chart by drawing a rectangle (the *region*) on the chart. Users define a rectangular region by clicking and holding the mouse button while they move the mouse, drawing a rectangle on the chart. On the `MOUSE_UP` event, the items inside the rectangular region are selected. The starting point for a rectangular range must be over the chart. You cannot start the rectangle outside of the chart control's bounds.

To select data points with region selection, the value of the chart's `selectionMode` property must be `multiple`. If it is `single` or `none`, then you cannot draw the selection rectangle on the chart.

For most charts, as long as any point inside the rectangle touches a data point (for example, a column in a ColumnChart control), you select that data point. For BubbleChart and PieChart controls, an item is selected only if its center is inside the selection rectangle.

Keyboard and mouse selection

To select chart items, you can use the arrow keys, space bar, and enter key on your keyboard or the mouse pointer. If you want to select more than data point, the value of the chart's `selectionMode` property must be `multiple`.

Left and right arrow keys

You use the left and right arrows to move up and down the data in the series.

Click the left arrow to select the previous item and the right arrow to select the next item in the series. When you reach the last item in a series, you move to the first item in the next series.

Up and down arrow keys

Click the up and down arrow keys to move to the next or previous series on the chart.

Click the up arrow key to select the next series in the chart's series array. Click the down arrow key to select the previous series.

The index of the item in each series remains the same. If there is only one series in the chart, then click the up arrow key to select the first data point in the series; click the down arrow key to select the last data point in the series.

Shift and control keys

You can use the shift and control keys in conjunction with the other keys to select or deselect data points and change the caret in the selection.

Hold the shift key down while clicking the right arrow key to add the next data point to the selection until you reach the end of the series. Click the left arrow key to remove the last data point from the selection.

Hold the shift key down while clicking the up arrow key to select the first item in the next series. Click the down arrow key to select the last item in the previous series.

Hold the control key down while using the arrow keys to move the caret while not deselecting the anchor item. You can then select the new caret by pressing the space bar.

Space bar

Click the space bar to toggle the selection of the caret item, if the control key is depressed. A deselected caret item appears highlighted, but the highlight color is not the same as the selected item color.

Page Up/Home and Page Down/End keys

Click the Page Up/Home and Page Down/End keys to move to the first and last items in the current series, respectively. Moving to an item makes that item the caret item, but does not select it. You can press the space bar to select it.

Mouse pointer

The default behavior of the mouse pointer is to select the data point under the mouse pointer when you click the mouse button. This also de-selects all other data points.

If you click the mouse button and drag it over a chart, you create a rectangular region that defines a selection range. All data points inside that range are selected if the `selectionMode` property is set to `multiple`.

If you select a data point, then hold the shift key down and click on another data point, you select the first point, the target point, and all points that appear inside the rectangular range that you just created. If you select a data point, then hold the control key down and click another data point, you select both data points, but not the data points in between. You can add more individual data points by continuing to hold the control key down while you select another data point.

If you click anywhere on the chart that does not have a data point without any keys held down, then you clear the selection. Clicking outside of the chart control's boundary does not clear the selection.

Programmatic selection

You can use the chart selection APIs to programmatically select one or more data points in a chart control. These APIs consist of methods and properties of the ChartBase, ChartItem, and chart series objects.

Selections with multiple items include a caret and an anchor. You can access these items by using the `caretItem` and `anchorItem` properties of the chart control.

Properties of the series

The series defines which ChartItem objects are selected. You can programmatically select items by setting the values of the following properties of the series:

- `selectedItem`
- `selectedItems`
- `selectedIndex`
- `selectedIndices`

The index properties refer to the index of the chart item in the series. This index is the same as the index in the data provider, assuming you did not sort or limit the series items.

Programmatically setting the values of these properties does not trigger a `change` event.

The following example increments and decrements the series' `selectedIndex` property to select each item, one after the other, in the series:

```

To cycle through ChartItem objects in a series, you can use methods such as `getNextItem()` and `getPreviousItem()`. For more information, see “Methods and properties of the ChartBase class” on page 1369.

The `selectedIndices` property lets you select any number of ChartItems in a chart control. The following example uses the `selectedIndices` property to select all items in all series when the user presses the Ctrl+a keys on the keyboard:

```
<?xml version="1.0" ?>
<!--  charts/SelectAllItems.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send();initApp();"
    height="600">

    </s:Panel>
</s:Application>
```

Methods and properties of the ChartBase class

The ChartBase class is the parent class of all chart controls. You can programmatically access ChartItem objects by using the following methods of this class:

- `getNextItem()`
- `getPreviousItem()`
- `getFirstItem()`
- `getLastItem()`

These methods return a ChartItem object, whether it is selected or not. Which object is returned depends on which one is currently selected, and which direction constant (`ChartBase.HORIZONTAL` or `ChartBase.VERTICAL`) you pass to the method.

The following example uses these methods to cycle through the data points in a ColumnChart control. It sets the value of the series' `selectedItem` property to identify the new ChartItem as the currently selected item.

```

</s:Application>
```

These item getter methods do not have associated setters. You cannot set the selected ChartItem objects in the same manner. Instead, you use the properties of the series, as described in “Properties of the series” on page 1363.

Calling the `getNextItem()` and `getPreviousItem()` methods provides more control over the item selection than simply incrementing and decrementing the series’ `selectedIndex` property as shown in “Properties of the series” on page 1363. With these methods, you can choose the direction in which you select the next or previous item, and then decide whether to make the item appear selected.

The item getter methods also account for when you get to the end of the series, for example. If no ChartItems are currently selected, then the `getNextItem()` method gets the first one in the series. If you are at the beginning of the series, the `getPreviousItem()` gets the last item in the series.

The ChartBase class defines two additional properties, `selectedChartItem` and `selectedChartItems`, that return a ChartItem object or an array of ChartItem objects that are selected. You cannot set the values of these properties to select chart items. These properties are read-only. They are useful if your chart has multiple series and you want to know which items across the series are selected without iterating over all the series.

Setting the current state of a ChartItem object

You can set the value of the `currentState` property of a ChartItem object to make it appear selected or deselected, or make it appear in some other state. The `currentState` property can be set to `none`, `rollOver`, `selected`, `disabled`, `focusedSelected`, and `focused`.

Setting the state of the item does not add it to the `selectedItems` array. It only changes the appearance of the chart item. Setting the value of this property also does not trigger a `change` event.

Defined range

You can use the `getItemsInRegion()` method to define a rectangular area and select those chart items that are within that region. The `getItemsInRegion()` method takes an instance of the Rectangle class as its only argument. This rectangle defines an area on the stage, in global coordinates.

Getting an array of ChartItem objects with the `getItemsInRegion()` method does not trigger a `change` event. The state of the items does not change.

The following example lets you specify the `x`, `y`, `height`, and `width` properties of a rectangular range. It then calls the `getItemsInRegion()` method and passes those values to define the range. All chart items that fall within this invisible rectangle are selected and their values are displayed in the TextArea control.

Working with ChartItem objects to access chart data

To work with the data of a ChartItem, you typically cast it to its specific series type. For example, in a ColumnChart control, the ChartItem objects are of type ColumnSeriesItem. Doing this lets you access series-specific properties such as the `yValue`, `xValue`, and `index` of the ChartItem. You can also then access the data provider's object by using the `item` property. Finally, you can access the properties of the series by casting the `element` property to a series object.

Assuming that `a[i]` is a reference to a ChartItem object from an Array, use the following syntax.

Access the properties of the series item

```
var csi:ColumnSeriesItem = ColumnSeriesItem(a[i]);
trace(csi.yValue);
```

Access the item's fields

```
var csi:ColumnSeriesItem = ColumnSeriesItem(a[i]);
trace(csi.item.Profit);
```

Access the series properties

```
var csi:ColumnSeriesItem = ColumnSeriesItem(a[i]);
var cs:ColumnSeries = ColumnSeries(csi.element);
trace(cs.displayName);
```

About selection events

When a user selects a chart item using mouse, keyboard or region selection, the chart's `change` event is dispatched. When the following properties are updated through user interaction, a `change` event is dispatched:

- `selectedChartItem` and `selectedChartItems` (on the chart)
- `selectedItem`, `selectedItems`, `selectedIndex`, and `selectedIndices` (on the chart's series)

The `change` event does not contain references to the HitData or HitSet of the selected chart items. To access that information, you can use the chart's `selectedChartItem` and `selectedChartItems` properties.

When you select an item programmatically, no `change` event is dispatched. When you change the `selectedState` property of a chart item, no `change` event is dispatched.

Clearing selections

You can clear all selected data points by using the chart control's `clearSelection()` method. The following example clears all selected data points when the user presses the ESC key:

```
<?xml version="1.0" ?>
<!--  charts/ClearItemSelection.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp();srv.send();"
    height="600">
    <fx:Declarations>
       <!-- View source of the following page to see the structure of the data that Flex uses
in this example. -->
        <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
        <!-- To see data in an HTML table, go to
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
    <fx:Script>
    <![CDATA[
        import flash.events.KeyboardEvent;
        import mx.core.FlexGlobals;

        private function initApp():void {
          FlexGlobals.topLevelApplication.addEventListener(KeyboardEvent.KEY_UP, keyHandler);
        }

        // Clears all chart items selected when the user presses the ESC key.
        private function keyHandler(event:KeyboardEvent):void {
            var curKeyCode:int = event.keyCode;
            if (curKeyCode == 27) { // 27 is the keycode value for ESC
                myChart.clearSelection();
            }
        }
    ]]>
    </fx:Script>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:Panel height="100%" width="100%">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <mx:PlotChart id="myChart"
            height="207"
            width="350"
            showDataTips="true"
            dataProvider="{srv.lastResult.data.result}"
            selectionMode="multiple">
            <mx:series>
                <mx:PlotSeries id="series1"
                    xField="expenses"
                    yField="profit"
                    displayName="Expenses/Profit"
                    selectable="true"/>
                <mx:PlotSeries id="series2"
                    xField="amount"
                    yField="expenses"
                    displayName="Amount/Expenses"
                    selectable="true"/>
                <mx:PlotSeries id="series3"
                    xField="profit"
                    yField="amount"
                    displayName="Profit/Amount"
                    selectable="true"/>
            </mx:series>
        </mx:PlotChart>
        <mx:Legend dataProvider="{myChart}" width="200"/>
        <s:Label text="Press ESC to clear selection."/>
    </s:Panel>
</s:Application>
```

In addition to clearing item selections programmatically, users can use the mouse or keyboard to clear items. If a user clicks anywhere on the chart control's background, and not over a data point, they clear all selections. If a user uses the up and down arrow keys to select a data point, they clear the existing data points. For more information, see "Keyboard and mouse selection" on page 1362.

Using the selection API to create new charts

You can use the selection API to get some or all of the ChartItem objects of one chart, and then create a new chart with them. To do this, you create a new data provider for the new chart. To do this, you can call the ArrayCollection's `getItemAt()` method on the original chart's data provider and pass to it the original series' selected indices. This method then returns an object whose values you then add to an object in the new data provider.

The `selectedIndex` and `selectedIndices` properties of a chart's series represent the position of the chart item in the series. This position is also equivalent to the position of the chart item's underlying data object in the data provider.

The following example creates a PieChart control from the selected columns in the ColumnChart control. The PieChart control also allows selection; you can explode a piece by selecting it.

```
<?xml version="1.0" ?>
<!--  charts/MakeChartFromSelection.mxml -->

```

Dragging and dropping ChartItem objects

As an extension of the selection API, you can drag and drop chart items from one chart to another (or from a chart to some other object altogether).

To use drag and drop operations in your chart controls:

- Make the source chart drag enabled by setting it's `dragEnabled` property to `true`.
- Make the target chart drop enabled by setting it's `dropEnabled` property to `true`.
- Add event listeners for the `dragEnter` and `dragDrop` events on the target chart.
- In the `dragEnter` event handler, get a reference to the target chart and register it with the DragManager. To be a drop target, a chart must define an event handler for this event. You must call the `DragManager.acceptDragDrop()` method for the drop target to receive the drag and drop events.
- In the `dragDrop` event handler, get an Array of chart items that are being dragged and add that Array to the target chart's data provider. You do this by using the `event.dragSource.dataForFormat()` method. You must specify the String `"chartitems"` as the argument to the `dataForFormat()` method. This is because the chart-based controls have predefined values for the data format of drag data. For all chart controls, the format String is `"chartitems"`.

The following example lets you drag chart items from the ColumnChart control to the PieChart control. When the application starts, there is no PieChart control, but it becomes visible when the first chart item is dragged onto the container. This example also examines the dragged chart items to ensure that they are not added more than once to the target chart. It does this by using the target data provider's `contains()` method.

    </s:Panel>
</s:Application>
```

Chart controls also support the standard drag and drop methods of List-based controls such as `hideDropFeedback()` and `showDropFeedback()`. These methods display indicators under the mouse pointer to indicate whether drag and drop operations are allowed and where the items will be dropped.

For more information about drag and drop operations, see “Drag and drop” on page 1893.

Dropping ChartItem objects onto components

The target of a drag and drop operation from a chart control does not need to be another chart control. Instead, you can drag an object onto any Flex component using simple drag and drop rules. The following example lets you drag a column from the chart onto the TextArea. The TextArea then extracts data from the dropped item and displays that information in text.

```
<?xml version="1.0" ?>
<!--  charts/DragDropToComponent.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">

        </s:HGroup>
    </s:Panel>
</s:Application>
```

Changing the drag image

When you drag a chart item off of a source chart, an outline of the underlyig chart item appears as the drag image. For example, if you drag a column from a ColumnChart control, a column appears under the mouse pointer to represent the item that is being dragged.

You can customize the image that is displayed during a drag operation by overriding the default defintion of the `dragImage` property in a custom chart class. You do this by embedding your new image (or defining it in ActionScript), overriding the `dragImage()` getter method, and returning the new image.

The default location, in coordinates, of the drag image is 0,0 unless you override the DragManager's `doDrag()` method. You can also set the starting location of the drag proxy image by using the x and y coordinates of the image proxy in the `dragImage()` getter.

The following example custom chart class embeds an image and returns it in the `dragImage()` getter method. This example also positions the drag image proxy so that the mouse pointer is near its lower right corner.

```
// charts/MyColumnChart.as
package {
    import mx.charts.ColumnChart;
    import mx.core.IUIComponent;
    import mx.controls.Image;
    public class MyColumnChart extends ColumnChart {
        [Embed(source="images/dollarSign.png")]
        public var dollarSign:Class;
        public function MyColumnChart() {
            super();
        }

        override protected function get dragImage():IUIComponent {
             var imageProxy:Image = new Image();
             imageProxy.source = dollarSign;

             var imageHeight:Number = 50;
             var imageWidth:Number = 32;

             imageProxy.height = imageHeight;
             imageProxy.width = imageWidth;
             // Position the image proxy above and to the left of
             // the mouse pointer.
             imageProxy.x = this.mouseX - imageWidth;
             imageProxy.y = this.mouseY - imageHeight;
             return imageProxy;
        }

    }
}
```

The following example uses the MyColumnChart example class to define its custom drag image:

```
<?xml version="1.0" ?>

Drawing on chart controls

Flex includes the ability to add graphical elements to your chart controls such as lines, boxes, and elipses. Graphical children of chart controls can also include any control that is a subclass of UIComponent, including list boxes, combo boxes, labels, and even other chart controls.

When working with chart controls, Flex converts x and y coordinates into data coordinates. Data coordinates define locations relative to the data in the chart's underlying data provider. This lets you position graphical elements relative to the location of data points in the chart without having to first convert their positions to x and y coordinates. For example, you can draw a line from the top of a column in a ColumnChart to the the top of another column, showing a trend line.

To add data graphics to a chart control, you use the mx.charts.chartClasses.CartesianDataCanvas (for Cartesian charts) class or the mx.charts.chartClasses.PolarDataCanvas (for polar charts) classes. You can either attach visual controls to the canvas or you can draw on the canvas by using drawing methods.

You attach visual controls to the data canvases in the same way that you programmatically add controls to an application: you add them as child controls. In this case, the method you call to add children is `addDataChild()`, which lets you add any DisplayObject instance to the canvas. This method lets you take advantage of the data coordinates that the canvas uses. As with most MX containers, you can also use the `addChild()` and `addChildAt()` methods. With these methods, you can then adjust the location of the DisplayObject to data coordinates by using the canvas' `updateDataChild()` method.

To draw on the data canvases, you use drawing methods that are similar to those used in MXML graphics. The canvases define a set of methods that you can use to create vector shapes such as circles, squares, lines, and other shapes. These methods include the line-drawing methods such as `lineTo()`, `moveTo()`, and `curveTo()`, as well as the fill methods such as `beginFill()`, `beginBitmapFill()`, and `endFill()`. Convenience methods such as `drawRect()`, `drawRoundedRect()`, `drawEllipse()`, and `drawCircle()` are also available on the data canvases. For more information about MXML graphics, see "MXML graphics" on page 1730.

All drawn graphics such as lines and shapes remain visible on the data canvas until you call the canvas' `clear()` method. To remove child objects from data canvases, use the `removeChild()`, `removeChildAt()`, and `removeAllChildren()` methods.

A canvas can either be in the foreground (in front of the data points) or in the background (behind the data points). To add a canvas to the foreground, you add it to the chart's `annotationElement` Array. To add a canvas to the background, you add it to the chart's `backgroundElements` Array.

The data canvases have the following limitations:

- There is no drag-and-drop support for children of the data canvases.
- You cannot use the chart selection APIs to select objects on the data canvases.

The following example adds a CartesianDataCanvas as an annotation element to the ColumnChart control. It uses the graphics methods to draw a line between the columns that you select.

                xField="month"
                yField="expenses"
                displayName="Expense"
                selectable="true"/>
        </mx:series>
     </mx:ColumnChart>
     <mx:Legend dataProvider="{myChart}"/>

     <s:HGroup>
        <s:Button id="b1"
            label="Connect Two Points"
            click="connectTwoPoints('Jan', 1500, 'Mar', 500);"/>
        <s:Button id="b2"
            click="canvas.clear()"
            label="Clear Line"/>
     </s:HGroup>

     <s:HGroup>
         <s:VGroup>
             <s:Label text="First Item"/>
             <s:Label id="l1"/>
             <s:Label id="l2"/>
         </s:VGroup>
         <s:VGroup>
             <s:Label text="Second Item"/>
             <s:Label id="l3"/>
             <s:Label id="l4"/>
         </s:VGroup>
     </s:HGroup>
   </s:Panel>
</s:Application>
```

The following example uses the `addDataChild()` method to add children to the data canvas. It adds labels to each of the columns that you select in the ColumnChart control.

```
<?xml version="1.0"?>
<!-- charts/AddLabelsWithLines.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">

         </s:VGroup>
     </s:HGroup>

  </s:Panel>
</s:Application>
```

You can access an array of the data children by using the `dataChildren` property of the canvas. This property is an array of the child objects on the canvas.

The following example uses the `updateDataChild()` method to add a label to a single data point on the line:

```
<?xml version="1.0"?>
<!-- charts/UpdateDataChildExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    height="600">
  <fx:Script><![CDATA[
    import mx.controls.Label;
    import mx.charts.chartClasses.CartesianCanvasValue;
     import mx.collections.ArrayCollection;
     [Bindable]
     public var expenses:ArrayCollection = new ArrayCollection([
        {Month:"Jan", Profit:2000, Expenses:1500, Amount:450},
        {Month:"Feb", Profit:1000, Expenses:200, Amount:600},
        {Month:"Mar", Profit:1500, Expenses:500, Amount:300}
     ]);

     public function drawData():void
     {
        canvas.clear();
        canvas.beginFill(0xFF0033, 1);
        canvas.drawCircle("Feb", 1000, 20);
        canvas.endFill();

        var myLabel:Label = new Label();
        myLabel.text = "X";
        myLabel.setStyle("fontWeight", "bold");
        myLabel.setStyle("fontSize", 20);
        canvas.addChild(myLabel);
        canvas.updateDataChild(myLabel, "Feb", 1100);
     }

  ]]></fx:Script>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <s:Panel title="Line Chart">
     <s:layout>
         <s:HorizontalLayout/>
     </s:layout>
     <mx:LineChart id="myChart" dataProvider="{expenses}"
        showDataTips="true" creationComplete="drawData()">
        <mx:annotationElements>
            <mx:CartesianDataCanvas id="canvas" includeInRanges="true" />
        </mx:annotationElements>
        <mx:horizontalAxis>
           <mx:CategoryAxis dataProvider="{expenses}" categoryField="Month"/>
        </mx:horizontalAxis>
        <mx:series>
           <mx:LineSeries yField="Profit" displayName="Profit"/>
           <mx:LineSeries yField="Expenses" displayName="Expenses"/>
        </mx:series>
     </mx:LineChart>
     <mx:Legend dataProvider="{myChart}"/>
  </s:Panel>
</s:Application>
```

Using offsets for data coordinates

The data canvas classes also let you add offsets to the position of data graphics. You do this by defining the data coordinates with the CartesianCanvasValue constructor rather than passing a data coordinate to the drawing or `addDataChild()` methods. When you define a data coordinate with the CartesianCanvasValue, you pass the data coordinate as the first argument, but you can pass an offset as the second argument.

The following example lets you specify an offset for the labels with an HSlider control. This offset is used when adding a data child to the canvas.

```
<?xml version="1.0"?>
<!-- charts/AddLabelsWithOffsetLines.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">

        snapInterval="1" tickInterval="10"
        labels="['-50','0','50']"
        allowTrackClick="true"
        liveDragging="true"
        change="labelOffset=hSlider.value"/>
  </s:Panel>
</s:Application>
```

Using multiple axes with data canvases

A CartesianDataCanvas is specific to a certain data space, which is defined by the bounds of the axis. If no axis is specified, the canvas uses the primary axes of the chart as its bounds. If you have a chart with multiple axes, you can specify which axes the data canvas should use by setting the values of the `horizontalAxis` or `verticalAxis` properties, as the following example illustrates:

```
<mx:ColumnChart width="100%" height="100%" creationComplete="createLabel();">
    <mx:annotationElements>
        <mx:CartesianDataCanvas id="canvas"
            includeInRanges="true"
            horizontalAxis={h1}
            verticalAxis={v1}/>
    </mx:annotationElements>
    ...
</mx:ColumnChart>
```

AdvancedDataGrid control

The AdvancedDataGrid control expands on the functionality of the standard MX DataGrid control to add data visualization capabilities to your applications built in Adobe® Flex™. These capabilities provide greater control of data display, data aggregation, and data formatting.

For more information on the DataGrid control, see "MX DataGrid control" on page 963.

There is also a Spark DataGrid control. For more information, see "Spark DataGrid and Grid controls" on page 545.

About the AdvancedDataGrid control

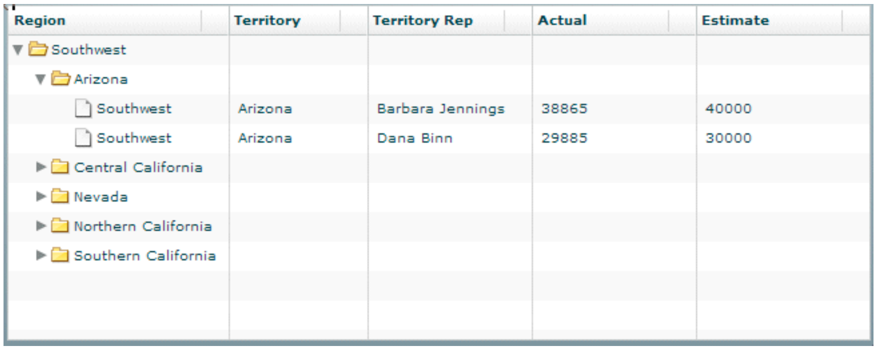
The AdvancedDataGrid control extends the capabilities of the standard DataGrid control to improve data visualization. The following table describes the main data visualization capabilities of the AdvancedDataGrid control:

Capability	**Description**
Sorting by multiple columns	Sort by multiple columns when you click in the column header. For more information, see "Sorting by multiple columns" on page 1399.
Styling rows and columns	Use the `styleFunction` property to specify a function to apply styles to rows and columns of the control. For more information, see "Styling rows and columns" on page 1401.
Displaying hierarchical and grouped data	Use an expandable navigation tree in a column to control the visible rows of the control. For more information, see "Hierarchical and grouped data display" on page 1409.
Creating column groups	Collect multiple columns under a single column heading. For more information, see "Creating column groups" on page 1436.
Using item renderers	Span multiple columns with an item renderer and use multiple item renderers in the same column. For more information, see "Using item renderers with the AdvancedDataGrid control" on page 1442.

Displaying hierarchical and grouped data

One of the most important aspects of the AdvancedDataGrid control is its support for the display of hierarchical and grouped data. *Hierarchical data* is data already in a structure of parent and child data items. *Grouped data* is flat data with no inherent hierarchy. Before passing flat data to the AdvancedDataGrid control, you specify one or more data fields that are used to group the flat data into a hierarchy.

To support the display of hierarchical and grouped data, the AdvancedDataGrid control displays a navigation tree in a column that lets you navigate the data hierarchy. The following example shows an AdvancedDataGrid control with a navigation tree in the first column that controls the visible rows of the control, but it can be in any column:



Region	Territory	Territory Rep	Actual	Estimate
▼ Southwest				
▼ Arizona				
Southwest	Arizona	Barbara Jennings	38865	40000
Southwest	Arizona	Dana Binn	29885	30000
▶ Central California				
▶ Nevada				
▶ Northern California				
▶ Southern California				

Migrating from the DataGrid control

Besides the major new features added to the AdvancedDataGrid control described in the section "About the AdvancedDataGrid control" on page 1397, the AdvancedDataGrid control adds the following property:

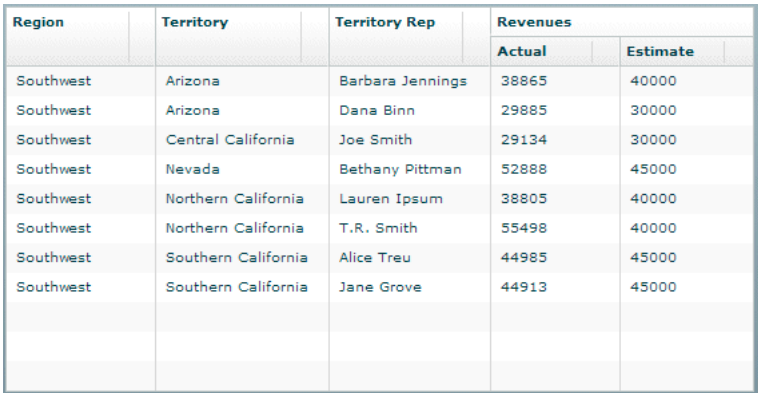
firstVisibleItem Specifies the item that is currently displayed in the top row of the AdvancedDataGrid control.

One consideration when migrating an existing application from the DataGrid control to the AdvancedDataGrid control is that the data type of many event objects dispatched by the AdvancedDataGrid control is of type AdvancedDataGridEvent, not of type DataGridEvent as it is for the DataGrid control. If your application references the event object by type, you must update your application so that it uses the correct data type.

To determine the type of the event object for any event, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Example: Creating column groups

Column grouping lets you collect multiple columns under a single column heading. The following example shows the Actual and Estimate columns grouped under the Revenues column:



Region	Territory	Territory Rep	Revenues	
			Actual	Estimate
Southwest	Arizona	Barbara Jennings	38865	40000
Southwest	Arizona	Dana Binn	29885	30000
Southwest	Central California	Joe Smith	29134	30000
Southwest	Nevada	Bethany Pittman	52888	45000
Southwest	Northern California	Lauren Ipsum	38805	40000
Southwest	Northern California	T.R. Smith	55498	40000
Southwest	Southern California	Alice Treu	44985	45000
Southwest	Southern California	Jane Grove	44913	45000

The AdvancedDataGrid control is defined by the mx.controls.AdvancedDataGrid class and additional classes in the package mx.controls.advancedDataGridClasses. This package includes the AdvancedDataGridColumn class that you use to define a column.

The following code creates the column grouping shown in the previous image:

```
<?xml version="1.0"?>
<!-- dpcontrols/adg/ColumnGroupADG.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;

            // Import the data used by the AdvancedDataGrid control.
            include "SimpleFlatData.as";
        ]]>
    </fx:Script>
    <mx:AdvancedDataGrid id="myADG"
        dataProvider="{dpFlat}"
        width="100%" height="100%">
        <mx:groupedColumns>
            <mx:AdvancedDataGridColumn dataField="Region"/>
            <mx:AdvancedDataGridColumn dataField="Territory"/>
            <mx:AdvancedDataGridColumn dataField="Territory_Rep"
                headerText="Territory Rep"/>
            <mx:AdvancedDataGridColumnGroup headerText="Revenues">
                <mx:AdvancedDataGridColumn dataField="Actual"/>
                <mx:AdvancedDataGridColumn dataField="Estimate"/>
            </mx:AdvancedDataGridColumnGroup>
        </mx:groupedColumns>
   </mx:AdvancedDataGrid>
</s:Application>
```

This example imports the data used by the AdvancedDataGrid control from a file named SimpleFlatData.as. You can see the contents of that file in the topic “Hierarchical and grouped data display” on page 1409.

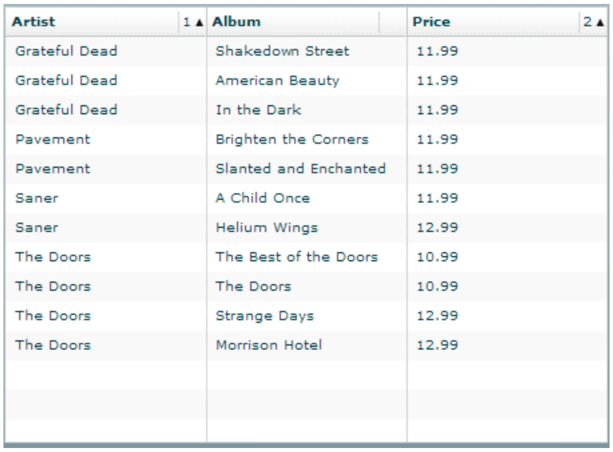
Sorting by multiple columns

By default, the AdvancedDataGrid control displays data in the order specified in the data passed to its `dataProvider` property. The AdvancedDataGrid control also lets you sort data after the control displays it in a single column or multiple columns.

To disable sorting for an entire AdvancedDataGrid control, set the `AdvancedDataGrid.sortableColumns` property to `false`. To disable sorting for an individual column, set the `AdvancedDataGridColumn.sortable` property to `false`.

The way that you sort multiple columns is based on the setting of the `sortExpertMode` property. By default, the `sortExpertMode` property is set to `false`. This setting means that you click in the header area of a column to sort the rows of the AdvancedDataGrid control by that column. Then you click in the multiple column sort area of the header to sort by additional columns. To use the Control key to select every column after the first column to perform sort, set the `sortExpertMode` property to `true`.

The following example shows an AdvancedDataGrid control with three columns with the `sortExpertMode` property set to `false`:



Artist 1 ▲	Album	Price 2 ▲
Grateful Dead	Shakedown Street	11.99
Grateful Dead	American Beauty	11.99
Grateful Dead	In the Dark	11.99
Pavement	Brighten the Corners	11.99
Pavement	Slanted and Enchanted	11.99
Saner	A Child Once	11.99
Saner	Helium Wings	12.99
The Doors	The Best of the Doors	10.99
The Doors	The Doors	10.99
The Doors	Strange Days	12.99
The Doors	Morrison Hotel	12.99

A. *Column header area* ***B*** *. Multiple column sort area*

Sort the columns with sortExpertMode set to false

1. Click in the column header area of any column in the AdvancedDataGrid control to sort by that column. For example, click in the column header for the Artist column to sort that column in ascending order. Click the Artist column header again to sort in descending order.
2. Click in the multiple column sort area of any other column header. For example, click in the multiple column sort area of the Price column to arrange it in ascending order while keeping the Artist column sorted in descending order. You can now find the least expensive album for each artist.
3. Click in the multiple column sort area for the Price column again to arrange it in descending order.
4. Click in the multiple column sort area for any other column header to include other columns in the sort.

Sort the columns with sortExpertMode set to true

1. Click in the column header area of any column in the AdvancedDataGrid control to sort by that column. For example, click in the column header for the Artist column to sort that column in ascending order. Click the Artist column header again to sort in descending order.
2. While holding down the Control key, click in any other column header. For example, click the column header for the Price column to arrange it in ascending order while keeping the Artist column sorted in descending order. You can now find the least expensive album for each artist.
3. While holding down the Control key, click the column header for the Price column again to arrange it in descending order.
4. While holding down the Control key, select any other column header to include other columns in the sort.

The following code implements multiple column sort when the `sortExpertMode` property is set to `true`:

```
<?xml version="1.0"?>
<!-- dpcontrols/adg/SimpleADG.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
      <![CDATA[
         import mx.collections.ArrayCollection;

         [Bindable]
         private var dpADG:ArrayCollection = new ArrayCollection([
           {Artist:'Pavement', Album:'Slanted and Enchanted', Price:11.99},
           {Artist:'Pavement', Album:'Brighten the Corners', Price:11.99},
           {Artist:'Saner', Album:'A Child Once', Price:11.99},
           {Artist:'Saner', Album:'Helium Wings', Price:12.99},
           {Artist:'The Doors', Album:'The Doors', Price:10.99},
           {Artist:'The Doors', Album:'Morrison Hotel', Price:12.99},
           {Artist:'Grateful Dead', Album:'American Beauty', Price:11.99},
           {Artist:'Grateful Dead', Album:'In the Dark', Price:11.99},
           {Artist:'Grateful Dead', Album:'Shakedown Street', Price:11.99},
           {Artist:'The Doors', Album:'Strange Days', Price:12.99},
           {Artist:'The Doors', Album:'The Best of the Doors', Price:10.99}
         ]);
      ]]>
    </fx:Script>
    <mx:AdvancedDataGrid
        width="100%" height="100%"
        sortExpertMode="true"
        dataProvider="{dpADG}">
        <mx:columns>
            <mx:AdvancedDataGridColumn dataField="Artist" />
            <mx:AdvancedDataGridColumn dataField="Album" />
            <mx:AdvancedDataGridColumn dataField="Price" />
        </mx:columns>
   </mx:AdvancedDataGrid>
</s:Application>
```

Styling rows and columns

You apply styles to the rows and columns of the AdvancedDataGrid control by using callback functions. To control the styling of a row, use the `AdvancedDataGrid.styleFunction` property to specify the callback function; to control the styling of a column, use the `AdvancedDataGridColumn.styleFunction` property to specify the callback function.

The callback function specified by the `AdvancedDataGrid.styleFunction` property is invoked first, followed by the function specified by the `AdvancedDataGridColumn.styleFunction` property. Therefore, the

AdvancedDataGrid control applies styles to rows first, and then to columns.

The callback function must have the following signature:

```
function_name(data:Object, column:AdvancedDataGridColumn):Object
```

The function returns an Object that contains one or more *styleName:value* pairs to specify a style setting, or null. The *styleName* field contains the name of a style property, such as `color`, and the *value* field contains the value for the style property, such as 0x00FF00. For example, you could return two styles using the following code:

```
{color:0xFF0000, fontWeight:"bold"}
```

The AdvancedDataGrid control invokes the callback function when it updates its display, such as when the control is first drawn on application start up, or when you call the `invalidateList()` method.

The examples in this section use callback functions to set the style of an AdvancedDataGrid control. All of the examples in this section use the following data from the StyleData.as file:

```
[Bindable]
private var dpADG:ArrayCollection = new ArrayCollection([
    {Artist:'Pavement', Album:'Slanted and Enchanted', Price:11.99},
    {Artist:'Pavement', Album:'Brighten the Corners', Price:11.99},
    {Artist:'Saner', Album:'A Child Once', Price:11.99},
    {Artist:'Saner', Album:'Helium Wings', Price:12.99},
    {Artist:'The Doors', Album:'The Doors', Price:10.99},
    {Artist:'The Doors', Album:'Morrison Hotel', Price:12.99},
    {Artist:'Grateful Dead', Album:'American Beauty', Price:11.99},
    {Artist:'Grateful Dead', Album:'In the Dark', Price:11.99},
    {Artist:'Grateful Dead', Album:'Shakedown Street', Price:11.99},
    {Artist:'The Doors', Album:'Strange Days', Price:12.99},
    {Artist:'The Doors', Album:'The Best of the Doors', Price:10.99}
]);
```

Styling rows

The following example uses the `AdvancedDataGrid.styleFunction` property to specify a callback function to apply styles to the rows of an AdvancedDataGrid control. In this example, you use Button controls to select an artist in the AdvancedDataGrid control. Then the callback function highlights in red all rows for the selected artist.

```
<?xml version="1.0"?>
<!-- dpcontrols/adg/SimpleADGRowStyleFunc.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
      <![CDATA[
          import mx.collections.ArrayCollection;
          import mx.controls.advancedDataGridClasses.AdvancedDataGridColumn;

          // Include the data for the AdvancedDataGrid control.
          include "StyleData.as"

          // Artist name to highlight.
          protected var artistName:String;

          // Event handler to set the selected artist's name
          // based on the selected Button control.
          public function setArtistName(event:Event):void {
             artistName=Button(event.currentTarget).label;
             // Refresh row display.
             myADG.invalidateList();
          }

          // Callback function that highlights in red
          // all rows for the selected artist.
          public function myStyleFunc(data:Object,
            col:AdvancedDataGridColumn):Object {
             if (data["Artist"] == artistName)
                return {color:0xFF0000};

             // Return null if the Artist name does not match.
             return null;
          }
      ]]>
    </fx:Script>
    <mx:AdvancedDataGrid id="myADG"
        width="100%" height="100%"
        dataProvider="{dpADG}"
        styleFunction="myStyleFunc">
        <mx:columns>
            <mx:AdvancedDataGridColumn dataField="Artist"/>
            <mx:AdvancedDataGridColumn dataField="Album"/>
            <mx:AdvancedDataGridColumn dataField="Price"/>
        </mx:columns>
    </mx:AdvancedDataGrid>

    <mx:HBox>
       <mx:Button label="Pavement" click="setArtistName(event);"/>
       <mx:Button label="Saner" click="setArtistName(event);"/>
       <mx:Button label="The Doors" click="setArtistName(event);"/>
    </mx:HBox>
</s:Application>
```

Styling columns

The following example modifies the example in the previous section to use a callback function to apply styles to the rows and one column of an AdvancedDataGrid control. In this example, the Price column displays all cells with a price less than $11.00 in green:

```
<?xml version="1.0"?>
<!-- dpcontrols/adg/SimpleADGColumnStyleFunc.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
      <![CDATA[
          import mx.collections.ArrayCollection;
          import mx.controls.advancedDataGridClasses.AdvancedDataGridColumn;

          // Include the data for the AdvancedDataGrid control.
          include "StyleData.as"

          // Artist name to highlight.
          protected var artistName:String;

          // Event handler to set the selected artist's name
          // based on the selected Button control.
          public function setArtistName(event:Event):void
          {
             artistName=Button(event.currentTarget).label;
```

```
            // Refresh row display.
            myADG.invalidateList();
         }

         // Callback function that highlights in red
         // all rows for the selected artist.
         public function myStyleFunc(data:Object,
           col:AdvancedDataGridColumn):Object
         {
            if (data["Artist"] == artistName)
               return {color:0xFF0000};

            // Return null if the Artist name does not match.
            return null;
         }
        // Callback function that hightlights in green
        // all entries in the Price column
        // with a value less than $11.00.
        public function myColStyleFunc(data:Object,
           col:AdvancedDataGridColumn):Object
        {
            if(data["Price"] <= 11.00)
                return {color:0x00FF00};

            return null;
        }
      ]]>
    </fx:Script>
    <mx:AdvancedDataGrid id="myADG"
        width="100%" height="100%"
        dataProvider="{dpADG}"
        styleFunction="myStyleFunc">
        <mx:columns>
            <mx:AdvancedDataGridColumn dataField="Artist"/>
            <mx:AdvancedDataGridColumn dataField="Album"/>
            <mx:AdvancedDataGridColumn dataField="Price"
                styleFunction="myColStyleFunc"/>
        </mx:columns>
    </mx:AdvancedDataGrid>

    <mx:HBox>
       <mx:Button label="Pavement" click="setArtistName(event);"/>
       <mx:Button label="Saner" click="setArtistName(event);"/>
       <mx:Button label="The Doors" click="setArtistName(event);"/>
    </mx:HBox>
</s:Application>
```

Using a data formatter in a column

The AdvancedDataGridColumn class contains a `formatter` property that lets you pass a class that implements the IFormatter interface to the column. This includes the Spark formatters such as CurrencyFormatter, DateTimeFormatter, and NumberFormatter, as well as subclasses of the Formatter class, including the MX CurrencyFormatter, DateFormatter, and NumberFormatter.

The formatter classes convert data into customized strings. For example, you can use the Spark or MX CurrencyFormatter class to prefix the value in the Price column with a dollar ($) sign.

You use a formatter class with a callback function specified by the `labelFunction` property or the `styleFunction` property. If you specify a callback function, Flex invokes that formatter class after invoking the callback functions.

The following example modifies the example from the section “Styling rows” on page 1402 to add a CurrencyFormatter class to the Price column to prefix the price with the $ sign:

```
<?xml version="1.0"?>
<!-- dpcontrols/adg/SimpleADGRowFormatter.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
      <![CDATA[
          import mx.collections.ArrayCollection;
          import mx.controls.advancedDataGridClasses.AdvancedDataGridColumn;

          // Include the data for the AdvancedDataGrid control.
          include "StyleData.as"

          // Artist name to highlight.
          protected var artistName:String;

          // Event handler to set the selected artist's name
          // based on the selected Button control.
          public function setArtistName(event:Event):void
          {
             artistName=Button(event.currentTarget).label;
             // Refresh row display.
             myADG.invalidateList();
          }

          // Callback function that hightlights in red
          // all rows for the selected artist.
          public function myStyleFunc(data:Object,
            col:AdvancedDataGridColumn):Object
          {
             if (data["Artist"] == artistName)
                return {color:0xFF0000};

             // Return null if the Artist name does not match.
             return null;
          }
      ]]>
    </fx:Script>
    <mx:AdvancedDataGrid id="myADG"
```

```
        width="100%" height="100%"
        dataProvider="{dpADG}"
        styleFunction="myStyleFunc">
        <mx:columns>
            <mx:AdvancedDataGridColumn dataField="Artist"/>
            <mx:AdvancedDataGridColumn dataField="Album"/>
            <mx:AdvancedDataGridColumn width="75" dataField="Price">
                <mx:formatter>
                    <s:CurrencyFormatter useCurrencySymbol="true"/>
               </mx:formatter>
            </mx:AdvancedDataGridColumn>
        </mx:columns>
    </mx:AdvancedDataGrid>

    <s:HGroup>
       <s:Button label="Pavement" click="setArtistName(event);"/>
       <s:Button label="Saner" click="setArtistName(event);"/>
       <s:Button label="The Doors" click="setArtistName(event);"/>
    </s:HGroup>
</s:Application>
```

Selecting multiple cells and rows

All list-based controls support the `allowMultipleSelection` property. Setting the `allowMultipleSelection` property to `true` lets you select more than one item in the control at the same time. For example, the DataGrid control lets you select multiple rows so that you can drag and drop them to another DataGrid control.

The AdvancedDataGrid control adds the capability of letting you select multiple cells. You can drag the selected cells to another AdvancedDataGrid control, copy them to the clipboard, or perform some other action on the cell data.

You use the `selectionMode` property of the AdvancedDataGrid control, with the `allowMultipleSelection` property to configure multiple selection. The default value of the `selectionMode` property is `singleRow`, which means that you can select only a single row at a time. You can also set the `selectionMode` property to `singleCell`, `multipleRows` or to `multipleCells`.

Select contiguous items in the control

1 Click the first item, either a row or cell, to select it.

2 Hold down the Shift key as you select an additional item.

- If the `selectionMode` property is set to `multipleRows`, click any cell in another row to select multiple, contiguous rows.
- If the `selectionMode` property is set to `multipleCells`, click any cell to select multiple, contiguous cells.

Select discontiguous items in the control

1 Click the first item, either a row or cell, to select it.

2 Hold down the Control key as you select an additional item.

- If the `selectionMode` property is set to `multipleRows`, click any cell in another row to select that single row.
- If the `selectionMode` property is set to `multipleCells`, click any cell to select that single cell.

As you select cells or rows in the AdvancedDataGrid control, the control updates the `selectedCells` property with information about your selection. The `selectedCells` property is an Array of Objects where each Object contains a `rowIndex` and `columnIndex` property that represents the location of the selected row or cell in the control.

The value of the `selectionMode` property determines the data in the `rowIndex` and `columnIndex` properties, as the following tables describes:

Value of selectionMode property	Value of rowIndex and columnIndex properties
`none`	No selection allowed in the control, and `selectedCells` is null.
`singleRow`	Click any cell in the row to select the row. After the selection, `selectedCells` contains a single Object: `[{rowIndex:`*`selectedRowIndex`*`, columnIndex: -1}]`

`multipleRows`	Click any cell in the row to select the row.
	• While holding down the Control key, click any cell in another row to select the row for discontiguous selection.
	• While holding down the Shift key, click any cell in another row to select multiple, contiguous rows.
	After the selection, `selectedCells` contains one Object for each selected row:
	`[{rowIndex: `*`selectedRowIndex1`*`, columnIndex: -1},`
	`{rowIndex: `*`selectedRowIndex2`*`, columnIndex: -1}, ...`
	`{rowIndex: `*`selectedRowIndexN`*`, columnIndex: -1} ]`

`singleCell`	Click any cell to select the cell. After the selection, `selectedCells` contains a single Object: `[{rowIndex: `*`selectedRowIndex`*`, columnIndex:`*`selectedColIndex`*`}]`

`multipleCells`	Click any cell to select the cell.
	• While holding down the Control key, click any cell to select the cell multiple discontiguous selection.
	• While holding down the Shift key, click any cell to select multiple, contiguous cells.
	After the selection, `selectedCells` contains one Object for each selected cell:
	`[{rowIndex: `*`selectedRowIndex1`*`, columnIndex: `*`selectedColIndex1`*`},`
	`{rowIndex: `*`selectedRowIndex2`*`, columnIndex: `*`selectedColIndex2`*`},`
	`...`
	`{rowIndex: `*`selectedRowIndexN`*`, columnIndex: `*`selectedColIndexN`*`} ]`

The following example sets the `selectionMode` property to `multipleCells` to let you select multiple cells in the control. This application uses an event handler for the `keyUp` event to recognize the Control+C key combination and, if detected, copies the selected cells from the AdvancedDataGrid control to your system's clipboard.

After you copy the cells, you can paste the cells in another location in the Flex application, or paste them in another application, such as Microsoft Excel. In this example, you paste them to the TextArea control located at the bottom of the application:

```
<?xml version="1.0"?>
<!-- dpcontrols/adg/CellSelectADG.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
      <![CDATA[
        import mx.collections.ArrayCollection;
        import flash.events.KeyboardEvent;
        import flash.system.System;

        include "StyleData.as"

        // Event handler to recognize when Ctrl-C is pressed,
        // and copy the selected cells to the system clipboard.
        private function myKeyUpHandler(event:KeyboardEvent):void
        {
          var keycode_c:uint = 67;
          if (event.ctrlKey && event.keyCode == keycode_c)
          {
              // Separator used between Strings sent to clipboard
              // to separate selected cells.
              var separator:String = ",";
              // The String sent to the clipboard
              var dataString:String = "";
              // Loop over the selectedCells property.
              // Data in selectedCells is ordered so that
              // the last selected cell is at the head of the list.
              // Process the data in reverse so
              // that it appears in the correct order in the clipboard.
              var n:int = event.currentTarget.selectedCells.length;
              for (var i:int = 0; i < n; i++)
              {
                  var cell:Object = event.currentTarget.selectedCells[i];
                  // Get the row for the selected cell.
                  var data:Object =
                    event.currentTarget.dataProvider[cell.rowIndex];
                  // Get the name of the field for the selected cell.
                  var dataField:String =
                    event.currentTarget.columns[cell.columnIndex].dataField;
                  // Get the cell data using the field name.
                  dataString = data[dataField] + separator + dataString;
              }
              // Remove trailing separator.
              dataString =
                dataString.substr(0, dataString.length - separator.length);
              // Write dataString to the clipboard.
              System.setClipboard(dataString);
          }
        }
      ]]>
    </fx:Script>
    <mx:AdvancedDataGrid width="100%" height="100%"
        dataProvider="{dpADG}"
        selectionMode="multipleCells"
        allowMultipleSelection="true"
        keyUp="myKeyUpHandler(event);">
        <mx:columns>
            <mx:AdvancedDataGridColumn dataField="Artist"/>
            <mx:AdvancedDataGridColumn dataField="Album"/>
            <mx:AdvancedDataGridColumn dataField="Price"/>
        </mx:columns>
   </mx:AdvancedDataGrid>

   <mx:TextArea id="myTA"/>
</s:Application>
```

Hierarchical and grouped data display

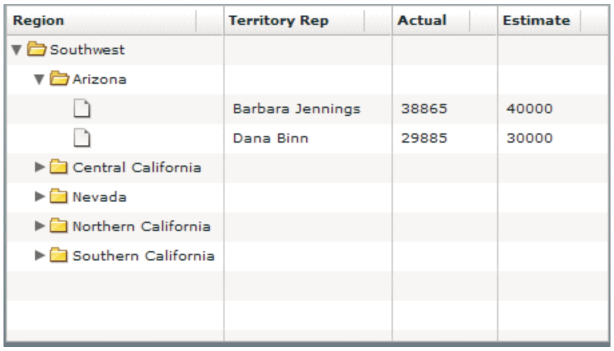
The AdvancedDataGrid control supports the display of hierarchical and grouped data. To support this display, the AdvancedDataGrid control displays a navigation tree in a column that lets you navigate the data hierarchy.

Hierarchical data is data already in a structure of parent and child data items. You can pass hierarchical data directly to the AdvancedDataGrid control. *Grouped data* is data that starts out as flat data with no inherent hierarchy. Before passing the flat data to the AdvancedDataGrid control, you specify one or more data fields that are used to group the flat data into a hierarchy.

The following code shows hierarchical data in the SimpleHierarchicalData.as file:

```
[Bindable]
private var dpHierarchy:ArrayCollection = new ArrayCollection([
  {Region:"Southwest", children: [
     {Region:"Arizona", children: [
        {Territory_Rep:"Barbara Jennings", Actual:38865, Estimate:40000},
        {Territory_Rep:"Dana Binn", Actual:29885, Estimate:30000}]},
     {Region:"Central California", children: [
        {Territory_Rep:"Joe Smith", Actual:29134, Estimate:30000}]},
     {Region:"Nevada", children: [
        {Territory_Rep:"Bethany Pittman", Actual:52888, Estimate:45000}]},
     {Region:"Northern California", children: [
        {Territory_Rep:"Lauren Ipsum", Actual:38805, Estimate:40000},
        {Territory_Rep:"T.R. Smith", Actual:55498, Estimate:40000}]},
     {Region:"Southern California", children: [
        {Territory_Rep:"Alice Treu", Actual:44985, Estimate:45000},
        {Territory_Rep:"Jane Grove", Actual:44913, Estimate:45000}]}
  ]}
]);
```

Notice that the data contains a top-level object that contains a Region field and multiple second-level children. Each second-level child also contains a Region field and one or more additional children. The following example shows the AdvancedDataGrid control displaying this data:



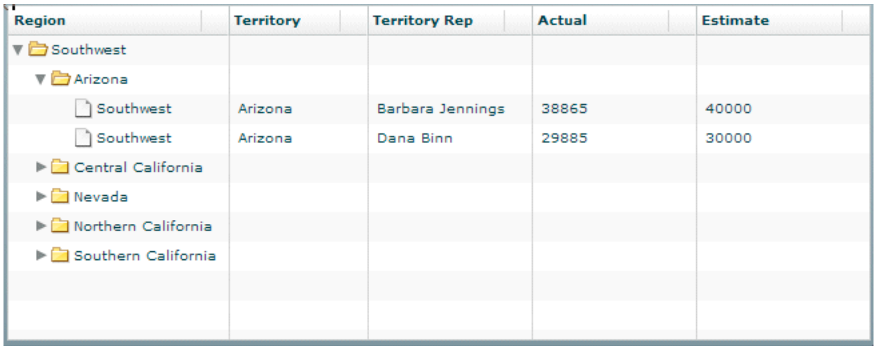
Region	Territory Rep	Actual	Estimate
▼ Southwest			
▼ Arizona			
	Barbara Jennings	38865	40000
	Dana Binn	29885	30000
▶ Central California			
▶ Nevada			
▶ Northern California			
▶ Southern California			

The code for this example is in the section “Controlling the navigation tree of the AdvancedDataGrid control” on page 1412.

To display flat data as a hierarchy, you group the rows of the flat data before passing the data to the AdvancedDataGrid control. The following code contains a variation on the hierarchical data shown in the previous image, but arranges the data in a flat data structure:

```
[Bindable]
private var dpFlat:ArrayCollection = new ArrayCollection([
  {Region:"Southwest", Territory:"Arizona",
     Territory_Rep:"Barbara Jennings", Actual:38865, Estimate:40000},
  {Region:"Southwest", Territory:"Arizona",
     Territory_Rep:"Dana Binn", Actual:29885, Estimate:30000},
  {Region:"Southwest", Territory:"Central California",
     Territory_Rep:"Joe Smith", Actual:29134, Estimate:30000},
  {Region:"Southwest", Territory:"Nevada",
     Territory_Rep:"Bethany Pittman", Actual:52888, Estimate:45000},
  {Region:"Southwest", Territory:"Northern California",
     Territory_Rep:"Lauren Ipsum", Actual:38805, Estimate:40000},
  {Region:"Southwest", Territory:"Northern California",
     Territory_Rep:"T.R. Smith", Actual:55498, Estimate:40000},
  {Region:"Southwest", Territory:"Southern California",
     Territory_Rep:"Alice Treu", Actual:44985, Estimate:45000},
  {Region:"Southwest", Territory:"Southern California",
     Territory_Rep:"Jane Grove", Actual:44913, Estimate:45000}
]);
```

In this example, the data contains a single level of individual records with no inherent hierarchy. To group the data, you specify one or more data fields used to arrange the data in a hierarchy. The following example shows the AdvancedDataGrid control where the flat data has been grouped by the Region field of the data:



Region	Territory	Territory Rep	Actual	Estimate
▼ Southwest				
▼ Arizona				
Southwest	Arizona	Barbara Jennings	38865	40000
Southwest	Arizona	Dana Binn	29885	30000
▶ Central California				
▶ Nevada				
▶ Northern California				
▶ Southern California				

The code for this example is in the section “Displaying grouped data” on page 1420.

Setting the data provider with hierarchical data

To configure the AdvancedDataGrid control to display hierarchical data and the navigation tree, you pass to the `dataProvider` property an instance of the HierarchicalData class or of the GroupingCollection2 class. Use the HierarchicalData class when your data is already arranged in a hierarchy. Use the GroupingCollection2 class when your data is in a flat structure. As part of configuring an instance of the GroupingCollection2 class, you specify one or more data fields that are used to arrange the flat data in a hierarchy.

When using the AdvancedDataGrid control with hierarchical data, you might have to free memory when you replace the data provider of the control. For more information, see the article Free memory when you replace the data provider of the AdvancedDataGrid control.

For more information on displaying hierarchical data, see “Displaying hierarchical data” on page 1418. For more information on displaying grouped data, see “Displaying grouped data” on page 1420.

You can create an instance of the HierarchicalData class or an instance of the GroupingCollection2 class from any data that you can use as a data provider. However, the AdvancedDataGrid control modifies its internal representation of the data as follows:

- An Array is represented internally by the AdvancedDataGrid control as an instance of the ArrayCollection class.
- An ArrayCollection class is represented internally by the AdvancedDataGrid control as an instance of the ArrayCollection class.
- A String that contains valid XML text is represented internally by the AdvancedDataGrid control as an instance of the XMLListCollection class.
- An XMLNode class or an XMLList class is represented internally by the AdvancedDataGrid control as an instance of the XMLListCollection class.
- Any object that implements the ICollectionView interface is represented internally by the AdvancedDataGrid control as an instance of the ICollectionView interface.
- An object of any other data type is wrapped in an Array instance with the object as its sole entry.

For example, you use an Array to create an instance of the HierarchicalData class, and then pass that HierarchicalData instance to the `AdvancedDataGrid.dataProvider` property. If you read the data back from the `AdvancedDataGrid.dataProvider` property, it is returned as an ArrayCollection instance.

Calling validateNow() after setting the data provider

In some situations, you may set the data provider of the AdvancedDataGrid control to hierarchical or grouped data, and then immediately try to perform an action based on the new data provider. This typically occurs when you set the `dataProvider` property in ActionScript, as the following example shows:

```
adg.dataProvider = groupedCollection;
adg.expandAll();
```

In this example, the call to `expandAll()` fails because the AdvancedDataGrid control is in the process of setting the `dataProvider` property, and the `expandAll()` method either processes the old value of the `dataProvider` property, if one existed, or does nothing.

In this situation, you must insert the `validateNow()` method after setting the data provider. The `validateNow()` method validates and updates the properties and layout of the control, and then redraws it, if necessary. The following example inserts the `validateNow()` method before the `expandAll()` method:

```
adg.dataProvider = groupedCollection;
adg.validateNow();
adg.expandAll();
```

Do not insert the `validateNow()` method every time you set the `dataProvider` property because it can affect the performance of your application; it is only required in some situations when you attempt to perform an operation on the control immediately after setting the `dataProvider` property.

Controlling the navigation tree of the AdvancedDataGrid control

The AdvancedDataGrid control is sometimes referred to as a *tree datagrid* because a column of the control uses an expandable tree to determine which rows are currently visible in the control. Often, the tree appears in the left-most column of the control, where the first column of the control is associated with a field of the control's data provider. That data field of the data provider provides the text for the labels of the tree nodes.

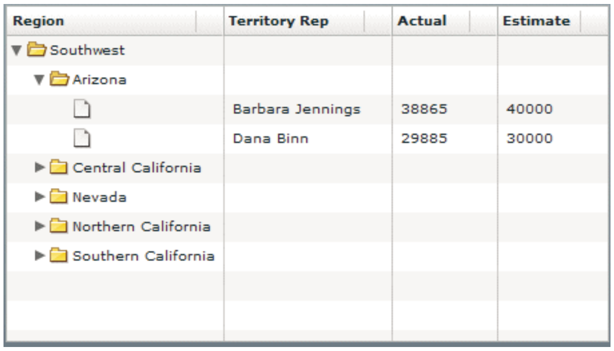
In the following example, you populate the AdvancedDataGrid control with the hierarchal data structure shown in "Hierarchical and grouped data display" on page 1409. The data contains a top-level object that contains a Region field, and multiple second-level children. Each second-level child also contains a Region field and one or more children.

The AdvancedDataGrid control in this example defines four columns to display the data: Region, Territory Rep, Actual, and Estimate.

```
<?xml version="1.0"?>
<!-- dpcontrols/adg/SimpleHierarchicalADG.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
  <fx:Script>
    <![CDATA[
          import mx.collections.ArrayCollection;

          include "SimpleHierarchicalData.as";
      ]]>
    </fx:Script>
    <mx:AdvancedDataGrid width="100%" height="100%">
        <mx:dataProvider>
            <mx:HierarchicalData source="{dpHierarchy}"/>
        </mx:dataProvider>
        <mx:columns>
            <mx:AdvancedDataGridColumn dataField="Region"/>
            <mx:AdvancedDataGridColumn dataField="Territory_Rep"
                headerText="Territory Rep"/>
            <mx:AdvancedDataGridColumn dataField="Actual"/>
            <mx:AdvancedDataGridColumn dataField="Estimate"/>
        </mx:columns>
    </mx:AdvancedDataGrid>
</s:Application>
```

The following image shows the AdvancedDataGrid control created by this example. The control displays a folder icon to represent branch nodes of the tree, and a file icon to represent leaf nodes. The first column of the control is associated with the Region field of the data provider, so the tree labels display the value of the Region field.



Region	Territory Rep	Actual	Estimate
▼ Southwest			
▼ Arizona			
	Barbara Jennings	38865	40000
	Dana Binn	29885	30000
▶ Central California			
▶ Nevada			
▶ Northern California			
▶ Southern California			

Notice that the leaf icon for the tree does not show a label. This is because the individual records for each territory representative do not contain a Region field.

While the tree is often positioned in the left-most column of the control, you can use the `treeColumn` property to specify any column in the control, as the following example shows:

```
<?xml version="1.0"?>
<!-- dpcontrols/adg/HierarchicalADGCategoriesTreeColumn.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
  <fx:Script>
    <![CDATA[
          import mx.collections.ArrayCollection;

          include "HierarchicalDataCategories.as";
      ]]>
    </fx:Script>
    <mx:AdvancedDataGrid
        width="100%" height="100%"
        treeColumn="{rep}">
        <mx:dataProvider>
            <mx:HierarchicalData source="{dpHierarchy}"
                childrenField="categories"/>
        </mx:dataProvider>
        <mx:columns>
            <mx:AdvancedDataGridColumn dataField="Region"/>
            <mx:AdvancedDataGridColumn id="rep"
                dataField="Territory_Rep"
                headerText="Territory Rep"/>
            <mx:AdvancedDataGridColumn dataField="Actual"/>
            <mx:AdvancedDataGridColumn dataField="Estimate"/>
        </mx:columns>
    </mx:AdvancedDataGrid>
</s:Application>
```

Setting navigation tree icons and labels

The navigation tree lets you control the icons and labels used for the branch and leaf nodes. For example, you can display a tree of labels with no icons, a tree with just folder icons, a tree with no labels at all, or a tree in its own column that is not associated with any data field.

The following table describes the style properties of the AdvancedDataGrid control that you use to set the tree icons:

Style property	Description
`defaultLeafIcon`	Specifies the leaf icon.
`disclosureClosedIcon`	Specifies the icon that is displayed next to a closed branch node. The default icon is a black triangle.
`disclosureOpenIcon`	Specifies the icon that is displayed next to an open branch node. The default icon is a black triangle.
`folderClosedIcon`	Specifies the folder closed icon for a branch node.
`folderOpenIcon`	Specifies the folder open icon for a branch node.

The following example sets the default leaf icon to null to hide it, and uses custom icons for the folder open and closed icons:

```
<?xml version="1.0"?>
<!-- dpcontrols/adg/SimpleHierarchicalADGTreeIcons.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
  <fx:Script>
    <![CDATA[
          import mx.collections.ArrayCollection;

          include "SimpleHierarchicalData.as";
      ]]>
    </fx:Script>
    <mx:AdvancedDataGrid width="100%" height="100%"
        defaultLeafIcon="{null}"
        folderOpenIcon="@Embed(source='assets/folderOpenIcon.jpg')"
        folderClosedIcon="@Embed(source='assets/folderClosedIcon.jpg')">
        <mx:dataProvider>
            <mx:HierarchicalData source="{dpHierarchy}"/>
        </mx:dataProvider>
        <mx:columns>
            <mx:AdvancedDataGridColumn dataField="Region"/>
            <mx:AdvancedDataGridColumn dataField="Territory_Rep"
                headerText="Territory Rep"/>
            <mx:AdvancedDataGridColumn dataField="Actual"/>
            <mx:AdvancedDataGridColumn dataField="Estimate"/>
        </mx:columns>
    </mx:AdvancedDataGrid>
</s:Application>
```

You can also specify the styles by using the `setStyle()` method, and by using an `<fx:Style>` tag, as the following example shows:

```
<fx:Style>
    @namespace s "library://ns.adobe.com/flex/spark";
    s|AdvancedDataGrid {
        defaultLeafIcon:ClassReference(null);
        folderOpenIcon:Embed(source='assets/folderOpenIcon.jpg');
        folderClosedIcon:Embed(source='assets/folderClosedIcon.jpg');
    }
</fx:Style>
```

Using the groupIconFunction and groupLabelFunction properties

Use the `groupIconFunction` and `groupLabelFunction` properties of the AdvancedDataGrid class to define callback functions to control the display of the leaf nodes of the navigation tree. The callback function specified by the `groupIconFunction` property controls the icon, and the callback function specified by the `groupLabelFunction` controls the label.

The following example uses the `groupIconFunction` property to display a custom icon for the top level node of the navigation tree, and display the default icon for all other leaf nodes of the tree:

```
<?xml version="1.0"?>
<!-- dpcontrols/adg/SimpleHierarchicalADGGroupIcon.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
  <fx:Script>
    <![CDATA[
          import mx.collections.ArrayCollection;

          include "SimpleHierarchicalData.as";
         // Embed the icon for the groups.
         [Bindable]
         [Embed(source="assets/topTreeIcon.png")]
         public var icn:Class;

         // Define the groupIconFunction callback function.
         public function myIconFunc(item:Object, depth:int):Class {
             if(depth == 1)
                 // If this is the top-level of the tree, return the icon.
                 return icn;
             else
                 // If this is any other level, return null.
                 return null;
         }
      ]]>
    </fx:Script>
    <mx:AdvancedDataGrid
        width="100%" height="100%"
        groupIconFunction="myIconFunc">
        <mx:dataProvider>
            <mx:HierarchicalData source="{dpHierarchy}"/>
        </mx:dataProvider>
        <mx:columns>
            <mx:AdvancedDataGridColumn dataField="Region"/>
            <mx:AdvancedDataGridColumn dataField="Territory_Rep"
                headerText="Territory Rep"/>
            <mx:AdvancedDataGridColumn dataField="Actual"/>
            <mx:AdvancedDataGridColumn dataField="Estimate"/>
        </mx:columns>
    </mx:AdvancedDataGrid>
</s:Application>
```

Creating a separate column for the navigation tree

In the examples in “Hierarchical and grouped data display” on page 1409, the first column also displays the Region field of the data. Therefore, as you expand the nodes of the navigation tree, the label of each tree node corresponds to the value of the Region field in the data provider for that row. For the leaf nodes of the tree, the data provider does not contain a value for the Region field, so the labels for the leaf nodes are blank.

You can also put the navigation tree in its own column, where the column is not associated with a data field, as the following example shows:

	Region	Territory Rep	Actual	Estimate
▼	Southwest			
▼	Arizona			
		Barbara Jennings	38865	40000
		Dana Binn	29885	30000
▶	Central California			
▶	Nevada			
▶	Northern Californi			
▶	Southern Californ			

This example does not associate a data field with the column that contains the tree, so the tree icons appear with no label. This example also sets the `folderClosedIcon`, `folderOpenIcon`, and `defaultLeafIcon` properties of the AdvancedDataGrid control to null, but does display the disclosure icons so that the user can still open and close tree nodes.

The following code implements this example. Notice that the first column is not associated with a data field. Because it is the first column in the data grid, the AdvancedDataGrid control automatically uses it to display the navigation tree.

```
<?xml version="1.0"?>
<!-- dpcontrols/adg/SimpleHierarchicalADGTreeColumn.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
  <fx:Script>
    <![CDATA[
          import mx.collections.ArrayCollection;

          include "SimpleHierarchicalData.as";
      ]]>
    </fx:Script>
    <mx:AdvancedDataGrid width="100%" height="100%"
        folderClosedIcon="{null}"
        folderOpenIcon="{null}"
        defaultLeafIcon="{null}">
        <mx:dataProvider>
            <mx:HierarchicalData source="{dpHierarchy}"/>
        </mx:dataProvider>
        <mx:columns>
            <mx:AdvancedDataGridColumn headerText="" width="50"/>
            <mx:AdvancedDataGridColumn dataField="Region"/>
            <mx:AdvancedDataGridColumn dataField="Territory_Rep"
                headerText="Territory Rep"/>
            <mx:AdvancedDataGridColumn dataField="Actual"/>
            <mx:AdvancedDataGridColumn dataField="Estimate"/>
        </mx:columns>
    </mx:AdvancedDataGrid>
</s:Application>
```

Displaying hierarchical data

Hierarchical data is data in a structured format where the data is already arranged in a hierarchy. To display hierarchical data in the AdvancedDataGrid control, you set the data provider of the control to an instance of the HierarchicalData class. The structure of the data in the data provider defines how the AdvancedDataGrid control displays the data.

Defining hierarchical data with an ArrayCollection

Using an ArrayCollection is a common way to create hierarchical data, as the following example shows in the SimpleHierarchicalData.as file. In this example, the data has three levels – a root level and two child levels:

```
[Bindable]
private var dpHierarchy:ArrayCollection = new ArrayCollection([
  {Region:"Southwest", children: [
     {Region:"Arizona", children: [
        {Territory_Rep:"Barbara Jennings", Actual:38865, Estimate:40000},
        {Territory_Rep:"Dana Binn", Actual:29885, Estimate:30000}]},
     {Region:"Central California", children: [
        {Territory_Rep:"Joe Smith", Actual:29134, Estimate:30000}]},
     {Region:"Nevada", children: [
        {Territory_Rep:"Bethany Pittman", Actual:52888, Estimate:45000}]},
     {Region:"Northern California", children: [
        {Territory_Rep:"Lauren Ipsum", Actual:38805, Estimate:40000},
        {Territory_Rep:"T.R. Smith", Actual:55498, Estimate:40000}]},
     {Region:"Southern California", children: [
        {Territory_Rep:"Alice Treu", Actual:44985, Estimate:45000},
        {Territory_Rep:"Jane Grove", Actual:44913, Estimate:45000}]}
  ]}
]);
```

This example uses the `children` keyword in the ArrayCollection definition to define the data hierarchy. The `children` keyword is the default keyword used by the HierarchicalData class to define the hierarchy.

You can use a different keyword to define the hierarchy. The following example shows the HierarchicalDataCategories.as file, which uses the `categories` keyword:

```
[Bindable]
private var dpHierarchy:ArrayCollection = new ArrayCollection([
  {Region:"Southwest", categories: [
     {Region:"Arizona", categories: [
        {Territory_Rep:"Barbara Jennings", Actual:38865, Estimate:40000},
        {Territory_Rep:"Dana Binn", Actual:29885, Estimate:30000}]},
     {Region:"Central California", categories: [
        {Territory_Rep:"Joe Smith", Actual:29134, Estimate:30000}]},
     {Region:"Nevada", categories: [
        {Territory_Rep:"Bethany Pittman", Actual:52888, Estimate:45000}]},
     {Region:"Northern California", categories: [
        {Territory_Rep:"Lauren Ipsum", Actual:38805, Estimate:40000},
        {Territory_Rep:"T.R. Smith", Actual:55498, Estimate:40000}]},
     {Region:"Southern California", categories: [
        {Territory_Rep:"Alice Treu", Actual:44985, Estimate:45000},
        {Territory_Rep:"Jane Grove", Actual:44913, Estimate:45000}]}
  ]}
]);
```

Use the `HierarchicalData.childrenField` property to specify the name of the field that defines the hierarchy, as the following example shows:

```
<?xml version="1.0"?>
<!-- dpcontrols/adg/HierarchicalADGCategories.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
  <fx:Script>
    <![CDATA[
          import mx.collections.ArrayCollection;

          include "HierarchicalDataCategories.as";
      ]]>
    </fx:Script>
    <mx:AdvancedDataGrid width="100%" height="100%">
        <mx:dataProvider>
            <mx:HierarchicalData source="{dpHierarchy}"
                childrenField="categories"/>
        </mx:dataProvider>
        <mx:columns>
            <mx:AdvancedDataGridColumn dataField="Region"/>
            <mx:AdvancedDataGridColumn dataField="Territory_Rep"
                headerText="Territory Rep"/>
            <mx:AdvancedDataGridColumn dataField="Actual"/>
            <mx:AdvancedDataGridColumn dataField="Estimate"/>
        </mx:columns>
    </mx:AdvancedDataGrid>
</s:Application>
```

Displaying hierarchical XML data

The examples in the previous section use an ArrayCollection to populate the AdvancedDataGrid control. You can also populate the control with hierarchical XML data. The following example modifies the data from the previous section to format it as XML, and then passes that data to the AdvancedDataGrid control:

```
<?xml version="1.0"?>
<!-- dpcontrols/adg/SimpleHierarchicalADGXML.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
            import mx.collections.HierarchicalData;
            import mx.collections.XMLListCollection;
        ]]>
    </fx:Script>
    <fx:Declarations>
        <fx:XMLList id="dpHierarchyXML" >
            <Region Region="Southwest">
                <Region Region="Arizona">
                    <Territory_Rep Territory_Rep="Barbara Jennings"
                        Actual="38865" Estimate="40000"/>
                    <Territory_Rep Territory_Rep="Dana Binn"
                        Actual="29885" Estimate="30000"/>
                </Region>
                <Region Region="Central California">
                    <Territory_Rep Territory_Rep="Joe Smith"
                        Actual="29134" Estimate="30000"/>
                </Region>
                <Region Region="Nevada">
                    <Territory_Rep Territory_Rep="Bethany Pittman"
                        Actual="52888" Estimate="45000"/>
                </Region>
                <Region Region="Northern California">
                    <Territory_Rep Territory_Rep="Lauren Ipsum"
                        Actual="38805" Estimate="40000"/>
                    <Territory_Rep Territory_Rep="T.R. Smith"
                        Actual="55498" Estimate="40000"/>
                </Region>
                <Region Region="Southern California">
                    <Territory_Rep Territory_Rep="Alice Treu"
                        Actual="44985" Estimate="45000"/>
                    <Territory_Rep Territory_Rep="Jane Grove"
                        Actual="44913" Estimate="45000"/>
                </Region>
            </Region>
        </fx:XMLList>
    </fx:Declarations>
    <mx:AdvancedDataGrid width="100%" height="100%"
        dataProvider="{new HierarchicalData(dpHierarchyXML)}">
        <mx:columns>
            <mx:AdvancedDataGridColumn dataField="@Region"
                headerText="Region"/>
            <mx:AdvancedDataGridColumn dataField="@Territory_Rep"
                headerText="Territory Rep"/>
            <mx:AdvancedDataGridColumn dataField="@Actual"
                headerText="Actual"/>
            <mx:AdvancedDataGridColumn dataField="@Estimate"
                headerText="Estimate"/>
        </mx:columns>
    </mx:AdvancedDataGrid>
</s:Application>
```

Displaying grouped data

Grouped data is flat data that you arrange in a hierarchy for display in the AdvancedDataGrid control. To group your data, you specify one or more data fields that collect the data into the hierarchy.

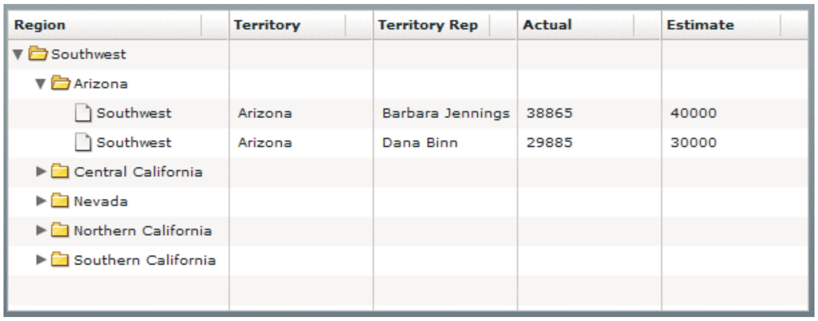
To populate the AdvancedDataGrid control with grouped data, create an instance of the GroupingCollection2 class from your flat data, and then pass that GroupingCollection2 instance to the data provider of the AdvancedDataGrid control. When you create the instance of the GroupingCollection2 from your flat data, you specify the fields for the data that are used to create the hierarchy.

Note: *In the previous release of Flex, you used the GroupingCollection class with the AdvancedDataGrid control. The GroupingCollection2 class is new for Flex 4 and provides better performance than GroupingCollection.*

Most of the examples in this section use the following flat data to create an instance of the GroupingCollection2 class:

```
[Bindable]
private var dpFlat:ArrayCollection = new ArrayCollection([
  {Region:"Southwest", Territory:"Arizona",
      Territory_Rep:"Barbara Jennings", Actual:38865, Estimate:40000},
  {Region:"Southwest", Territory:"Arizona",
      Territory_Rep:"Dana Binn", Actual:29885, Estimate:30000},
  {Region:"Southwest", Territory:"Central California",
      Territory_Rep:"Joe Smith", Actual:29134, Estimate:30000},
  {Region:"Southwest", Territory:"Nevada",
      Territory_Rep:"Bethany Pittman", Actual:52888, Estimate:45000},
  {Region:"Southwest", Territory:"Northern California",
      Territory_Rep:"Lauren Ipsum", Actual:38805, Estimate:40000},
  {Region:"Southwest", Territory:"Northern California",
      Territory_Rep:"T.R. Smith", Actual:55498, Estimate:40000},
  {Region:"Southwest", Territory:"Southern California",
      Territory_Rep:"Alice Treu", Actual:44985, Estimate:45000},
  {Region:"Southwest", Territory:"Southern California",
      Territory_Rep:"Jane Grove", Actual:44913, Estimate:45000}
]);
```

The following image shows an AdvancedDataGrid control that uses this data as input. This example specifies two fields that are used to group the data: Region and Territory. The first column of the AdvancedDataGrid control is associated with the Region field, so the navigation tree uses the Region field to define the labels for the leaf nodes of the tree.



Region	Territory	Territory Rep	Actual	Estimate
▼ Southwest				
▼ Arizona				
Southwest	Arizona	Barbara Jennings	38865	40000
Southwest	Arizona	Dana Binn	29885	30000
▶ Central California				
▶ Nevada				
▶ Northern California				
▶ Southern California				

The following code implements this example:

```
<?xml version="1.0"?>
<!-- dpcontrols/adg/SimpleGroupADGMXML.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;

            include "SimpleFlatData.as"
        ]]>
    </fx:Script>
    <mx:AdvancedDataGrid id="myADG"
        width="100%" height="100%"
        initialize="gc.refresh();">
        <mx:dataProvider>
            <mx:GroupingCollection2 id="gc" source="{dpFlat}">
                <mx:grouping>
                    <mx:Grouping label="Region">
                        <mx:GroupingField name="Region"/>
                        <mx:GroupingField name="Territory"/>
                    </mx:Grouping>
                </mx:grouping>
            </mx:GroupingCollection2>
        </mx:dataProvider>

        <mx:columns>
            <mx:AdvancedDataGridColumn dataField="Region"/>
            <mx:AdvancedDataGridColumn dataField="Territory"/>
            <mx:AdvancedDataGridColumn dataField="Territory_Rep"
                headerText="Territory Rep"/>
            <mx:AdvancedDataGridColumn dataField="Actual"/>
            <mx:AdvancedDataGridColumn dataField="Estimate"/>
        </mx:columns>
   </mx:AdvancedDataGrid>
</s:Application>
```

The GroupingCollection2 instance reformats the data based on these fields so that internally it is represented by the GroupingCollection2 instance, as the following example shows:

```
[{GroupLabel:"Southwest", children:[
    {GroupLabel:"Arizona", children:[
      {Region:"Southwest", Territory:"Arizona",
        Territory_Rep:"Barbara Jennings", Actual:38865, Estimate:40000},
      {Region:"Southwest", Territory:"Arizona",
        Territory_Rep:"Dana Binn", Actual:29885, Estimate:30000}]}
    {GroupLabel:"Central California", children:[
      {Region:"Southwest", Territory:"Central California",
        Territory_Rep:"Joe Smith", Actual:29134, Estimate:30000}]}
    {GroupLabel:"Nevada", children:[
      {Region:"Southwest", Territory:"Nevada",
        Territory_Rep:"Bethany Pittman", Actual:52888, Estimate:45000}]}
    {GroupLabel:"Northern California", children:[
      {Region:"Southwest", Territory:"Northern California",
        Territory_Rep:"Lauren Ipsum", Actual:38805, Estimate:40000},
      {Region:"Southwest", Territory:"Northern California",
        Territory_Rep:"T.R. Smith", Actual:55498, Estimate:40000}]}
    {GroupLabel:"Southern California", children:[
      {Region:"Southwest", Territory:"Southern California",
        Territory_Rep:"Alice Treu", Actual:44985, Estimate:45000},
      {Region:"Southwest", Territory:"Southern California",
        Territory_Rep:"Jane Grove", Actual:44913, Estimate:45000}]}
]}]
```

Notice that the representation consists of a data hierarchy based on the Region and Territory fields of the flat data. The GroupingCollection2 instance still contains the original rows of the input flat data, but those rows are now arranged in a hierarchy based on the grouping fields.

Using synchronous or asynchronous refresh with the AdvancedDataGrid control

The `GroupingCollection2.refresh()` method applies the settings of the GroupingCollection2 class to the data. You must call this method any time you modify the GroupingCollection2 class, such as by setting the `grouping`, `source`, or `summaries` properties of the GroupingCollection2 class. You also call the `GroupingCollection2.refresh()` method when you modify a GroupingField of the GroupingCollection2 class, such as by changing the `caseInsensitive`, `compareFunction`, or `groupingFunction` properties.

Notice that in the previous example, the AdvancedDataGrid control calls the `GroupingCollection2.refresh()` method in response to the `initialize` event of the AdvancedDataGrid control.

The `GroupingCollection2.refresh()` method has the following signature:

```
public function refresh(async:Boolean = false, dispatchCollectionEvents:Boolean =
false):Boolean
```

Set the `async` parameter to `false`, the default value, for synchronous refresh of the groups and any group summaries. Set it to `true` for asynchronous refresh.

For synchronous refresh, all groups and summaries are updated together before the method returns. That means your application cannot perform other processing operations for the duration of the call. It also prevents the user from interacting with the control until the refresh completes. Synchronous refresh is optimized for small data sets. Because a synchronous refresh updates all groups and summaries together, it has better performance than an asynchronous refresh. However, for large data sets, users might notice that the application pauses for the duration of the refresh.

In asynchronous refresh, all groups and summaries are updated individually. The `refresh()` method returns before the groups and summaries are updated so that your application can continue execution. Also, the control is updated during the refresh so that the user can continue to interact with it. For example, in asynchronous refresh, if the `displayItemsExpanded` property is `true`, the navigation tree is updated as new groups are created.

The overhead of updating groups and summaries individually, rather than all at once, makes an asynchronous refresh take longer than a synchronous one. However, for large data sets, your application continues to operate during the refresh.

The `dispatchCollectionEvents` parameter configures the dispatching of events in synchronous mode. If `false`, the default value, then no events are dispatched during the refresh. This setting provides the best performance for creating groups and summaries. If `true`, then events are dispatched as groups and summaries are calculated to update the control. However, the navigation tree is not updated as new groups are created.

For an asynchronous refresh, the `dispatchCollectionEvents` parameter is always set to `true`.

Using the default MXML property of the GroupingCollection2 class

The `grouping` property is the default MXML property of the GroupingCollection2 class, so you can rewrite the previous example as follows:

```
<?xml version="1.0"?>
<!-- dpcontrols/adg/SimpleGroupADGMXMLDefaultProp.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;

            include "SimpleFlatData.as"
        ]]>
    </fx:Script>
    <mx:AdvancedDataGrid id="myADG"
        width="100%" height="100%"
        initialize="gc.refresh();">
        <mx:dataProvider>
            <mx:GroupingCollection2 id="gc" source="{dpFlat}">
                    <mx:Grouping label="Region">
                        <mx:GroupingField name="Region"/>
                        <mx:GroupingField name="Territory"/>
                    </mx:Grouping>
            </mx:GroupingCollection2>
        </mx:dataProvider>

        <mx:columns>
            <mx:AdvancedDataGridColumn dataField="Region"/>
            <mx:AdvancedDataGridColumn dataField="Territory"/>
            <mx:AdvancedDataGridColumn dataField="Territory_Rep"
                headerText="Territory Rep"/>
            <mx:AdvancedDataGridColumn dataField="Actual"/>
            <mx:AdvancedDataGridColumn dataField="Estimate"/>
        </mx:columns>
   </mx:AdvancedDataGrid>
</s:Application>
```

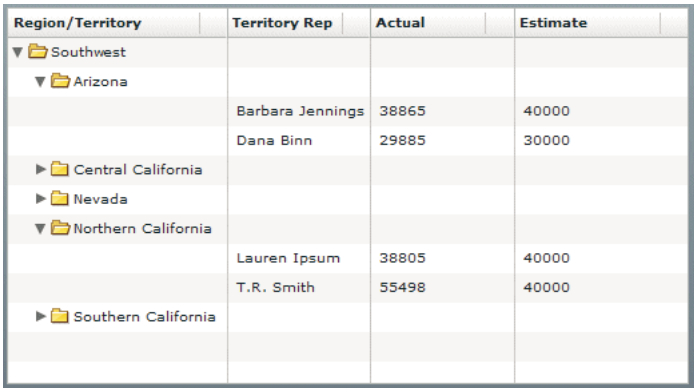
Setting the name of the GroupLabel field

By default, GroupLabel is the field name for the data items added to the flat data to create the hierarchy. For an example of the data structure created by the GroupingCollection2 class that uses the default field name, see “Displaying grouped data” on page 1420.

Use the `Grouping.label` property to specify a different name so that you can create a different group label for each level of the generated hierarchy. You should always set the `Grouping.label` property for the top level in your hierarchy. That property is required to sort the nodes of the navigation tree.

Creating a column for the GroupLabel field

The AdvancedDataGrid control uses the GroupLabel field to define the labels for the branch nodes of the navigation tree. One option when displaying grouped data is to create a column for the top-level data items that the grouping fields create. For example, you group your flat data by the Region and Territory fields. These fields appear as the labels for the branch nodes of the navigation tree, so you omit separate columns for those fields, as the following example shows:



Region/Territory	Territory Rep	Actual	Estimate
▼ Southwest			
▼ Arizona			
	Barbara Jennings	38865	40000
	Dana Binn	29885	30000
▶ Central California			
▶ Nevada			
▼ Northern California			
	Lauren Ipsum	38805	40000
	T.R. Smith	55498	40000
▶ Southern California			

The following code creates this example. Notice that this example includes an AdvancedDataGridColumn instance for the GroupLabel field, and no column definitions for the Region and Territory fields.

```
<?xml version="1.0"?>
<!-- dpcontrols/adg/SimpleGroupADGGroupLabelMXML.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;

            include "SimpleFlatData.as";
        ]]>
    </fx:Script>
    <mx:AdvancedDataGrid id="myADG"
        width="100%" height="100%"
        defaultLeafIcon="{null}"
        initialize="gc.refresh();">
        <mx:dataProvider>
            <mx:GroupingCollection2 id="gc" source="{dpFlat}">
                <mx:Grouping>
                    <mx:GroupingField name="Region"/>
                    <mx:GroupingField name="Territory"/>
                </mx:Grouping>
            </mx:GroupingCollection2>
        </mx:dataProvider>

        <mx:columns>
            <mx:AdvancedDataGridColumn dataField="GroupLabel"
                headerText="Region/Territory"/>
            <mx:AdvancedDataGridColumn dataField="Territory_Rep"
                headerText="Territory Rep"/>
            <mx:AdvancedDataGridColumn dataField="Actual"/>
            <mx:AdvancedDataGridColumn dataField="Estimate"/>
        </mx:columns>
   </mx:AdvancedDataGrid>
</s:Application>
```

Creating groups in ActionScript

The example in the previous section created the groups in MXML. However, you could let the user define the grouping at run time. The following example creates the groups in ActionScript by using an event handler:

```
<?xml version="1.0"?>
<!-- dpcontrols/adg/SimpleGroupADG.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
      <![CDATA[
        import mx.collections.GroupingField;
        import mx.collections.Grouping;
        import mx.collections.GroupingCollection2;
        import mx.collections.ArrayCollection;

        include "SimpleFlatData.as";
        [Bindable]
        public var myGColl:GroupingCollection2 = new GroupingCollection2();

        private var myGrp:Grouping = new Grouping();
        private function initDG():void {
            // Initialize the GroupingCollection2 instance.
            myGColl.source = dpFlat;

            // The Grouping instance defines the grouping fields
            // in the collection, and the order of the groups
            // in the hierarchy.
            myGrp.fields =
              [new GroupingField("Region"), new GroupingField("Territory")];
            myGrp.label = "Region";

            // The grouping property contains a Grouping instance.
            myGColl.grouping = myGrp;
            // Specify the GroupedCollection as the data provider for
            // the AdvancedDataGrid control.
            myADG.dataProvider=myGColl;

            // Refresh the display.
            myGColl.refresh();
        }
      ]]>
    </fx:Script>
    <mx:AdvancedDataGrid id="myADG"
        width="100%" height="100%"
        creationComplete="initDG();">
        <mx:columns>
            <mx:AdvancedDataGridColumn dataField="Region"/>
            <mx:AdvancedDataGridColumn dataField="Territory"/>
            <mx:AdvancedDataGridColumn dataField="Territory_Rep"
                headerText="Territory Rep"/>
            <mx:AdvancedDataGridColumn dataField="Actual"/>
            <mx:AdvancedDataGridColumn dataField="Estimate"/>
        </mx:columns>
   </mx:AdvancedDataGrid>
</s:Application>
```

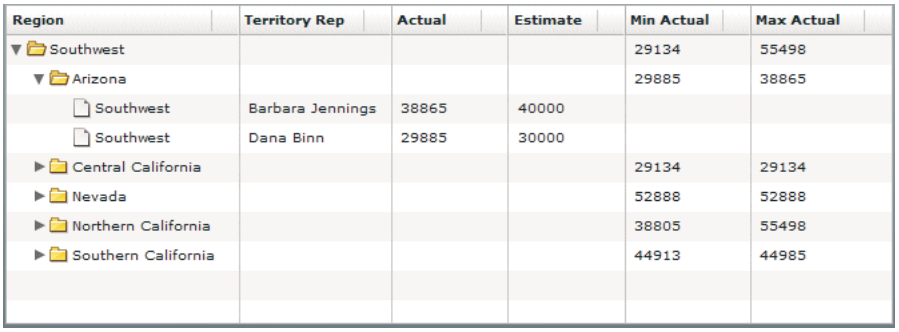
Creating summary rows

Summary data provides a way for you to extract information from your data for display in the AdvancedDataGrid control. For example, you can add summary data that contains the average value of a field across all rows of your data, that contains the maximum field value, the minimum field value, or that contains other types of summaries.

***Note:** Summary data is not supported for hierarchical data represented by the HierarchicalData class. You can only create summary data for data represented by the GroupingCollection2 class.*

You create summary data about your groups by using the `summaries` property of the GroupingField class. You can display the summary data in an existing row of the AdvancedDataGrid control, or display it in a separate row.

The following example shows an AdvancedDataGrid control that displays two summary fields, Min Actual and Max Actual:



Region	Territory Rep	Actual	Estimate	Min Actual	Max Actual
▼ Southwest				29134	55498
▼ Arizona				29885	38865
Southwest	Barbara Jennings	38865	40000		
Southwest	Dana Binn	29885	30000		
▶ Central California				29134	29134
▶ Nevada				52888	52888
▶ Northern California				38805	55498
▶ Southern California				44913	44985

The Min Actual and Max Actual fields in the top row correspond to summaries for all rows in the group, and the Min Actual and Max Actual fields for each Territory correspond to summaries for all rows in the territory subgroup.

The following code creates this control:

```
<?xml version="1.0"?>
<!-- dpcontrols/adg/SummaryGroupADG.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;

            include "SimpleFlatData.as"
      ]]>
    </fx:Script>
    <mx:AdvancedDataGrid id="myADG"
        width="100%" height="100%"
        initialize="gc.refresh();">
        <mx:dataProvider>
            <mx:GroupingCollection2 id="gc" source="{dpFlat}">
                <mx:Grouping label="Region">
                    <mx:GroupingField name="Region">
                        <mx:summaries>
                          <mx:SummaryRow summaryPlacement="group">
                            <mx:fields>
                                <mx:SummaryField2 dataField="Actual"
                                    label="Min Actual" summaryOperation="MIN"/>
                                <mx:SummaryField2 dataField="Actual"
```

```
                                    label="Max Actual" summaryOperation="MAX"/>
                            </mx:fields>
                          </mx:SummaryRow>
                        </mx:summaries>
                    </mx:GroupingField>
                    <mx:GroupingField name="Territory">
                        <mx:summaries>
                          <mx:SummaryRow summaryPlacement="group">
                            <mx:fields>
                                <mx:SummaryField2 dataField="Actual"
                                    label="Min Actual" summaryOperation="MIN"/>
                                <mx:SummaryField2 dataField="Actual"
                                    label="Max Actual" summaryOperation="MAX"/>
                            </mx:fields>
                          </mx:SummaryRow>
                        </mx:summaries>
                    </mx:GroupingField>
                </mx:Grouping>
            </mx:GroupingCollection2>
        </mx:dataProvider>

        <mx:columns>
            <mx:AdvancedDataGridColumn dataField="Region"/>
            <mx:AdvancedDataGridColumn dataField="Territory_Rep"
                headerText="Territory Rep"/>
            <mx:AdvancedDataGridColumn dataField="Actual"/>
            <mx:AdvancedDataGridColumn dataField="Estimate"/>
            <mx:AdvancedDataGridColumn dataField="Min Actual"/>
            <mx:AdvancedDataGridColumn dataField="Max Actual"/>
        </mx:columns>
   </mx:AdvancedDataGrid>
</s:Application>
```

Notice in this example that you use the `GroupingField.summaries` property to specify the SummaryRow instance. The SummaryRow instance contains all the information about a data summary. In this example, you use the `summaryPlacement` property to add the summary data to the grouped data. Optionally, you can add new rows to contain the summary data.

Each SummaryRow instance specifies one or more SummaryField2 instances that create the data summary. In this example, you use the `dataField` property to specify that the summaries are determined by the data in the Actual data field, the `label` property to specify the name of the data field created to hold the summary data, and the `summaryOperation` property to specify how to create the summary for numeric fields. You can specify one of the following values: `SUM`, `MIN`, `MAX`, `AVG`, or `COUNT`.

Note: *In the previous release of Flex, you used the SummaryField class to create summary data. The SummaryField2 class is new for Flex 4 and provides better performance than SummaryField.*

Internally, the GroupingCollection2 class represents the grouped data, with the new summary data fields, as the following example shows:

```
[{GroupLabel:"Southwest", Max Actual:55498, Min Actual:29134, children:[
  {GroupLabel:"Arizona", Max Actual:38865, Min Actual:29885, children:[
    {Region:"Southwest", Territory:"Arizona",
      Territory_Rep:"Barbara Jennings", Actual:38865, Estimate:40000},
    {Region:"Southwest", Territory:"Arizona",
      Territory_Rep:"Dana Binn", Actual:29885, Estimate:30000}]}
  {GroupLabel:"Central California", Max Actual:29134, Min Actual:29134, children:[
    {Region:"Southwest", Territory:"Central California",
      Territory_Rep:"Joe Smith", Actual:29134, Estimate:30000}]}
  {GroupLabel:"Nevada", Max Actual:52888, Min Actual:52888, children:[
    {Region:"Southwest", Territory:"Nevada",
      Territory_Rep:"Bethany Pittman", Actual:52888, Estimate:45000}]}
  {GroupLabel:"Northern California", Max Actual:55498, Min Actual:38805, children:[
    {Region:"Southwest", Territory:"Northern California",
      Territory_Rep:"Lauren Ipsum", Actual:38805, Estimate:40000},
    {Region:"Southwest", Territory:"Northern California",
      Territory_Rep:"T.R. Smith", Actual:55498, Estimate:40000}]}
  {GroupLabel:"Southern California", Max Actual:44985, Min Actual:44913, children:[
    {Region:"Southwest", Territory:"Southern California",
      Territory_Rep:"Alice Treu", Actual:44985, Estimate:45000},
    {Region:"Southwest", Territory:"Southern California",
      Territory_Rep:"Jane Grove", Actual:44913, Estimate:45000}]}
]}]
```

Using the default properties of the GroupingField and SummaryRow classes

The `GroupingField.summaries` property is the default property for the GroupingField class, and the `SummaryRow.fields` property is the default property for the SummaryRow class; therefore, you can omit those properties in your code and rewrite the previous example, as the following example shows:

```
<?xml version="1.0"?>
<!-- dpcontrols/adg/SummaryGroupADGDefProp.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;

            include "SimpleFlatData.as"
      ]]>
    </fx:Script>
    <mx:AdvancedDataGrid id="myADG"
        width="100%" height="100%"
        initialize="gc.refresh();">
        <mx:dataProvider>
            <mx:GroupingCollection2 id="gc" source="{dpFlat}">
                <mx:Grouping label="Region">
                    <mx:GroupingField name="Region">
                          <mx:SummaryRow summaryPlacement="group">
                                <mx:SummaryField2 summaryOperation="MIN"
                                    dataField="Actual" label="Min Actual"/>
                                <mx:SummaryField2 summaryOperation="MAX"
                                    dataField="Actual" label="Max Actual"/>
                          </mx:SummaryRow>
                    </mx:GroupingField>
                    <mx:GroupingField name="Territory">
```

```
                          <mx:SummaryRow summaryPlacement="group">
                                <mx:SummaryField2 summaryOperation="MIN"
                                    dataField="Actual" label="Min Actual"/>
                                <mx:SummaryField2 summaryOperation="MAX"
                                    dataField="Actual" label="Max Actual"/>
                          </mx:SummaryRow>
                    </mx:GroupingField>
                </mx:Grouping>
            </mx:GroupingCollection2>
        </mx:dataProvider>

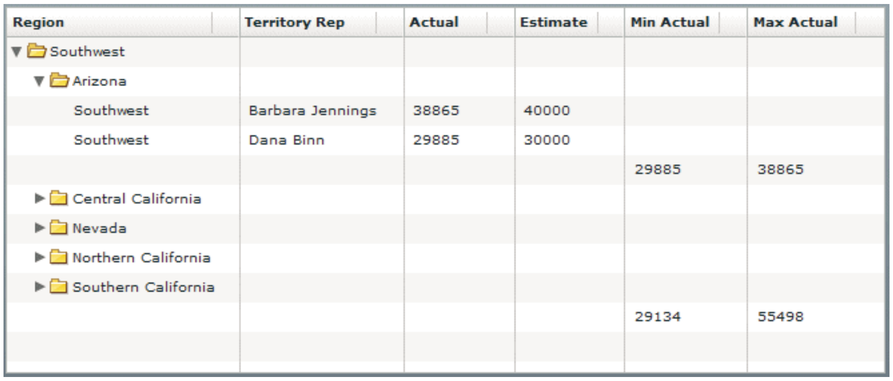
        <mx:columns>
            <mx:AdvancedDataGridColumn dataField="Region"/>
            <mx:AdvancedDataGridColumn dataField="Territory_Rep"
                headerText="Territory Rep"/>
            <mx:AdvancedDataGridColumn dataField="Actual"/>
            <mx:AdvancedDataGridColumn dataField="Estimate"/>
            <mx:AdvancedDataGridColumn dataField="Min Actual"/>
            <mx:AdvancedDataGridColumn dataField="Max Actual"/>
        </mx:columns>
    </mx:AdvancedDataGrid>
</s:Application>
```

Specifying the display location of the summary data in the AdvancedDataGrid control

The SummaryRow class contains the `summaryPlacement` property that determines where the summary data appears in the AdvancedDataGrid control. The following table describes the values of the `summaryPlacement` property:

Value of summaryPlacement property	Description
`first`	Creates a summary row as the first row in the group.
`last`	Creates a summary row as the last row in the group.
`group`	Adds the summary data to the row corresponding to the group.

The previous example named SummaryGroupADG.mxml shows an example of summary data added to the group by specifying `group` as the value of the `summaryPlacement` property. The following example shows the same grouped data but with the `summaryPlacement` property set to `last`:



Region	Territory Rep	Actual	Estimate	Min Actual	Max Actual
▼ Southwest					
▼ Arizona					
Southwest	Barbara Jennings	38865	40000		
Southwest	Dana Binn	29885	30000		
				29885	38865
▶ Central California					
▶ Nevada					
▶ Northern California					
▶ Southern California					
				29134	55498

You can specify multiple values to the `summaryPlacement` property, separated by a space; for example, a value of `last group` specifies to show the summary at the group level and as the last row of the group.

Internally, the GroupingCollection2 represents the grouped data, with the new summary data fields, as the following example shows:

```
[{GroupLabel:"Southwest", children:[
  {GroupLabel:"Arizona", children:[
    {Region:"Southwest", Territory:"Arizona",
      Territory_Rep:"Barbara Jennings", Actual:38865, Estimate:40000},
    {Region:"Southwest", Territory:"Arizona",
      Territory_Rep:"Dana Binn", Actual:29885, Estimate:30000},
    {Max Actual:38865, Min Actual:29885}]}
  {GroupLabel:"Central California", children:[
    {Region:"Southwest", Territory:"Central California",
      Territory_Rep:"Joe Smith", Actual:29134, Estimate:30000},
    {Max Actual:29134, Min Actual:29134}]}
  {GroupLabel:"Nevada", children:[
    {Region:"Southwest", Territory:"Nevada",
      Territory_Rep:"Bethany Pittman", Actual:52888, Estimate:45000},
    {Max Actual:52888, Min Actual:52888}]}
  {GroupLabel:"Northern California", children:[
    {Region:"Southwest", Territory:"Northern California",
      Territory_Rep:"Lauren Ipsum", Actual:38805, Estimate:40000},
    {Region:"Southwest", Territory:"Northern California",
      Territory_Rep:"T.R. Smith", Actual:55498, Estimate:40000},
    {Max Actual:55498, Min Actual:38805}]}
  {GroupLabel:"Southern California", children:[
    {Region:"Southwest", Territory:"Southern California",
      Territory_Rep:"Alice Treu", Actual:44985, Estimate:45000},
    {Region:"Southwest", Territory:"Southern California",
      Territory_Rep:"Jane Grove", Actual:44913, Estimate:45000},
    {Max Actual:44985, Min Actual:44913}]}
  {Max Actual:55498, Min Actual:29134}
]}]
```

Notice that a new row is added to the entire group to hold the summary data, and a new row is added to each subgroup to hold its summary data.

Creating multiple summaries

You can specify multiple SummaryRow instances in a single GroupingField instance. In the following example, you create summary data to define the following fields: Min Actual, Max Actual, Min Estimate, and Max Estimate for the Region group.

```
<?xml version="1.0"?>
<!-- dpcontrols/adg/SummaryGroupADGMultipleSummaries.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;

            include "SimpleFlatData.as"
      ]]>
    </fx:Script>
    <mx:AdvancedDataGrid id="myADG"
        width="100%" height="100%"
        initialize="gc.refresh();">
        <mx:dataProvider>
            <mx:GroupingCollection2 id="gc" source="{dpFlat}">
                <mx:Grouping label="Region">
                    <mx:GroupingField name="Region">
                          <mx:SummaryRow summaryPlacement="group">
                                <mx:SummaryField2 summaryOperation="MIN"
                                   dataField="Actual" label="Min Actual"/>
                                <mx:SummaryField2 summaryOperation="MAX"
                                   dataField="Actual" label="Max Actual"/>
                          </mx:SummaryRow>
                          <mx:SummaryRow summaryPlacement="group">
                                <mx:SummaryField2 summaryOperation="MIN"
                                   dataField="Estimate" label="Min Estimate"/>
                                <mx:SummaryField2 summaryOperation="MAX"
                                   dataField="Estimate" label="Max Estimate"/>
                          </mx:SummaryRow>
                    </mx:GroupingField>
                    <mx:GroupingField name="Territory"/>
                </mx:Grouping>
            </mx:GroupingCollection2>
        </mx:dataProvider>

        <mx:columns>
            <mx:AdvancedDataGridColumn dataField="Region"/>
            <mx:AdvancedDataGridColumn dataField="Territory_Rep"
                headerText="Territory Rep"/>
            <mx:AdvancedDataGridColumn dataField="Actual"/>
            <mx:AdvancedDataGridColumn dataField="Estimate"/>
            <mx:AdvancedDataGridColumn dataField="Min Actual"/>
            <mx:AdvancedDataGridColumn dataField="Max Actual"/>
            <mx:AdvancedDataGridColumn dataField="Min Estimate"/>
            <mx:AdvancedDataGridColumn dataField="Max Estimate"/>
        </mx:columns>
   </mx:AdvancedDataGrid>
</s:Application>
```

Creating a custom summary function

Use the `SummaryRow.summaryObjectFunction` property and the `SummaryField2.summaryOperation` property to add custom summary logic to your application. Your custom summary can perform many types of actions, but the result of the summary calculation must be of type Number.

The `SummaryRow.summaryObjectFunction` property defines a callback function that defines an instance of the SummaryObject class that collects the summary data. The AdvancedDataGrid control adds the SummaryObject instance to the data provider to display the summary data in the control. Therefore, you define within the SummaryObject instance the properties to display. In the following example, the callback function adds a property named Territory_Rep. This field appears in the Territory Rep column of the control for the summary row.

The `SummaryField2.summaryOperation` property takes an object that implements the mx.collections.ISummaryCalculator interface. That interface defines the following groups of methods:

- Implement the `summaryCalculationBegin()`, `calculateSummary()`, and `returnSummary()` methods to compute a summary of the values.
- Implement the `summaryOfSummaryCalculationBegin()`, `calculateSummaryOfSummary()`, and `returnSummaryOfSummary()` methods to compute a summary of summary values.

The following definition for the class MySummaryCalculator implements the ISummaryCalculator interface to create a class to summarize a field in every other row of a group:

```
package myComponents
{
    // dpcontrols/adg/myComponents/MySummaryCalculator.as
    import mx.collections.ISummaryCalculator;
    import mx.collections.SummaryField2;

    public class MySummaryCalculator implements ISummaryCalculator
    {
        public function MySummaryCalculator() {
        }

        // Define the summary object.
        protected var summObj:Object = new Object();
        // Define a var to hold the record count.
        protected var count:int;

        public function summaryCalculationBegin(field:SummaryField2):Object {
            // Initialize the variables.
            summObj.oddCount = 0;
            count = 1;
            return summObj;
        }

      public function calculateSummary(data:Object, field:SummaryField2, rowData:Object):void {
            // Only add the current value for every other row.
            if (count % 2 != 0)
            {
                summObj.oddCount = summObj.oddCount + rowData[field.dataField];
            }
            count++;
        }
        public function returnSummary(data:Object, field:SummaryField2):Number {
            // Return the summary value.
            return summObj.oddCount;
        }

        // Implement these methods if you are creating a summary of summaries.
        public function summaryOfSummaryCalculationBegin(value:Object,
field:SummaryField2):Object {
            return null;
        }

        public function calculateSummaryOfSummary(value:Object, newValue:Object,
field:SummaryField2):void {
        }

        public function returnSummaryOfSummary(value:Object, field:SummaryField2):Number {
            return 0;
        }
    }
}
```

Notice that this class implements the `summaryOfSummaryCalculationBegin()`, `calculateSummaryOfSummary()`, and `returnSummaryOfSummary()` methods but leaves the implementation empty.

The following example implements callback functions for the `summaryObjectFunction` and use the MySummaryCalculator class to calculate a summary of the actual sales revenue for every other row of each territory:

```
<?xml version="1.0"?>
<!-- dpcontrols/adg/SummaryGroupADGCustomSummary.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
            import mx.collections.IViewCursor;
            import mx.collections.SummaryObject;
            import mx.controls.advancedDataGridClasses.AdvancedDataGridColumn;
            import mx.collections.ArrayCollection;

            import myComponents.MySummaryCalculator;

            include "SimpleFlatData.as"

            // Callback function to create
            // the SummaryObject used to hold the summary data.
            private function summObjFunc():SummaryObject {

                // Define the object containing the summary data.
                var obj:SummaryObject = new SummaryObject();
                // Add a field containing a value for the Territory_Rep column.
                obj.Territory_Rep = "Alternating Reps";

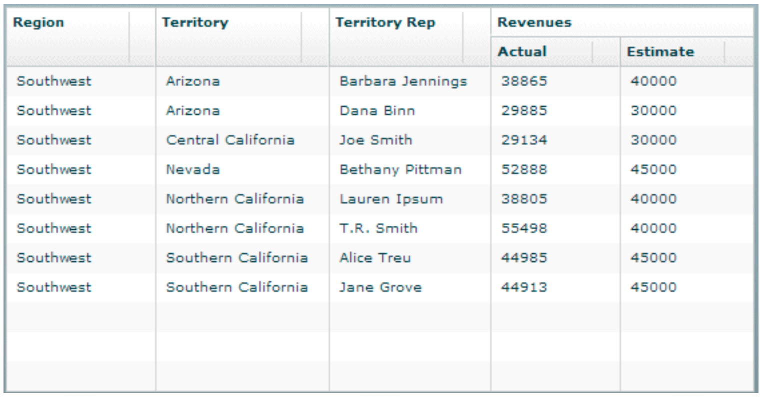
                return obj;
            }
      ]]>
    </fx:Script>
    <mx:AdvancedDataGrid id="myADG"
```

```
        width="100%" height="100%"
        initialize="gc.refresh();">
        <mx:dataProvider>
            <mx:GroupingCollection2 id="gc" source="{dpFlat}">
                <mx:Grouping label="Region">
                   <mx:GroupingField name="Region"/>
                   <mx:GroupingField name="Territory">
                      <mx:summaries>
                         <mx:SummaryRow summaryObjectFunction="summObjFunc"
                            summaryPlacement="first">
                            <mx:fields>
                               <mx:SummaryField2 dataField="Actual"
                                summaryOperation="{new myComponents.MySummaryCalculator()}"/>
                            </mx:fields>
                         </mx:SummaryRow>
                      </mx:summaries>
                   </mx:GroupingField>
                </mx:Grouping>
            </mx:GroupingCollection2>
        </mx:dataProvider>

        <mx:columns>
            <mx:AdvancedDataGridColumn dataField="Region"/>
            <mx:AdvancedDataGridColumn dataField="Territory_Rep"
                headerText="Territory Rep"/>
            <mx:AdvancedDataGridColumn dataField="Actual"/>
            <mx:AdvancedDataGridColumn dataField="Estimate"/>
        </mx:columns>
   </mx:AdvancedDataGrid>
</s:Application>
```

Creating column groups

You collect multiple columns under a single column heading by using column groups, as the following example shows:



Region	Territory	Territory Rep	Revenues	
			Actual	Estimate
Southwest	Arizona	Barbara Jennings	38865	40000
Southwest	Arizona	Dana Binn	29885	30000
Southwest	Central California	Joe Smith	29134	30000
Southwest	Nevada	Bethany Pittman	52888	45000
Southwest	Northern California	Lauren Ipsum	38805	40000
Southwest	Northern California	T.R. Smith	55498	40000
Southwest	Southern California	Alice Treu	44985	45000
Southwest	Southern California	Jane Grove	44913	45000

In this example, you use flat data to populate the data grid, and group the Actual and Estimate columns under a single column named Revenues.

To group columns in an AdvancedDataGrid control, you must do the following:

- Use the `AdvancedDataGrid.groupedColumns` property, rather than the `AdvancedDataGrid.columns` property, to specify the columns.

- Use the AdvancedDataGridColumnGroup class to specify the column groups.

The following code implements the AdvancedDataGrid control shown in the previous figure:

```
<?xml version="1.0"?>
<!-- dpcontrols/adg/ColumnGroupADG.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;

            // Import the data used by the AdvancedDataGrid control.
            include "SimpleFlatData.as";
        ]]>
    </fx:Script>
    <mx:AdvancedDataGrid id="myADG"
        dataProvider="{dpFlat}"
        width="100%" height="100%">
        <mx:groupedColumns>
            <mx:AdvancedDataGridColumn dataField="Region"/>
            <mx:AdvancedDataGridColumn dataField="Territory"/>
            <mx:AdvancedDataGridColumn dataField="Territory_Rep"
                headerText="Territory Rep"/>
            <mx:AdvancedDataGridColumnGroup headerText="Revenues">
                <mx:AdvancedDataGridColumn dataField="Actual"/>
                <mx:AdvancedDataGridColumn dataField="Estimate"/>
            </mx:AdvancedDataGridColumnGroup>
        </mx:groupedColumns>
   </mx:AdvancedDataGrid>
</s:Application>
```

The `groupedColumns` property contains instances of the AdvancedDataGridColumn class and of the AdvancedDataGridColumn class. Instances of the AdvancedDataGridColumn class appear in the control as stand-alone columns. All the columns specified in an AdvancedDataGridColumnGroup instance appear together as a grouped column.

You can add multiple groups to the control. The following example adds groups named Area and Revenues:

```
<?xml version="1.0"?>
<!-- dpcontrols/adg/ColumnGroupADG2Groups.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;

            include "SimpleFlatData.as";
        ]]>
    </fx:Script>
    <mx:AdvancedDataGrid id="myADG"
        dataProvider="{dpFlat}"
        width="100%" height="100%">
        <mx:groupedColumns>
            <mx:AdvancedDataGridColumn dataField="Territory_Rep"
                headerText="Territory Rep"/>
            <mx:AdvancedDataGridColumnGroup headerText="Area">
                <mx:AdvancedDataGridColumn dataField="Region"/>
                <mx:AdvancedDataGridColumn dataField="Territory"/>
            </mx:AdvancedDataGridColumnGroup>
            <mx:AdvancedDataGridColumnGroup headerText="Revenues">
                <mx:AdvancedDataGridColumn dataField="Actual"/>
                <mx:AdvancedDataGridColumn dataField="Estimate"/>
            </mx:AdvancedDataGridColumnGroup>
        </mx:groupedColumns>
   </mx:AdvancedDataGrid>
</s:Application>
```

You can nest groups so that one column group contains multiple column groups, as the following example shows:

```
<?xml version="1.0"?>
<!-- dpcontrols/adg/ColumnGroupADG2NestedGroups.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;

            include "SimpleFlatData.as";
        ]]>
    </fx:Script>
    <mx:AdvancedDataGrid id="myADG"
        dataProvider="{dpFlat}"
        width="100%" height="100%">
        <mx:groupedColumns>
            <mx:AdvancedDataGridColumn dataField="Territory_Rep"
                headerText="Territory Rep"/>
            <mx:AdvancedDataGridColumnGroup headerText="All Groups">
                <mx:AdvancedDataGridColumnGroup headerText="Area">
                    <mx:AdvancedDataGridColumn dataField="Region"/>
                    <mx:AdvancedDataGridColumn dataField="Territory"/>
                </mx:AdvancedDataGridColumnGroup>
                <mx:AdvancedDataGridColumnGroup headerText="Revenues">
                    <mx:AdvancedDataGridColumn dataField="Actual"/>
                    <mx:AdvancedDataGridColumn dataField="Estimate"/>
                </mx:AdvancedDataGridColumnGroup>
            </mx:AdvancedDataGridColumnGroup>
        </mx:groupedColumns>
   </mx:AdvancedDataGrid>
</s:Application>
```

Dragging and dropping columns in the group

By default, you can drag the columns in a group within the group to reposition them. You can also drag the entire group to reposition it in the AdvancedDataGrid control.

To disable dragging of all columns in a group, set the `AdvancedDataGridColumnGroup.childrenDragEnabled` property to `false`.

Using grouped columns with hierarchical data

You can use column groups with hierarchical data, as well as flat data. The following example modifies the example in the section "Creating a separate column for the navigation tree" on page 1416 to group the Actual and Estimates columns under the Revenues group column:

```
<?xml version="1.0"?>
<!-- dpcontrols/adg/SimpleHierarchicalADGGroupCol.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
  <fx:Script>
    <![CDATA[
          import mx.collections.ArrayCollection;

          include "SimpleHierarchicalData.as";
      ]]>
    </fx:Script>
    <mx:AdvancedDataGrid width="100%" height="100%">
        <mx:dataProvider>
            <mx:HierarchicalData source="{dpHierarchy}"/>
        </mx:dataProvider>
        <mx:groupedColumns>
            <mx:AdvancedDataGridColumn dataField="Region"/>
            <mx:AdvancedDataGridColumn dataField="Territory_Rep"
                headerText="Territory Rep"/>
            <mx:AdvancedDataGridColumnGroup headerText="Revenues">
                <mx:AdvancedDataGridColumn dataField="Actual"/>
                <mx:AdvancedDataGridColumn dataField="Estimate"/>
            </mx:AdvancedDataGridColumnGroup>
        </mx:groupedColumns>
    </mx:AdvancedDataGrid>
</s:Application>
```

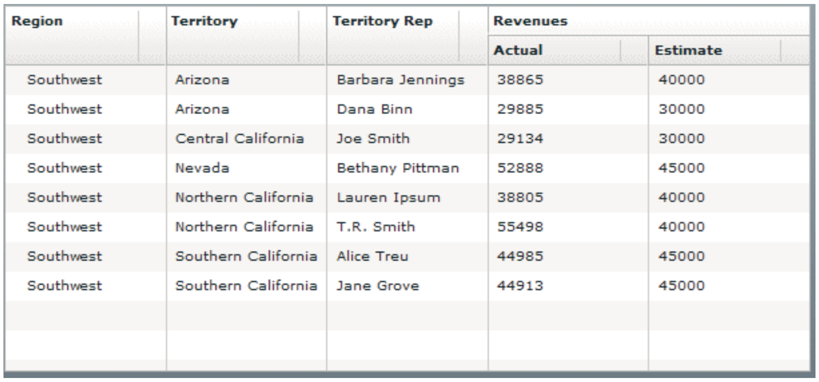
Specify a data field for the AdvancedDataGridColumnGroup class

The previous examples for column groups do not specify a data field for the AdvancedDataGridColumnGroup class. However, the AdvancedDataGridColumnGroup class is designed to work with hierarchical data. Therefore, if you specify a data field for the AdvancedDataGridColumnGroup class, it automatically creates a column group for the subfields of that data field.

In the following example, the HierarchicalDataForGroupedColumns.as file defines a hierarchical data set where the Revenues field contains two subfields, Actual and Estimate:

```
[Bindable]
private var dpHierarchy:ArrayCollection = new ArrayCollection([
  {Region:"Southwest", Territory:"Arizona",
      Territory_Rep:"Barbara Jennings",
      Revenues:{Actual:38865, Estimate:40000}},
  {Region:"Southwest", Territory:"Arizona",
      Territory_Rep:"Dana Binn",
      Revenues:{Actual:29885, Estimate:30000}},
  {Region:"Southwest", Territory:"Central California",
      Territory_Rep:"Joe Smith",
      Revenues:{Actual:29134, Estimate:30000}},
  {Region:"Southwest", Territory:"Nevada",
      Territory_Rep:"Bethany Pittman",
      Revenues:{Actual:52888, Estimate:45000}},
  {Region:"Southwest", Territory:"Northern California",
      Territory_Rep:"Lauren Ipsum",
      Revenues:{Actual:38805, Estimate:40000}},
  {Region:"Southwest", Territory:"Northern California",
      Territory_Rep:"T.R. Smith",
      Revenues:{Actual:55498, Estimate:40000}},
  {Region:"Southwest", Territory:"Southern California",
      Territory_Rep:"Alice Treu",
      Revenues:{Actual:44985, Estimate:45000}},
  {Region:"Southwest", Territory:"Southern California",
      Territory_Rep:"Jane Grove",
      Revenues:{Actual:44913, Estimate:45000}}
]);
```

The following example uses this data and specifies the Revenues field as the value of the `AdvancedDataGridColumnGroup.dataField` property, and creates the following output:



Region	Territory	Territory Rep	Revenues	
			Actual	Estimate
Southwest	Arizona	Barbara Jennings	38865	40000
Southwest	Arizona	Dana Binn	29885	30000
Southwest	Central California	Joe Smith	29134	30000
Southwest	Nevada	Bethany Pittman	52888	45000
Southwest	Northern California	Lauren Ipsum	38805	40000
Southwest	Northern California	T.R. Smith	55498	40000
Southwest	Southern California	Alice Treu	44985	45000
Southwest	Southern California	Jane Grove	44913	45000

The following code implements this example:

```
<?xml version="1.0"?>
<!-- dpcontrols/adg/ColumnGroupHierarchData.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
            import mx.collections.ArrayCollection;

            include "HierarchicalDataForGroupedColumns.as";
        ]]>
    </fx:Script>
    <mx:AdvancedDataGrid id="myADG"
        width="100%" height="100%"
        defaultLeafIcon="{null}">
        <mx:dataProvider>
            <mx:HierarchicalData source="{dpHierarchy}"/>
        </mx:dataProvider>
        <mx:groupedColumns>
            <mx:AdvancedDataGridColumn dataField="Region"/>
            <mx:AdvancedDataGridColumn dataField="Territory"/>
            <mx:AdvancedDataGridColumn dataField="Territory_Rep"
                headerText="Territory Rep"/>
            <mx:AdvancedDataGridColumnGroup dataField="Revenues">
                <mx:AdvancedDataGridColumn dataField="Actual"/>
                <mx:AdvancedDataGridColumn dataField="Estimate"/>
            </mx:AdvancedDataGridColumnGroup>
        </mx:groupedColumns>
   </mx:AdvancedDataGrid>
</s:Application>
```

Using item renderers with the AdvancedDataGrid control

You customize the appearance and behavior of cells in an AdvancedDataGrid control by creating custom item renderers and item editors. Use the same process for assigning item editors and item renderers to columns of the AdvancedDataGrid control as you do with the DataGrid control.

For an introduction to item renderers and item editors, see “MX item renderers and item editors” on page 1006.

The AdvancedDataGrid control adds capabilities to support item renderers. These capabilities let you perform the following actions:

- Create rows or columns not associated with data in the data provider. For example, you can create summary rows from the data provider.
- Span multiple columns with a renderer.
- Use multiple renderers in the same column. For example, when displaying hierarchical data, you can use a different renderer in the column based on the level of the row in the hierarchy.

***Note:** These capabilities support item renderers only; use item editors as you do with the DataGrid control.*

Using an item renderer

To use the item renderer capabilities of the AdvancedDataGrid control, you assign the item renderer to the AdvancedDataGrid control itself, not to a specific column, by using the `AdvancedDataGrid.rendererProviders` property. The following example assigns an item renderer to the Estimate column:

```
<mx:AdvancedDataGrid>
    <mx:columns>
        <mx:AdvancedDataGridColumn dataField="Region"/>
        <mx:AdvancedDataGridColumn dataField="Territory_Rep" headerText="Territory Rep"/>
        <mx:AdvancedDataGridColumn dataField="Actual"/>
        <mx:AdvancedDataGridColumn dataField="Estimate"/>
    </mx:columns>

    <mx:rendererProviders>
        <mx:AdvancedDataGridRendererProvider
            columnIndex="3"
            columnSpan="1"
            renderer="myComponents.EstimateRenderer"/>
    </mx:rendererProviders>
</mx:AdvancedDataGrid>
```

The `rendererProviders` property contains an Array of AdvancedDataGridRendererProvider instances. Each AdvancedDataGridRendererProvider instance defines the characteristics for a single item renderer.

In the previous example, the AdvancedDataGridRendererProvider instance specifies to use the EstimateRenderer for column 3, where the first column in the control is column 0, and the renderer spans a single column. If you set the `columnSpan` property to 0, the renderer spans all columns in the row.

Rather than using the column index to assign the renderer, you specify an `id` property for the column, and then use the `column` property to associate the renderer with the column, as the following example shows:

```
<mx:AdvancedDataGrid>
    <mx:columns>
        <mx:AdvancedDataGridColumn dataField="Region"/>
        <mx:AdvancedDataGridColumn dataField="Territory_Rep" headerText="Territory Rep"/>
        <mx:AdvancedDataGridColumn dataField="Actual"/>
        <mx:AdvancedDataGridColumn id="estCol" dataField="Estimate"/>
    </mx:columns>

    <mx:rendererProviders>
        <mx:AdvancedDataGridRendererProvider
            column="{estCol}"
            columnSpan="1"
            renderer="myComponents.EstimateRenderer"/>
    </mx:rendererProviders>
</mx:AdvancedDataGrid>
```

The `depth` property lets you associate the renderer with a specific level in the hierarchy of the navigation tree of an AdvancedDataGrid control, where the depth of the top-most node in the navigation tree is 1. The following example associates the renderer with the third level of a navigation tree:

```
    <mx:rendererProviders>
        <mx:AdvancedDataGridRendererProvider
            columnIndex="3"
            depth="3"
            columnSpan="1"
            renderer="myComponents.EstimateRenderer"/>
    </mx:rendererProviders>
```

In the previous example, the AdvancedDataGrid control uses the default renderer for the column until you expand it to the third level of the navigation tree, and then it uses EstimateRenderer component. You use the `depth` property to assign different renderers to the same column, where the `depth` property specifies the renderer to use for each level of the tree.

A renderer can span multiple columns. In the following example, you create a renderer that spans two columns:

```
<mx:AdvancedDataGrid>
    <mx:columns>
        <mx:AdvancedDataGridColumn dataField="Region"/>
        <mx:AdvancedDataGridColumn dataField="Territory_Rep" headerText="Territory Rep"/>
        <mx:AdvancedDataGridColumn id="actCol" dataField="Actual"/>
        <mx:AdvancedDataGridColumn dataField="Estimate"/>
    </mx:columns>

    <mx:rendererProviders>
        <mx:AdvancedDataGridRendererProvider
            column="{actCol}"
            depth="3"
            columnSpan="2"
            renderer="myComponents.SummaryRenderer"/>
    </mx:rendererProviders>
</mx:AdvancedDataGrid>
```

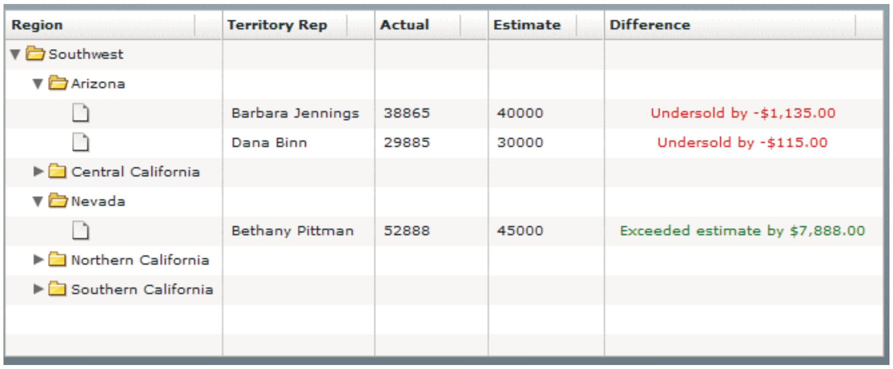
The previous example uses a single renderer that spans the Actual and Estimate columns to display a combined view of the data for these columns. For an implementation of the SummaryRenderer component, see “Using a renderer to generate column data” on page 1445.

The following table describes the properties of the AdvancedDataGridRendererProvider class that you use to configure the renderer:

Property	Description
`column`	The ID of the column for which the renderer is used. If you omit this property, you can use the `columnIndex` property to specify the column.
`columnIndex`	The column index for which the renderer is used, where the first column has an index of 0.
`columnSpan`	The number of columns that the renderer spans. Set this property to 0 to span all columns. The default value is 1.
`dataField`	The data field in the data provider for the renderer. This property is optional.
`depth`	The depth in the tree at which the renderer is used, where the top-most node of the tree has a depth of 1. Use this property when the renderer should be used only when the tree is expanded to a certain depth, not for all nodes in the tree. By default, the control uses the renderer for all levels of the tree.
`renderer`	The renderer.
`rowSpan`	The number of rows that the renderer spans. The default value is 1.

Using a renderer to generate column data

The following example shows the results when an item renderer is used to calculate the value of the Difference column of the AdvancedDataGrid control:



Region	Territory Rep	Actual	Estimate	Difference
▼ Southwest				
▼ Arizona				
	Barbara Jennings	38865	40000	Undersold by -$1,135.00
	Dana Binn	29885	30000	Undersold by -$115.00
▶ Central California				
▼ Nevada				
	Bethany Pittman	52888	45000	Exceeded estimate by $7,888.00
▶ Northern California				
▶ Southern California				

This example defines a column with the `id` of diffCol that is not associated with a data field in the data provider. Instead, you use the `rendererProvider` property to assign an item renderer to the column. The item renderer calculates the difference between the actual and estimate values, and then displays a message based on whether the representative exceeded or missed their estimate.

The following code implements this example:

```
<?xml version="1.0"?>
<!-- dpcontrols/adg/HierarchicalADGSimpleRenderer.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    width="750">
    <fx:Script>
        <![CDATA[
              import mx.collections.ArrayCollection;

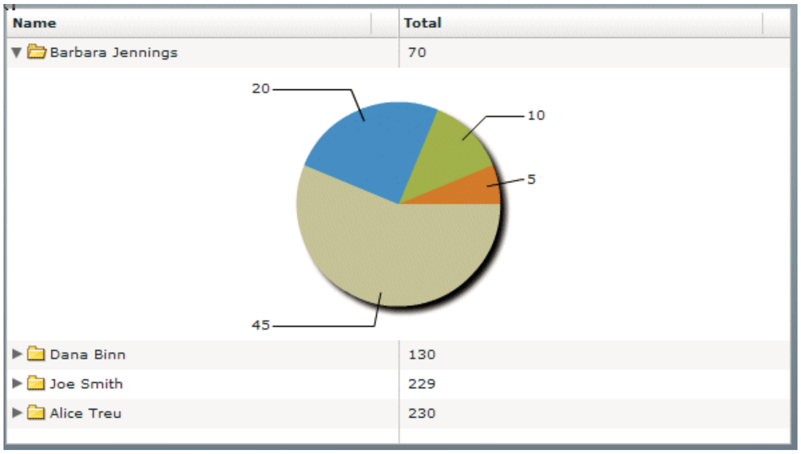
              include "SimpleHierarchicalData.as";
        ]]>
    </fx:Script>
    <mx:AdvancedDataGrid width="100%" height="100%">
        <mx:dataProvider>
            <mx:HierarchicalData source="{dpHierarchy}"/>
        </mx:dataProvider>
        <mx:columns>
            <mx:AdvancedDataGridColumn dataField="Region"/>
            <mx:AdvancedDataGridColumn dataField="Territory_Rep"
                headerText="Territory Rep"/>
            <mx:AdvancedDataGridColumn dataField="Actual"/>
            <mx:AdvancedDataGridColumn dataField="Estimate"/>
            <mx:AdvancedDataGridColumn id="diffCol"
                headerText="Difference"/>
        </mx:columns>
        <mx:rendererProviders>
            <mx:AdvancedDataGridRendererProvider column="{diffCol}"
                depth="3" renderer="myComponents.SummaryRenderer"/>
        </mx:rendererProviders>
    </mx:AdvancedDataGrid>
</s:Application>
```

The following code shows the SummaryRenderer component:

```
<?xml version="1.0"?>
<!-- dpcontrols/adg/myComponents/SummaryRenderer.mxml -->
<mx:Label xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark" textAlign="center">
    <fx:Script>
        <![CDATA[
        override public function set data(value:Object):void
        {
            // Calculate the difference.
            var diff:Number =
                Number(value["Actual"]) - Number(value["Estimate"]);
            if (diff < 0)
            {
                // If Estimate was greater than Actual,
                // display results in red.
                setStyle("color", "red");
                text = "Undersold by " + usdFormatter.format(diff);
            }
            else
            {
                // If Estimate was less than Actual,
                // display results in green.
                setStyle("color", "green");
                text = "Exceeded estimate by " + usdFormatter.format(diff);
            }
        }
        ]]>
    </fx:Script>
    <fx:Declarations>
        <s:CurrencyFormatter id="usdFormatter"
            useCurrencySymbol="true" negativeCurrencyFormat="1"/>
    </fx:Declarations>
</mx:Label>
```

Using an item renderer that spans an entire row

You can use an item renderer with a hierarchical data set to display an entire row of data. The following example shows a PieChart control that displays the data from the detail field of the hierarchical data set. Each row contains detailed information about sales revenues for the representative, which is rendered as a segment of the pie chart:



Name	Total
▼ Barbara Jennings	70
▶ Dana Binn	130
▶ Joe Smith	229
▶ Alice Treu	230

The following code implements this example:

```
<?xml version="1.0"?>
<!-- dpcontrols/adg/GroupADGChartRenderer.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
  <fx:Script>
    <![CDATA[
      import mx.collections.ArrayCollection;

      [Bindable]
      private var dpHierarchy:ArrayCollection= new ArrayCollection([
        {name:"Barbara Jennings", region: "Arizona", total:70, children:[
          {detail:[{amount:5},{amount:10},{amount:20},{amount:45}]}]},
        {name:"Dana Binn", region: "Arizona", total:130,  children:[
          {detail:[{amount:15},{amount:25},{amount:35},{amount:55}]}]},
        {name:"Joe Smith", region: "California", total:229,  children:[
          {detail:[{amount:26},{amount:32},{amount:73},{amount:123}]}]},
        {name:"Alice Treu", region: "California", total:230, children:[
          {detail:[{amount:159},{amount:235},{amount:135},{amount:155}]}
        ]}
      ]);
    ]]>
  </fx:Script>
  <mx:AdvancedDataGrid id="myADG"
    width="100%" height="100%"
    variableRowHeight="true">
    <mx:dataProvider>
       <mx:HierarchicalData source="{dpHierarchy}"/>
    </mx:dataProvider>
    <mx:columns>
        <mx:AdvancedDataGridColumn dataField="name" headerText="Name"/>
        <mx:AdvancedDataGridColumn dataField="total" headerText="Total"/>
    </mx:columns>

    <mx:rendererProviders>
        <mx:AdvancedDataGridRendererProvider
            dataField="detail"
            renderer="myComponents.ChartRenderer"
            columnIndex="0"
            columnSpan="0"/>
    </mx:rendererProviders>
  </mx:AdvancedDataGrid>
</s:Application>
```

The following code renders the ChartRenderer.mxml component:

```
<?xml version="1.0"?>
<!-- dpcontrols/adg/myComponents/ChartRenderer.mxml -->
<mx:VBox height="200" width="100%" xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <mx:PieChart dataProvider="{data.detail}"
        width="100%"
        height="100%"
        showDataTips="true">
        <mx:series>
            <mx:PieSeries labelPosition="callout" field="amount"/>
        </mx:series>
    </mx:PieChart>
</mx:VBox>
```

You can modify this example to display the PieChart control in a column. In the following example, you add a Detail column to the control, and then specify that the item renderer is for column 2 of the control:

```
<?xml version="1.0"?>
<!-- dpcontrols/adg/GroupADGChartRendererOneRow.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
  <fx:Script>
    <![CDATA[
      import mx.collections.ArrayCollection;

      [Bindable]
      private var dpHierarchy:ArrayCollection= new ArrayCollection([
        {name:"Barbara Jennings", region: "Arizona", total:70, children:[
          {detail:[{amount:5},{amount:10},{amount:20},{amount:45}]}]},
        {name:"Dana Binn", region: "Arizona", total:130,  children:[
          {detail:[{amount:15},{amount:25},{amount:35},{amount:55}]}]},
        {name:"Joe Smith", region: "California", total:229,  children:[
          {detail:[{amount:26},{amount:32},{amount:73},{amount:123}]}]},
        {name:"Alice Treu", region: "California", total:230, children:[
          {detail:[{amount:159},{amount:235},{amount:135},{amount:155}]}
        ]}
      ]);
    ]]>
  </fx:Script>
  <mx:AdvancedDataGrid id="myADG"
    width="100%" height="100%"
    variableRowHeight="true">
    <mx:dataProvider>
       <mx:HierarchicalData source="{dpHierarchy}"/>
    </mx:dataProvider>
    <mx:columns>
        <mx:AdvancedDataGridColumn dataField="name" headerText="Name"/>
        <mx:AdvancedDataGridColumn dataField="total" headerText="Total"/>
        <mx:AdvancedDataGridColumn dataField="detail" headerText="Detail"/>
    </mx:columns>

    <mx:rendererProviders>
        <mx:AdvancedDataGridRendererProvider
            dataField="detail"
            renderer="myComponents.ChartRenderer"
            columnIndex="2"/>
    </mx:rendererProviders>
  </mx:AdvancedDataGrid>
</s:Application>
```

Keyboard navigation

The following keystrokes are built into the AdvancedDataGrid control to let users navigate the control:

Keyboard action	**Key assignments**
Standard	• Use the Up and Down Arrow keys to scroll vertically by one row. • Type characters to do incremental type-ahead look-ups in the first column. • Use the Home and End keys to move to the first and last rows. • Use the Page Up and Page Down keys to move to the last visible row and then scroll vertically by the number of rows specified by the `rowcount` property.
In editable mode	• Use the Tab and Shift+Tab keys to move to the next and previous cells, and start editing. • Use the Escape or Control+Period keys to cancel editing. • Use the Enter key based on the value of the `AdvancedDataGridColumn.editorUsesEnterKey` property: • If `editorUsesEnterKey=true`, the Enter key is considered to be part of the input text. • If `editorUsesEnterKey=false`, if single-line editor, the Enter key saves the item and moves down a row. • If you use the Tab key to move focus to the AdvancedDataGrid control, focus is placed on the position of the last edited item. • Use the Control click keys to select multiple discontiguous items.
For the expandable tree	• Use the Multiply key on the number pad (asterisk) to open or close all nodes under the current node, with no animation. • Use the Add key on the number pad or the Space key to open nodes with animation. • Use the Subtract key on the number pad to close nodes with animation. • Use the Control+Shift+Space key to open a closed node, or close an open node. • Use the Control+Shift+Right Arrow key to open a closed node, or select the parent node of a leaf node. • Use the Control+Shift+Left Arrow to close open nodes. • Use the Up and Down Arrow keys to move up and down one row.

Keyboard action	**Key assignments**
For column headers	• Use the arrow keys to move focus to a column header. • The first Space key pressed when a column header has focus sorts the column in descending order. Each subsequent press of the Space key toggles the sort order between ascending and descending order. • Use the Control+Space keys when a header has focus to sort multiple columns. • Use the Left Arrow and Right Arrow keys to move to the previous or next header, without column wrapping.
To scroll vertically and horizontally in pages	• The first Page Up or Page Down key pressed move to the first or last visible row. The next Page Up or Page Down key pressed scrolls vertically up or down by a page, which corresponds to the number of visible rows. • Use the Shift+Page Up and Shift+Page Down keys to move to first or last visible column.

Keyboard action	Key assignments
To move focus out of AdvancedDataGrid while editing is in progress	When you set `AdvancedDataGrid.editable=true` or `AdvancedDataGridColumn=true`: • Use the Tab key to move focus to the AdvancedDataGrid control. • Use the Tab key again to move focus to the next component. • Use the Left, Right, Up, and Down Arrow keys to move between cells. • Use the Shift+Home and Shift+End keys to move to the first and last column in current row. • Cells are only selected by default, they are not editable. • Press the F2 key to make a cell editable. • Use the arrow keys to move the cursor in the editing area. • Use the Escape key to cancel editing. • Use the Enter key to commit editing changes. • Same behavior as when `editable=true`, but the F2 key does not make the cell editable. • Use the Home and End keys to move to first and last rows. • Use the Page Up and Page Down keys to move to the previous and next pages. When focus is on the AdvancedDataGrid control: • Use the Left, Right, Up, and Down Arrow keys to move between cells. • Use the Shift+Home and Shift+End keys to move to the first and last column in current row. • Cells are only selected by default, they are not editable. • Press the F2 key to make a cell editable. • Use the arrow keys to move the cursor in the editing area. • Use the Escape key to cancel editing. • Use the Enter key to commit editing changes. • Same behavior as when `editable=true`, but the F2 key does not make the cell editable. • Use the Home and End keys to move to first and last rows. • Use the Page Up and Page Down keys to move to the previous and next pages. When editing the cell: • Use the arrow keys to move the cursor in the editing area. • Use the Escape key to cancel editing. • Use the Enter key to commit editing changes. • Same behavior as when `editable=true`, but the F2 key does not make the cell editable. • Use the Home and End keys to move to first and last rows. • Use the Page Up and Page Down keys to move to the previous and next pages. When you set `AdvancedDataGrid.editable=false` or `AdvancedDataGridColumn=false`: • Same behavior as when `editable=true`, but the F2 key does not make the cell editable. • Use the Home and End keys to move to first and last rows. • Use the Page Up and Page Down keys to move to the previous and next pages.

OLAPDataGrid control

The OLAPDataGrid control lets you aggregate large amounts of data for easy display and interpretation. The control supports a two-dimensional grid layout, where the columns and rows of the control can display a single level of information, or you can create hierarchical rows and columns to display more complex data.

The OLAPDataGrid controls is a subclass of the AdvancedDataGrid control, and therefore supports many of the features of the AdvancedDataGrid control. For more information on the AdvancedDataGrid control, see "AdvancedDataGrid control" on page 1397.

About OLAP data grids

When working with large amounts of data, you can quickly get overwhelmed with the scope and size of the data. For example, you collect sales information for different products, in different regions, and for different customers in a typical two-dimensional spreadsheet. That spreadsheet could easily contain hundreds of rows and tens or even hundreds of columns. Extracting useful information for such a large data collection can be difficult, and trying to identify trends or other patterns in the data can be even harder.

Data visualization is a technique for examining large amounts of data in a compact format. One type of data visualization technique is to use a chart, such as a bar, column, or pie chart. Adobe® Flex™ supports many types of charts. For more information, see "Introduction to charts" on page 1075.

Another data visualization technique is to aggregate the data in a compact format, such as in an OLAP (online analytical processing) data grid. An OLAP data grid is similar to a pivot table in Microsoft Excel. An OLAP data grid displays data aggregations in a two-dimensional grid of rows and columns, like a spreadsheet, but the data is condensed based on your aggregation settings.

***Note:** While the Flex OLAP data grid is similar to a pivot table, it provides a much greater set of features for aggregating data.*

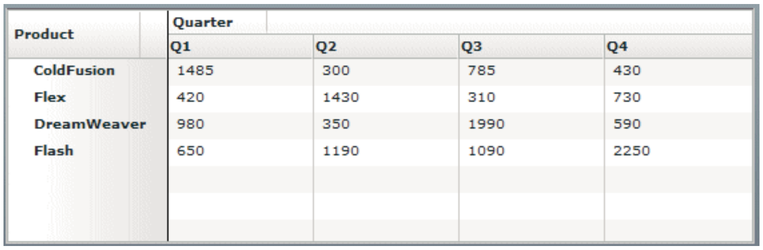
For example, you collect sales information on a server in a flat data structure of records, where each record contains information for a single customer transaction, for a single product, in a single quarter. The following code shows the format of this flat data:

```
data:Object = {
    customer:"AAA",
    product:"ColdFusion",
    year:"2007",
    quarter:"Q1"
    revenue: "100.00"
}
```

For a large company with hundreds of customers and tens or hundreds of products, this table could easily contain several thousand rows. Rather than display this information in a standard spreadsheet, you download your data to a Flex application to aggregate sales data by product and quarter, and then display the aggregated data in an OLAP data grid. From this data aggregation, you can determine trends in sales of each product over time.

About the OLAPDataGrid control

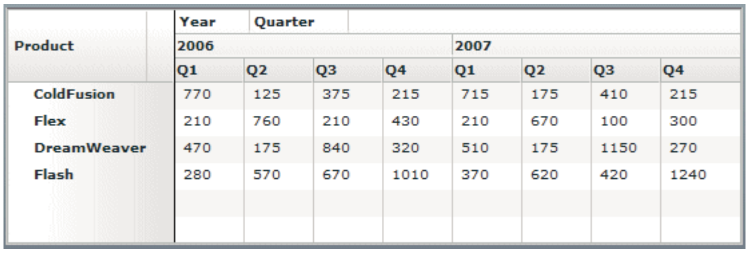
You use the Flex OLAPDataGrid control to display an OLAP data grid. The following image shows the OLAPDataGrid control displaying the aggregated sales information for product and quarter:



Product	Quarter			
	Q1	Q2	Q3	Q4
ColdFusion	1485	300	785	430
Flex	420	1430	310	730
DreamWeaver	980	350	1990	590
Flash	650	1190	1090	2250

Like all Flex data grid controls, the OLAPDataGrid control is designed to display data in a two-dimensional representation of rows and columns.

You can modify this example to compare quarterly sales from two different years, as the following example shows:

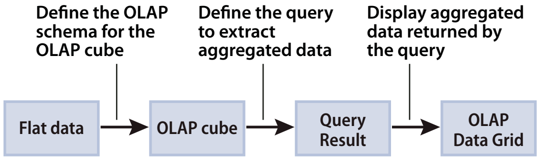


Product	Year	Quarter						
	2006				2007			
	Q1	Q2	Q3	Q4	Q1	Q2	Q3	Q4
ColdFusion	770	125	375	215	715	175	410	215
Flex	210	760	210	430	210	670	100	300
DreamWeaver	470	175	840	320	510	175	1150	270
Flash	280	570	670	1010	370	620	420	1240

In the previous figure, the columns of the OLAPDataGrid control show a hierarchy of information for year and quarter. You can add multiple-level hierarchies for both the columns and the rows of the control.

About creating an OLAP data grid

The following figure shows the data flow that you use to aggregate your data for display in the OLAPDataGrid control:



Define the OLAP schema for the OLAP cube
Define the query to extract aggregated data
Display aggregated data returned by the query
Flat data
OLAP cube
Query Result
OLAP Data Grid

The following steps describe this process in more detail:

1 Start with flat data, which is typically data arranged as a set of records where each record contains the same data fields. For example, you might start with flat data from a spreadsheet, or with data from a table of a relational database.

  The following code shows an example format of flat data:

```
data:Object = {
    customer:"AAA",
    product:"ColdFusion",
    quarter:"Q1"
    revenue: "100.00"
}
```

2 Define an OLAP schema that describes how your data gets transformed from a flat representation into an OLAP cube. An OLAP schema defines the representation of your flat data in an OLAP cube, and defines how to aggregate your data for an OLAP query.

An OLAP cube is analogous to a table in a relational database. But whereas a table typically has two dimensions (row and column), an OLAP cube can have any number of dimensions. In this example, the cube has three dimensions: customer, product, and quarter. Every possible set of values for customer, product, and quarter defines a unique point in the cube. The value at each point in the cube is the sales revenue for that set of values of customer, product, and quarter.

3 Create queries to extract aggregated data from the OLAP cube for display in the OLAPDataGrid control.

After your data is in an OLAP cube, you write queries to extract aggregated data for display in the OLAPDataGrid control. You can write multiple queries to create different types of data aggregations.

4 Use the query results as input to the OLAPDataGrid control to display the results.

About OLAP cubes

An OLAP cube can have any number of dimensions. In its simplest form, the *dimensions* of an OLAP cube correspond to a field of the flat data set. For example, you have flat data that contains three fields:

```
data:Object = {
    product:"ColdFusion"
    quarter :"Q1"
    revenue: "100.00",
}
```

The data fields of each record can contain the following values:

- The product field can have the values: ColdFusion, Flex, Dreamweaver, and Illustrator.
- The quarter field can have the values: Q1, Q2, Q3, and Q4.
- The revenue field contains the sales, in dollars, of the product for the quarter.

To aggregate your data, you create an OLAP cube with two dimensions: quarter and product. The value along each dimension of the cube is called a *member*. For example, the product dimension of the cube has the following members: ColdFusion, Flex, Dreamweaver, and Illustrator. For the quarter dimension, the members are Q1, Q2, Q3, and Q4.

The value at any point in the cube defined by the two dimensions is called a *measure* of the cube. For example, the measure at the point in the cube defined by (Q1, ColdFusion) is 100.00. A schema can define one or more measures for a single point in the OLAP cube.

Flex supports only numeric values for the measure of a cube. The advantage of numeric values is that they can be easily aggregated for display in the OLAPDataGrid control. Some typical aggregation types include sum, average, minimum, and maximum. For example, you specify the aggregation method of the revenue measure as `SUM`. You then extract sales information from the cube for ColdFusion. The aggregated sales data contains the sum of all ColdFusion sales for each quarter.

About OLAP schemas

To convert flat data into an OLAP cube, you create an OLAP *schema* that defines the dimensions of the cube, the fields of the flat data that supply the members along each dimension, and the fields of the flat data that supply the measure for any point in the cube.

For example, you have the following flat data that contains sales records:

```
data:Object = {
    customer:"AAA",
    product:"ColdFusion",
    quarter:"Q1"
    revenue: "100.00"
}
```

The following example shows the definition for an OLAPCube that includes the definition of the OLAP schema used to represent this data in the cube. This schema defines a three-dimensional OLAP cube based on the customer, product, and quarter fields of the data.

```
<mx:OLAPCube name="FlatSchemaCube"
    dataProvider="{flatData}"
    id="myMXMLCube"
    complete="runQuery(event);">

    <mx:OLAPDimension name="CustomerDim">
        <mx:OLAPAttribute name="Customer" dataField="customer"/>
        <mx:OLAPHierarchy name="CustomerHier" hasAll="true">
            <mx:OLAPLevel attributeName="Customer"/>
        </mx:OLAPHierarchy>
    </mx:OLAPDimension>

    <mx:OLAPDimension name="ProductDim">
        <mx:OLAPAttribute name="Product" dataField="product"/>
        <mx:OLAPHierarchy name="ProductHier" hasAll="true">
            <mx:OLAPLevel attributeName="Product"/>
        </mx:OLAPHierarchy>
    </mx:OLAPDimension>
    <mx:OLAPDimension name="QuarterDim">
        <mx:OLAPAttribute name="Quarter" dataField="quarter"/>
        <mx:OLAPHierarchy name="QuarterHier" hasAll="true">
            <mx:OLAPLevel attributeName="Quarter"/>
        </mx:OLAPHierarchy>
    </mx:OLAPDimension>

    <mx:OLAPMeasure name="Revenue"
        dataField="revenue"
        aggregator="SUM"/>
</mx:OLAPCube>
```

Notice that in this schema:

- All dimensions are defined first, and then all measures.
- The first line of each dimension associates a data field of the flat data with an OLAPAttribute instance. You then use the `OLAPLevel.attributeName` property to associate the attribute with a level of the dimension to populate the members of the dimension. For example, in this schema you populate the Customer level of the CustomerDim dimension with the data from the customer field of the data.
- A dimension of an OLAP schema always contains a hierarchy of one or more levels. In this schema, the hierarchy of each dimension contains only a single level corresponding to a field of the flat data. This is the simplest form of a dimension. Other schemas could define multiple levels in a hierarchy to create a complex dimension. For more information, see "Creating an OLAP schema" on page 1462.

- A measure definition specifies the data field of the flat data that contains the value for each point in the OLAP cube, and how the measure is aggregated by an OLAP query. In this example, you aggregate revenue by summing it. That means all queries of this OLAP cube will return revenue summations. Other types of aggregation methods include maximum, minimum, and average.
- This definition of the OLAPCube specifies an event handler for the `complete` event. You cannot invoke a query on the cube until it completes initialization, which is signalled by the cube when it dispatches the `complete` event.

Based on the requirements of your application, you might create multiple OLAP cubes from the same flat data set, where each cube uses a different schema to create its own arrangement of dimensions and measures. For more information and examples of OLAP schemas, see "Creating an OLAP schema" on page 1462.

About OLAP queries

OLAP queries extract aggregated data from an OLAP cube for display in an OLAPDataGrid control. The query specifies the dimensions that define the characteristics of the query, and the measure or measures aggregated to create the query results.

In the previous section, you defined an OLAP schema for sales information where the schema defines CustomerDim, ProductDim, and QuarterDim dimensions, and a single measure for revenue aggregated by the `SUM` aggregation method. Therefore, you can create a query to sum revenue by the following criteria:

- Product for each quarter
- Customer for each product
- Customer for each quarter
- Any other combination of members from each dimension

You construct a query in ActionScript as an instance of the OLAPQuery class, and then execute the query by calling the `OLAPCube.execute()` method, which returns an instance of the AsyncToken class.

A query is required to have two axes, a row axis and a column axis, of type IOLAPQueryAxis. The row axis defines the data aggregation information for each row of the OLAPDataGrid control, and the column axis defines the data aggregation information for each column of the control.

You use the OLAPSet class to specify the data aggregation information for each axis, as the following example shows:

```
// Create an instance of OLAPQuery to represent the query.
var query:OLAPQuery = new OLAPQuery;

// Get the row axis from the query instance.
var rowQueryAxis:IOLAPQueryAxis = query.getAxis(OLAPQuery.ROW_AXIS);
// Create an OLAPSet instance to configure the axis.
var productSet:OLAPSet = new OLAPSet;
// Add the Product to the row to aggregate data
// by the Product dimension.
productSet.addElements(
    cube.findDimension("ProductDim").findAttribute("Product").children);
// Add the OLAPSet instance to the axis.
rowQueryAxis.addSet(productSet);

// Get the column axis from the query instance, and configure it
// to aggregate the columns by the Quarter dimension.
var colQueryAxis:IOLAPQueryAxis = query.getAxis(OLAPQuery.COLUMN_AXIS);
var quarterSet:OLAPSet= new OLAPSet;
quarterSet.addElements(
    cube.findDimension("QuarterDim").findAttribute("Quarter").children);
colQueryAxis.addSet(quarterSet);

// Execute the query.
var token:AsyncToken = cube.execute(query);
// Set up handlers for the query results.
token.addResponder(new AsyncResponder(showResult, showFault));
```

Notice that in this query:

- You initialize each axis by calling the `OLAPQuery.getAxis()` method.
- You configure each OLAPSet instance by calling the `OLAPSet.addElements()` method to specify the information used to populate the axis.
- You set up two functions to handle the query result defined by the AsyncToken class. In this example, the function `showResult()` handles the query results when the query succeeds, and the function `showFault()` handles any errors detected during query execution. For more information on using the AsyncToken class, see “Executing a query and returning the results to an OLAPDataGrid control” on page 1469.

For more information and examples of OLAP queries, see “Creating OLAP queries” on page 1466.

The differences between the OLAPDataGrid and the AdvancedDataGrid control

You use the OLAPDataGrid control to display the results of an OLAP query. The OLAPDataGrid control is a subclass of the AdvancedDataGrid control and inherits much of its functionality. However, because of the way you pass data to the OLAPDataGrid control, it has several differences from the AdvancedDataGrid control:

- Column dragging is not allowed in the OLAPDataGrid control.
- You cannot edit cells in the OLAPDataGrid control because cell data is a result of a query and does not correspond to a single data value in the OLAP cube.
- You cannot sort columns by clicking on headers in the OLAPDataGrid control. Sorting is supported at the dimension level so that you can change the order of members of that dimension. Note that you can only use sorting while preparing the query, and then use it to get the member names displayed along the rows and column headers.

You populate an OLAPDataGrid control with data by setting its data provider to an instance of the OLAPResult class, which contains the results of an OLAP query. For a complete example that uses this control, see “Example using the OLAPDataGrid control” on page 1460.

Example using the OLAPDataGrid control

The following example shows the complete code for creating the OLAPDataGrid control that appears in the section "About OLAP data grids" on page 1454. This example aggregates product sales by quarter. The example uses flat data from the dataIntro.as file, which contains sales records in the following format:

```
data:Object = {
    customer:"AAA",
    product:"ColdFusion",
    quarter:"Q1"
    revenue: "100.00"
}
```

The following code implements this example:

```
<?xml version="1.0"?>
<!-- olapdatagrid/OLAPDG_Intro.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
        creationComplete="creationCompleteHandler();">
    <fx:Script>
      <![CDATA[
        import mx.rpc.AsyncResponder;
        import mx.rpc.AsyncToken;
        import mx.rpc.events.FaultEvent;
        import mx.olap.OLAPQuery;
        import mx.olap.OLAPSet;
        import mx.olap.IOLAPQuery;
        import mx.olap.IOLAPQueryAxis;
        import mx.olap.IOLAPCube;
        import mx.olap.OLAPResult;
        import mx.events.CubeEvent;
        import mx.controls.Alert;
        import mx.collections.ArrayCollection;

        include "dataIntro.as"
        private function creationCompleteHandler():void {
            // You must initialize the cube before you
            // can execute a query on it.
            myMXMLCube.refresh();
        }
        // Create the OLAP query.
        private function getQuery(cube:IOLAPCube):IOLAPQuery {
            // Create an instance of OLAPQuery to represent the query.
            var query:OLAPQuery = new OLAPQuery;

            // Get the row axis from the query instance.
            var rowQueryAxis:IOLAPQueryAxis =
                query.getAxis(OLAPQuery.ROW_AXIS);
            // Create an OLAPSet instance to configure the axis.
            var productSet:OLAPSet = new OLAPSet;
            // Add the Product to the row to aggregate data
            // by the Product dimension.
            productSet.addElements(
                cube.findDimension("ProductDim").findAttribute("Product").children);
            // Add the OLAPSet instance to the axis.
            rowQueryAxis.addSet(productSet);
            // Get the column axis from the query instance, and configure it
            // to aggregate the columns by the Quarter dimension.
            var colQueryAxis:IOLAPQueryAxis =
                query.getAxis(OLAPQuery.COLUMN_AXIS);
            var quarterSet:OLAPSet= new OLAPSet;
            quarterSet.addElements(
                cube.findDimension("QuarterDim").findAttribute("Quarter").children);
            colQueryAxis.addSet(quarterSet);

            return query;
        }
        // Event handler to execute the OLAP query
        // after the cube completes initialization.
        private function runQuery(event:CubeEvent):void {
            // Get cube.
            var cube:IOLAPCube = IOLAPCube(event.currentTarget);
            // Create a query instance.
            var query:IOLAPQuery = getQuery(cube);
            // Execute the query.
            var token:AsyncToken = cube.execute(query);
            // Set up handlers for the query results.
            token.addResponder(new AsyncResponder(showResult, showFault));
        }
        // Handle a query fault.
        private function showFault(error:FaultEvent, token:Object):void {
            Alert.show(error.fault.faultString);
        }
        // Handle a successful query by passing the query results to
        // the OLAPDataGrid control..
        private function showResult(result:Object, token:Object):void {
            if (!result) {
                Alert.show("No results from query.");
                return;
            }
            myOLAPDG.dataProvider= result as OLAPResult;
        }
      ]]>
    </fx:Script>
    <fx:Declarations>
        <mx:OLAPCube name="FlatSchemaCube"
            dataProvider="{flatData}"
            id="myMXMLCube"
            complete="runQuery(event);">

            <mx:OLAPDimension name="CustomerDim">
                <mx:OLAPAttribute name="Customer" dataField="customer"/>
                <mx:OLAPHierarchy name="CustomerHier" hasAll="true">
                    <mx:OLAPLevel attributeName="Customer"/>
                </mx:OLAPHierarchy>
            </mx:OLAPDimension>
            <mx:OLAPDimension name="ProductDim">
                <mx:OLAPAttribute name="Product" dataField="product"/>
                <mx:OLAPHierarchy name="ProductHier" hasAll="true">
                    <mx:OLAPLevel attributeName="Product"/>
                </mx:OLAPHierarchy>
            </mx:OLAPDimension>
            <mx:OLAPDimension name="QuarterDim">
                <mx:OLAPAttribute name="Quarter" dataField="quarter"/>
                <mx:OLAPHierarchy name="QuarterHier" hasAll="true">
                    <mx:OLAPLevel attributeName="Quarter"/>
                </mx:OLAPHierarchy>
            </mx:OLAPDimension>

            <mx:OLAPMeasure name="Revenue"
                dataField="revenue"
                aggregator="SUM"/>
        </mx:OLAPCube>
    </fx:Declarations>
    <mx:OLAPDataGrid id="myOLAPDG" width="100%" height="100%"/>
</s:Application>
```

Creating an OLAP schema

An OLAP schema defines the representation of your flat data in an OLAP cube, and defines how to aggregate your data for an OLAP query. You typically define your schema in MXML. While you can construct a schema programmatically in ActionScript, that method requires much more coding than MXML.

The following table describes the classes and interfaces that you use to define an OLAP schema:

Class	Interface	Description
OLAPSchema	IOLAPSchema	The schema instance.
OLAPCube	IOLAPCube	The OLAP cube created by the schema.
OLAPDimension	IOLAPDimension	A dimension of the schema.
OLAPAttribute	IOLAPAttribute	An attribute of a dimension
OLAPHierarchy	IOLAPHierarchy	A hierarchy of a dimension.
OLAPLevel	IOLAPLevel	A level of a hierarchy.
OLAPMeasure	IOLAPMeasure	A measure of a dimension.

General form of a schema definition

In MXML, you can define an OLAP schema as part of the definition of an OLAPCube instance. In MXML, you declare an OLAPCube in an `<fx:Declarations>` tag because it is not a visual component.

Typically, you set any properties of the OLAPCube instance as tag attributes, and set the `OLAPCube.dimensions` and `OLAPCube.measures` properties as child tags, as the following example shows:

```
<fx:Declarations>
    <mx:OLAPCube name="FlatSchemaCube"
        dataProvider="{flatData}"
        id="myMXMLCube"
        complete="runQuery(event);">

        <!-- Define dimensions. -->
        <mx:OLAPDimension ... />

        <mx:OLAPDimension ... />
        ...

        <!-- Define measures. -->
        <mx:OLAPMeasure ... />
        ...
    </mx:OLAPCube>
</fx:Declarations>
```

The order of the OLAPDimension and OLAPMeasure definitions is not important, but you should not place OLAPMeasure definitions between OLAPDimension definitions.

Specifying the aggregation method for a measure

As part of creating an OLAP schema, you specify the data field that provides the value of the measure for each point in the cube. The measure corresponds to the data value at that point in the OLAP cube. For example, if you define a schema for sales information, you might specify as a measure of the cube the revenue for a product, and the aggregation type as `SUM`.

A schema can define one or more measures for a single point in the OLAP cube. The first measure in the schema is called the *default measure*, and is the measure returned by an OLAP query when you do not explicitly specify the measure to return. For more information on selecting a specific measure, see “Creating a query using a nondefault measure” on page 1484.

The following example shows a section of an MXML schema definition that specifies two measures for the schema:

```
<mx:OLAPMeasure name="Revenue" dataField="revenue" aggregator="SUM"/>
<mx:OLAPMeasure name="Cost" dataField="cost" aggregator="SUM"/>
```

When creating a schema, you specify the name of the measure, the data field in the input flat data that contains the data for the measure, and an aggregation method of the measure. In this example, the aggregation method is `SUM`. That means when you create an OLAP query for a measure, the query sums all revenue fields to generate the values displayed by the OLAPDataGrid control. You could use this schema to define a cube so that you can total sales and cost information for products, regions, and other characteristics of your data.

To aggregate the revenue data using a different aggregation method, such as average or maximum, create another schema to define a second OLAP cube. The following example shows a section of another MXML schema definition that specifies the aggregation method as `MAX` for the sales data and `MIN` for the cost data:

```
<mx:OLAPMeasure name="Revenue" dataField="revenue" aggregator="MAX"/>
<mx:OLAPMeasure name="Cost" dataField="cost" aggregator="MIN"/>
```

You should take care in how you define your schema because it can limit the types of queries that you can run on it, or the level of detail at which you can create aggregations.

Creating a schema dimension

An OLAPSchema instance can define any number of dimensions, limited only by your input data. A dimension can be a simple dimension with a single level, or it can be a complex dimension with multiple levels. The dimension of a schema always has the same basic form:

```
<mx:OLAPDimension name="QuarterDim">
    <mx:OLAPAttribute name="Quarter" dataField="quarter"/>
    ...
    <mx:OLAPHierarchy name="QuarterHier" hasAll="true">
        <mx:OLAPLevel attributeName="Quarter"/>
        ...
    </mx:OLAPHierarchy>
</mx:OLAPDimension>
```

Notice that in this schema:

- The dimension first uses OLAPAttribute class to specify the data fields of the input data set used to populate the members of the dimension.

  The dimension defines an instance of the OLAPHierarchy class. Therefore, a dimension is always assumed to contain a hierarchy of levels, even if that hierarchy contains only a single level.

- The dimension specifies one or more instances of the OLAPLevel class to associate a field of the input with the dimension.

Defining a dimension that contains a single level

To create a simple dimension (a dimension that contains a single level), you define a dimension hierarchy, as the following example shows:

```
<mx:OLAPDimension name="CustomerDim">
    <mx:OLAPAttribute name="Customer" dataField="customer"/>
    <mx:OLAPHierarchy name="CustomerHier" hasAll="true">
        <mx:OLAPLevel attributeName="Customer"/>
    </mx:OLAPHierarchy>
</mx:OLAPDimension>
```

In this example, the customer field of the input data defines the entire measure of the dimension.

Defining a dimension that contains multiple levels

Instead of creating a separate dimension for each field of your data, you can choose to group related data fields along a single dimension. For example, your data might contain several fields related to the time of a transaction, such as month, quarter, and year. Or your data might contain multiple fields associated with the geographical area of a transaction, such as region, state, province, or country.

The TimeDim dimension in the following example defines hierarchical dimensions that contain two levels, one for year and one for quarter:

```
<mx:OLAPCube name="FlatSchemaCube"
    dataProvider="{flatData}"
    id="myMXMLCube">

    <mx:OLAPDimension name="TimeDim">
        <mx:OLAPAttribute name="Year" dataField="year"/>
        <mx:OLAPAttribute name="Quarter" dataField="quarter"/>
        <mx:OLAPHierarchy name="Time-PeriodHier" hasAll="true">
            <mx:OLAPLevel attributeName="Year"/>
            <mx:OLAPLevel attributeName="Quarter"/>
        </mx:OLAPHierarchy>
    </mx:OLAPDimension>

    <mx:OLAPMeasure name="Revenue"dataField="revenue" aggregator="SUM"/>
</mx:OLAPCube>
```

With this schema definition, you can aggregate data for all time, for individual years, for individual quarters, or for individual quarters of a specific year.

Notice that the TimeDim dimension contains a Year level, the most general level, and a Quarter level, the more detailed level. The first level in the hierarchy typically defines the most general level, and each subsequent level provides a greater level of detail.

If your data contained a month field with the month of the year for a transaction, you can add the Month level to the TimeDim dimension. Since month is a more detailed measure of time than quarter, add the Month level after the Quarter level, as the following example shows:

```
<mx:OLAPDimension name="TimeDim">
    <mx:OLAPAttribute name="Year" dataField="year"/>
    <mx:OLAPAttribute name="Quarter" dataField="quarter"/>
    <mx:OLAPAttribute name="Month" dataField="month"/>
    <mx:OLAPHierarchy name="Time-PeriodHier" hasAll="true">
        <mx:OLAPLevel attributeName="Year"/>
        <mx:OLAPLevel attributeName="Quarter"/>
        <mx:OLAPLevel attributeName="Month"/>
    </mx:OLAPHierarchy>
</mx:OLAPDimension>
```

The advantage of creating a hierarchical schema is that you can write queries to extract top-level data aggregations or to drill down into the data to extract more granular data. For the previous schema definition, you can write an OLAP query to aggregate data by the most general field, such as year, or drill down to obtain more granular results by aggregating your data by quarter in each year, by month in each quarter, or by month in each year.

Creating a default member in a schema

Most of the OLAP schemas shown so far have been defined in the following form:

```
<mx:OLAPDimension name="TimeDim">
    <mx:OLAPAttribute name="Year" dataField="year"/>
    <mx:OLAPAttribute name="Quarter" dataField="quarter"/>
    <mx:OLAPHierarchy name="Time-PeriodHier" hasAll="true">
        <mx:OLAPLevel attributeName="Year"/>
        <mx:OLAPLevel attributeName="Quarter"/>
    </mx:OLAPHierarchy>
</mx:OLAPDimension>
```

In this schema, the hierarchy sets the `OLAPHierarchy.hasAll` property to `true` to create a default member for the hierarchy. The default member is created automatically for the hierarchy and contains an aggregation of all levels in the hierarchy. In the previous schema, the default member contains an aggregation of the measure of the schema for all years and all quarters.

The default member is used by OLAP queries when you do not specify any criteria to aggregate the dimension. For example, your OLAP schema contains a ProductDim, TimeDim, and CustomerDim dimension. You then write a query to extract data by product and customer, but omit any specification in the query for time. The OLAP query automatically uses the default member of the dimension to aggregate the information for the TimeDim dimension.

The default value of the `OLAPHierarchy.hasAll` property is `true`. If you set it to `false`, the OLAP query uses the first level in the hierarchy to aggregate the dimension. The following schema sets the `hasAll` property to `false`:

```
<mx:OLAPDimension name="TimeDim">
    <mx:OLAPAttribute name="Year" dataField="year"/>
    <mx:OLAPAttribute name="Quarter" dataField="quarter"/>
    <mx:OLAPHierarchy name="Time-PeriodHier" hasAll="false">
        <mx:OLAPLevel attributeName="Year"/>
        <mx:OLAPLevel attributeName="Quarter"/>
    </mx:OLAPHierarchy>
</mx:OLAPDimension>
```

Because the `hasAll` property is `false`, an OLAP query automatically aggregates the data in the dimension by the Year level when you omit the TimeDim dimension from the query.

By default, the OLAP cube adds a member to the dimension named `(All)` to represent the default member. You can use the `OLAPHierarchy.allLevelName` property to specify a different name, as the following example shows:

```
<mx:OLAPDimension name="TimeDim">
    <mx:OLAPAttribute name="Year" dataField="year" allLevelname="AllTime"/>
    <mx:OLAPAttribute name="Quarter" dataField="quarter"/>
    <mx:OLAPHierarchy name="Time-PeriodHier" hasAll="true">
        <mx:OLAPLevel attributeName="Year"/>
        <mx:OLAPLevel attributeName="Quarter"/>
    </mx:OLAPHierarchy>
</mx:OLAPDimension>
```

When you execute an OLAP query, you choose whether or not to include the default member in the query results. For more information, see "Using the default member in a query" on page 1471.

Creating OLAP queries

You use an OLAP query to extract data from an OLAP cube for display by the OLAPDataGrid control. An OLAP query defines a result set in a two-dimensional table of rows and columns so that the data can be viewed in the OLAPDataGrid control.

The following table describes the classes and interfaces that you use the define a query:

Class	Interface	Description
AsyncToken		The result of the `OLAPQuery.execute()` method.
OLAPCell	IOLAPCell	An area of the cube defined by a tuple.
OLAPMember	IOLAPMember	A member of a dimension.
OLAPQuery	IOLAPQuery	The query instances.
OLAPQueryAxis	IOLAPQueryAxis	An axis of the query.

Class	Interface	Description
OLAPResult	IOLAPResult	The query result.
OLAPSet		A set of members for an axis.
OLAPTuple	IOLAPTuple	A tuple containing one or more members.

***Note:** Many of the examples in this topic use interfaces rather than classes. One of the reasons to use interfaces is that if you define customized versions of classes that implement these interfaces, you do not have to modify your code.*

Creating a query

The process of creating a query has the following steps:

1 Prepare the cube for a query. For more information, see "Preparing a cube for a query" on page 1467.

2 Define an instance of the OLAPQuery class to represent the query. For more information, see "Creating a query axis" on page 1468.

3 Define an instance of the OLAPQueryAxis class to represent the rows of the query.

4 Define an instance of the OLAPSet class to define the members that provide the row axis information. For more information, see "Writing a query for a simple OLAP cube" on page 1471 and "Writing a query for a complex OLAP cube" on page 1478.

5 Define an instance of the OLAPQueryAxis class to represent the columns of the query.

6 Define an instance of the OLAPSet class to define the members that provide the axis column information.

7 Optionally define an instance of the OLAPQueryAxis class to specify a slicer axis. For more information, see "Creating a slicer axis" on page 1484

8 Define an instance of the OLAPSet class to define the members that provide the slicer axis information.

9 Execute the query on the cube by calling `OLAPCube.execute()`. For more information, see "Executing a query and returning the results to an OLAPDataGrid control" on page 1469.

10 Pass the query results to the OLAPDataGrid control.

Preparing a cube for a query

Before you can run the first query on an OLAP cube, you must call the `OLAPCube.refresh()` method to initialize the cube from the input data. Upon completion of cube initialization, the OLAP cube dispatches the `complete` event to signal that the cube is ready for you to query.

You can use event handlers to initialize the cube and to invoke the query. The following example uses the application's `creationComplete` event to initialize the cube, and then uses the cube's `complete` event to execute the query:

```
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="creationCompleteHandler();">

<fx:Script>
    <![CDATA[

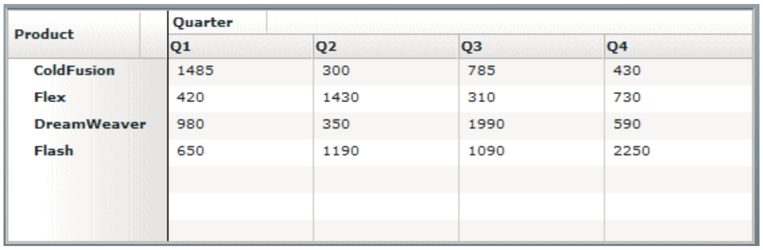
        private function creationCompleteHandler():void {
            // You must initialize the cube before you
            // can execute a query on it.
            myMXMLCube.refresh();
        }

        // Event handler to execute the OLAP query
        // after the cube completes initialization.
        private function runQuery(event:CubeEvent):void {
            ...
        }
    ]]>
</fx:Script>
<fx:Dclarations>
    <mx:OLAPCube name="FlatSchemaCube"
        dataProvider="{flatData}"
        id="myMXMLCube"
        complete="runQuery(event);">
        ...
    </mx:OLAPCube>
</fx:Declarations>

...
</s:Application>
```

Creating a query axis

The following example shows an OLAPDataGrid control containing the results of a query for the sales of different products for different quarters:



Product	Quarter			
	Q1	Q2	Q3	Q4
ColdFusion	1485	300	785	430
Flex	420	1430	310	730
DreamWeaver	980	350	1990	590
Flash	650	1190	1090	2250

To create a query, you must define a row axis, a column axis, and optionally a slicer axis, where each axis is an instance of the IOLAPQueryAxis interface. The following table describes the different types of axes:

Axis	Description
Row	Defines the data that appears in each row of the OLAPDataGrid control. In the previous image, you define the row to show each product. This axis is required.
Column	Defines the data displayed in the column. In the previous image, you define the columns to show each year. This axis is required.
Slicer	Optionally defines a filter to reduce the size of the query results, often to reduce the dimensionality of the results from a dimension greater than two so that you can display the results in an OLAPDataGrid control. You also use a slicer access to return data aggregations for the nondefault measure. For more information on using a slicer axis, see "Creating a slicer axis" on page 1484.

When you construct the OLAPQueryAxis instance, you use the `OLAPQuery.getAxis()` method to initialize the axis to configure it as either a row, column, or slicer axis, as the following example shows:

```
// Create an instance of OLAPQuery to represent the query.
var query:OLAPQuery = new OLAPQuery;

// Get the row axis from the query instance.
var rowQueryAxis:IOLAPQueryAxis = query.getAxis(OLAPQuery.ROW_AXIS);
// Create an OLAPSet instance to configure the axis.
...

var colQueryAxis:IOLAPQueryAxis = query.getAxis(OLAPQuery.COLUMN_AXIS);
...
```

Populating a query axis

You use the OLAPSet class to specify the members of the dimensions of the OLAP cube that populate a query axis. To add a member to an OLAPSet instance, you call the OLAPSet.addElement() or OLAPSet.addElements() method. The following table describes these methods:

OLAPSet method	Description
`addElement(e:IOLAPElement):void`	Adds a single element to the set. • If you pass an IOLAPHierarchy or IOLAPAttributeHierarchy instance to the method, it adds the default member of the hierarchy to the set. • If you pass an IOLAPLevel instance to the method, it adds all the members of the level to the set. • If you pass an IOLAPMember instance, it adds the member to the set.
`addElements(members:IList):void`	Adds multiple elements to the set.

For more information, see "Writing a query for a simple OLAP cube" on page 1471 and "Writing a query for a complex OLAP cube" on page 1478.

Executing a query and returning the results to an OLAPDataGrid control

OLAP cubes can be complex, so you do not want your application to pause while Flex calculates the results of an OLAP query. Therefore, when you execute a query, you also set up two callback functions that handle the results of the query. Flex then calls these functions when the query completes. This architecture lets the query run asynchronously so that your application can continue to execute during query processing.

You execute a query by calling the `OLAPCube.execute()` method, where the `OLAPCube.execute()` method returns an instance of the AsyncToken class. You use the AsyncToken class, along with the AsyncResponder class, to specify the two callback functions to handle the query results when execution completes.

In this example, the function `showResult()` handles the query results when the query succeeds, and the function `showFault()` handles any errors detected during query execution:

```
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="creationCompleteHandler();">

<fx:Script>
    <![CDATA[

        private function creationCompleteHandler():void {
            // You must initialize the cube before you
            // can execute a query on it.
            myMXMLCube.refresh();
        }

        // Create the OLAP query.
        private function getQuery(cube:IOLAPCube):IOLAPQuery {
            ...
        }

        // Event handler to execute the OLAP query
        // after the cube completes initialization.
        private function runQuery(event:CubeEvent):void {
            // Get cube.
            var cube:IOLAPCube = IOLAPCube(event.currentTarget);
            // Create a query instance.
            var query:IOLAPQuery = getQuery(cube);
            // Execute the query.
            var token:AsyncToken = cube.execute(query);
            // Set up handlers for the query results.
            token.addResponder(new AsyncResponder(showResult, showFault));
        }

        // Handle a query fault.
        private function showFault(error:ErrorMessage, token:Object):void {
            Alert.show(error.faultString);
        }

        // Handle a query success.
        private function showResult(result:Object, token:Object):void {
            if (!result) {
                Alert.show("No results from query.");
                return;
            }

            myOLAPDG.dataProvider= result as OLAPResult;
        }
    ]]>
</fx:Script>

<fx:Declarations>
    <mx:OLAPCube name="FlatSchemaCube"
        dataProvider="{flatData}"
        id="myMXMLCube"
        complete="runQuery(event);">
        ...
    </mx:OLAPCube>
<fx:Declarations>

<mx:OLAPDataGrid id="myOLAPDG" width="100%" height="100%" />

</s:Application>
```

Using the default member in a query

Many of the queries shown so far have referenced only two dimensions of the OLAP cube, such as ProductDim and TimeDim. But what happens to the other dimensions when you omit them from the query?

All dimensions have a default member, either explicit or implicit. When you execute a query that does not reference a dimension, the query aggregates the data for that dimension using the default member. For information on defining the default member of a schema, see "Creating a default member in a schema" on page 1465.

Specifying a default cell string for the OLAPDataGrid control

When you define your query, you might create a situation where a cell of the OLAPDataGrid does not contain a value. For example, when aggregating data by customer and product, you might have a customer that has never purchased Illustrator. For that customer and product combination, the corresponding cell of the OLAPDataGrid displays the String "NaN".

You can customize this String by setting the `OLAPDataGrid.defaultCellString`. For example, if you want to set the String to "No value", you would create an OLAPDataGrid control as shown here:

```
<mx:OLAPDataGrid id="myOLAPDG"
    defaultCellString="No value"
    width="100%" height="100%"/>
```

Writing a query for a simple OLAP cube

In a simple OLAP cube, all of the dimensions of the cube define a single level. For example, you have flat data that contains three fields:

```
data:Object = {
    product:"ColdFusion"
    quarter :"Q1"
    revenue: "100.00",
}
```

The data fields of each record can contain the following values:

- The product field can have the values: ColdFusion, Flex, Dreamweaver, and Illustrator.

- The quarter field can have the values: Q1, Q2, Q3, and Q4.

The OLAP schema for this data defines two dimensions, each with a single level, as the following code shows:

```
<mx:OLAPCube name="FlatSchemaCube"
    dataProvider="{flatData}"
    id="myMXMLCube"
    complete="runQuery(event);">

    <mx:OLAPDimension name="ProductDim">
        <mx:OLAPAttribute name="Product" dataField="product"/>
        <mx:OLAPHierarchy name="ProductHier" hasAll="true">
            <mx:OLAPLevel attributeName="Product"/>
        </mx:OLAPHierarchy>
    </mx:OLAPDimension>

    <mx:OLAPDimension name="QuarterDim">
        <mx:OLAPAttribute name="Quarter" dataField="quarter"/>
        <mx:OLAPHierarchy name="QuarterHier" hasAll="true">
            <mx:OLAPLevel attributeName="Quarter"/>
        </mx:OLAPHierarchy>
    </mx:OLAPDimension>

    <mx:OLAPMeasure name="Revenue"
        dataField="revenue"
        aggregator="SUM"/>
</mx:OLAPCube>
```

After you call the `OLAPCube.refresh()` method to initialize the cube, it has the following structure:

```
ProductDim                 // Dimension
    Product                    // Hierarchy
        (All)                      // Member
        ColdFusion                 // Member
        Flex                       // Member
        Dreamweaver                // Member
        Illustrator                // Member

    ProductHier                // Hierarchy
        (All)                      // Level
            ColdFusion                 // Member
            Flex                       // Member
            Dreamweaver                // Member
            Illustrator                // Member

        Product                    // Level
            ColdFusion                 // Member
            Flex                       // Member
            Dreamweaver                // Member
            Illustrator                // Member
```

```
QuarterDim                  // Dimension
    Quarter                     // Hierarchy
        (All)                       // Member
        Q1                          // Member
        Q2                          // Member
        Q3                          // Member
        Q4                          // Member

    QuarterHier                 // Hierarchy
        (All)                       // Level
            Q1                          // Member
            Q2                          // Member
            Q3                          // Member
            Q4                          // Member

        Quarter                     // Level
            Q1                          // Member
            Q2                          // Member
            Q3                          // Member
            Q4                          // Member
```

Notice in this cube:

- The ProductDim dimension contains two hierarchies: Product and ProductHier. The cube creates a hierarchy for each level specified by the OLAPLevel class, and for each hierarchy specified by the OLAPHierarchy class. The same is true for the QuarterDim dimension; it also contains two hierarchies.
- The order of the members, meaning the values along each dimension, is based on the order in which the members appear in the flat data. In this example, the quarters appear in order of Q1, Q2, Q3, and Q4 because the flat data was sorted by quarter. However, if the data was not sorted by quarter, the members along the QuarterDim could appear in any order.
- Each dimension contains a single level; therefore the `(All)` level contains the same data as the first level in the hierarchy. For example, the `(All)` level of the ProdcutHier hierarchy contains the same data as the Product level. For a complex cube, the `(All)` level would contain additional information.

For an example of a complex cube, see “Writing a query for a complex OLAP cube” on page 1478.

Defining a query for a simple cube

An OLAP query has the following basic form:

```
// Create an instance of OLAPQuery to represent the query.
var query:OLAPQuery = new OLAPQuery;

// Get the row axis from the query instance.
var rowQueryAxis:IOLAPQueryAxis = query.getAxis(OLAPQuery.ROW_AXIS);
// Create an OLAPSet instance to configure the axis.
var productSet:OLAPSet = new OLAPSet;
// Use OLAPSet.addElements() or OLAPSet.addElement() to add members to the row axis.
productSet.addElements(...);
// Add the OLAPSet instance to the axis.
rowQueryAxis.addSet(productSet);

// Get the column axis from the query instance, and configure it
// to aggregate the columns by the Quarter dimension.
var colQueryAxis:IOLAPQueryAxis = query.getAxis(OLAPQuery.COLUMN_AXIS);
var quarterSet:OLAPSet= new OLAPSet;
// Use OLAPSet.addElements() or OLAPSet.addElement() to add members to the column axis.
productSet.addElements(...);
colQueryAxis.addSet(quarterSet);
```

You use the following methods and properties to extract information from an OLAP cube based on the attributes of the dimension, and pass it to the `OLAPSet.addElements()` or `OLAPSet.addElement()` method:

Method and property	Description
`OLAPCube.findDimension(name:String):IOLAPDimension`	Returns a dimension of a schema as an instance of the OLAPDimension class.
`OLAPDimension.findAttribute(name:String):IOLAPAttributeHierarchy`	Returns an instance of the IOLAPAttributeHierarchy interface, which is an attribute hierarchy that includes an IList instance of all members of the attribute.
`OLAPDimension.findMember(name:String):IOLAPMember`	Returns an IOLAPMember instance that represents a member with the specified name within the dimension.
`IOLAPAttributeHierarchy.children`	Contains all members of the level as an IList instance, but does not include the (All) member.
`IOLAPAttributeHierarchy.members`	Contains all members of the level as an IList instance, including the (All) member.

The following table shows the information returned for combinations of these methods and properties:

Reference to method and property	Returns
`findDimension("ProductDim").findAttribute("Product").children`	ColdFusion, Flex, Dreamweaver, and Illustrator
`findDimension("ProductDim").findAttribute("Product").members`	(All), ColdFusion, Flex, Dreamweaver, and Illustrator
`findDimension("ProductDim").findMember("Flex")`	Flex
`findDimension("QuarterDim").findAttribute("Quarter").children`	Q1, Q2, Q3, and Q4
`findDimension("QuarterDim").findAttribute("Quarter").members`	(All), Q1, Q2, Q3, and Q4
`findDimension("QuarterDim").findMember("Q2")`	Q2

Rather than use the `findAttribute()` method, you can drill down through the hierarchy of the cube by calling the following methods:

Method	Description
`OLAPDimension.findHierarchy(name:String):IOLAPHierarchy`	Returns a hierarchy of a dimension as an instance of OLAPHierarchy. You can specify either an OLAPHierarchy or an OLAPLevel instance to this method.
`OLAPHierarchy.findLevel(name:String):IOLAPLevel`	Returns a level of a hierarchy as an instance of OLAPLevel.
`OLAPLevel.findMember(name:String):IList`	Returns an IList instance that contains all IOLAPMember instances that match the String argument. You can then use the `IList.getItemAt()` method to access the any element in the IList.

The following table shows the information returned for different combinations of these methods:

Reference to method	Returns
`findDimension("ProductDim").findhHierarchy("ProductHier").findLevel("Product").children`	ColdFusion, Flex, Dreamweaver, and Illustrator
`findDimension("ProductDim").findHierarchy("ProductHier").findLevel("Product").members`	(All), ColdFusion, Flex, Dreamweaver, and Illustrator
`IOLAPElement(cube.findDimension("ProductDim").findHierarchy("ProductHier").findLevel("Product").findMember("Flex").getItemAt(0))`	Flex. Cast the result to an instance of IOLAPElement because `getItemAt()` returns an Object.
`findDimension("QuarterDim").findHierarchy("QuarterHier").findLevel("Quarter").children`	Q1, Q2, Q3, and Q4
`findDimension("QuarterDim").findHierarchy("QuarterHier").findLevel("Quarter").members`	(All), Q1, Q2, Q3, and Q4
`IOLAPElement(cube.findDimension("QuarterDim").findHierarchy("QuarterHier").findLevel("Quarter").findMember("Q2").getItemAt(0))`	Q2. Cast the result to an instance of IOLAPElement because `getItemAt()` returns an Object.

In the case of a simple cube, the `OLAPDimension.findHierarchy()`, `OLAPHierarchy.findLevel()`, and `OLAPLevel.findMember()` methods do not provide you with additional functionality from the `OLAPDimension.findAttribute()` and `OLAPDimension.findMember()` methods. They are more commonly used with complex cubes that contain dimensions with multiple levels. For more information, see "Writing a query for a complex OLAP cube" on page 1478.

Add all members to an axis

The most common type of query returns a data aggregation for all members of an attribute of a schema. For example, you define an OLAP cube using a schema that contains a ProductDim and a QuarterDim dimension, as shown in the section "Writing a query for a simple OLAP cube" on page 1471. You then want to generate a query for all products for all quarters. The following query extracts this information:

```
private function getQuery(cube:IOLAPCube):IOLAPQuery {
    // Create an instance of OLAPQuery to represent the query.
    var query:OLAPQuery = new OLAPQuery;

    // Get the row axis from the query instance.
    var rowQueryAxis:IOLAPQueryAxis = query.getAxis(OLAPQuery.ROW_AXIS);
    // Create an OLAPSet instance to configure the axis.
    var productSet:OLAPSet = new OLAPSet;
    productSet.addElements(
        cube.findDimension("ProductDim").findAttribute("Product").children);
    rowQueryAxis.addSet(productSet);

    var colQueryAxis:IOLAPQueryAxis = query.getAxis(OLAPQuery.COLUMN_AXIS);
    var quarterSet:OLAPSet= new OLAPSet;
    quarterSet.addElements(
        cube.findDimension("QuarterDim").findAttribute("Quarter").children);
    colQueryAxis.addSet(quarterSet);

    return query;
}
```

In this example, the column axis uses the `findDimension()` and `findAttribute()` methods to drill down into the ProductDim and QuarterDim dimensions to extract sales data. For each axis, you use the `IOLAPAttributeHierarchy.children` property to populate it with the all members of the attribute, but do not include the `(All)` member.

This query uses the default measure to populate the query result, where the default measure is the first measure defined in the cube's schema. Therefore, you do have to specify the measure as part of the query. For information on explicitly specifying the measure in the query, see "Creating a query using a nondefault measure" on page 1484.

Notice that in this example, you did not have to specify the hierarchy name, ProductHier and QuarterDim, to extract the member from the schema. It is unnecessary to specify the hierarchy name when you only want to extract data for a single level of a dimension.

However, you could rewrite this example to explicitly drill down through the cube by calling the methods `OLAPDimension.findHierarchy()` and `OLAPHierarchy.findLevel()`, as the following example shows:

```
private function getQuery(cube:IOLAPCube):IOLAPQuery {
    // Create an instance of OLAPQuery to represent the query.
    var query:OLAPQuery = new OLAPQuery;

    // Get the row axis from the query instance.
    var rowQueryAxis:IOLAPQueryAxis = query.getAxis(OLAPQuery.ROW_AXIS);
    // Create an OLAPSet instance to configure the axis.
    var productSet:OLAPSet = new OLAPSet;
    productSet.addElements(cube.findDimension(
        "ProductDim").findHierarchy("ProductHier").findLevel("Product").members);
    rowQueryAxis.addSet(productSet);

    var colQueryAxis:IOLAPQueryAxis = query.getAxis(OLAPQuery.COLUMN_AXIS);
    var quarterSet:OLAPSet= new OLAPSet;
    quarterSet.addElements(
        cube.findDimension("QuarterDim").findHierarchy("QuarterHier").
        findLevel("Quarter").members);
    colQueryAxis.addSet(quarterSet);

    return query;
}
```

In this example, you drill down through the dimension to access the Product and Quarter levels. You typically use this technique with complex cubes where you are interested in an explicit member of a dimension.

Add explicit members to a query

In the query shown in the previous section, you obtain sales data for all members of the Product and Quarter levels of the schema. But, what if you only want sales data for a single product, or for a single quarter? When you drill down into a dimension, you can specify the individual member of the dimension that you want to query.

For example, you want to create a query to aggregate quarterly sales data only for Flex, but not for any other products. You therefore use the `OLAPDimension.findMember()` method to specify the name of the member. This method takes a String containing the name of the member, and returns an IOLAPMember instance that defines the member, as the following example shows:

```
private function getQuery(cube:IOLAPCube):IOLAPQuery {
    // Create an instance of OLAPQuery to represent the query.
    var query:OLAPQuery = new OLAPQuery;

    // Get the row axis from the query instance.
    var rowQueryAxis:IOLAPQueryAxis = query.getAxis(OLAPQuery.ROW_AXIS);
    // Create an OLAPSet instance to configure the axis.
    var productSet:OLAPSet = new OLAPSet;
    productSet.addElement(cube.findDimension("ProductDim").findMember("Flex"));
    rowQueryAxis.addSet(productSet);

    var colQueryAxis:IOLAPQueryAxis =
    query.getAxis(OLAPQuery.COLUMN_AXIS);
    var quarterSet:OLAPSet= new OLAPSet;
    quarterSet.addElements(
        cube.findDimension("QuarterDim").findAttribute("Quarter").children);
    colQueryAxis.addSet(quarterSet);

    return query;
}
```

Notice that in the previous example, you use the `OLAPSet.addElement()` method to add the Flex member to the OLAPSet instance, rather than the `OLAPSet.addElements()` method. This is because you are adding a single member to the axis, rather than multiple members.

The only issue with using the `OLAPDimension.findMember()` method is that it returns the first IOLAPMember instance in the cube that matches the String argument. If you think that you might have multiple instances of a member, you can rewrite this example to explicitly drill down through the cube by calling the `OLAPDimension.findHierarchy()`, `OLAPHierarchy.findLevel()`, and `OLAPLevel.findMember()` methods. This situation is more common with cubes that contain complex dimensions. For more information and examples, see "Writing a query for a complex OLAP cube" on page 1478.

The `OLAPLevel.findMember()` method returns an IList instance that contains all IOLAPMember instances that match the String argument. You can then use the `IList.getItemAt()` method to access any element in the IList, as the following example shows:

```
private function getQuery(cube:IOLAPCube):IOLAPQuery {
    // Create an instance of OLAPQuery to represent the query.
    var query:OLAPQuery = new OLAPQuery;

    // Get the row axis from the query instance.
    var rowQueryAxis:IOLAPQueryAxis = query.getAxis(OLAPQuery.ROW_AXIS);
    // Create an OLAPSet instance to configure the axis.
    var productSet:OLAPSet = new OLAPSet;
    // Get the first IOLAPElement instance in the IList instance.
    productSet.addElement(
        IOLAPElement(cube.findDimension("ProductDim").findHierarchy("ProductHier").
        findLevel("Product").findMember("Flex").getItemAt(0)));
    rowQueryAxis.addSet(productSet);

    var colQueryAxis:IOLAPQueryAxis = query.getAxis(OLAPQuery.COLUMN_AXIS);
    var quarterSet:OLAPSet= new OLAPSet;
    quarterSet.addElement(IOLAPMember(cube.findDimension("TimeDim").
        findHierarchy("Month").findMember("January")));
    quarterSet.addElement(IOLAPMember(cube.findDimension("TimeDim").
        findHierarchy("Month").findMember("February")));
    colQueryAxis.addSet(quarterSet);

    return query;
}
```

Writing a query for a complex OLAP cube

In a complex cube, at least one dimension of the schema contains multiple levels. For example, you have flat data that contains three fields:

```
data:Object = {
    product:"ColdFusion"
    year :"2006"
    quarter :"Q1"
    revenue: "100.00",
}
```

The data fields of each record can contain the following values:

- The product field can have the values: ColdFusion, Flex, Dreamweaver, and Illustrator.
- The year field can have the values: 2006 and 2007.

- The quarter field can have the values: Q1, Q2, Q3, and Q4.

In this example, your schema defines two dimensions, with the TimeDim dimension containing levels for year and quarter, as the following code shows:

```
<mx:OLAPCube name="FlatSchemaCube"
    dataProvider="{flatData}"
    id="myMXMLCube"
    complete="runQuery(event);">

    <mx:OLAPDimension name="ProductDim">
        <mx:OLAPAttribute name="Product" dataField="product"/>
        <mx:OLAPHierarchy name="ProductHier" hasAll="true">
            <mx:OLAPLevel attributeName="Product"/>
        </mx:OLAPHierarchy>
    </mx:OLAPDimension>

    <mx:OLAPDimension name="TimeDim">
        <mx:OLAPAttribute name="Year" dataField="year"/>
        <mx:OLAPAttribute name="Quarter" dataField="quarter"/>
        <mx:OLAPHierarchy name="Time-PeriodHier" hasAll="true">
            <mx:OLAPLevel attributeName="Year"/>
            <mx:OLAPLevel attributeName="Quarter"/>
        </mx:OLAPHierarchy>
    </mx:OLAPDimension>

    <mx:OLAPMeasure name="Revenue"
        dataField="revenue"
        aggregator="SUM"/>
</mx:OLAPCube>
```

The cube has the following structure:

```
ProductDim                  // Dimension
    Product                     // Hierarchy
        (All)                       // Member
        ColdFusion                  // Member
        Flex                        // Member
        Dreamweaver                 // Member
        Illustrator                 // Member

    ProductHier                 // Hierarchy
        (All)                       // Level
            ColdFusion                  // Member
            Flex                        // Member
            Dreamweaver                 // Member
            Illustrator                 // Member

        Product                     // Level
            ColdFusion                  // Member
            Flex                        // Member
            Dreamweaver                 // Member
            Illustrator                 // Member

TimeDim                     // Dimension
    Year                        // Hierarchy
        (All)                       // Member
        2006                        // Member
        2007                            // Member

    Quarter                         // Hierarchy
        (All)                           // Member
        Q1                              // Member
        Q2                              // Member
        Q3                              // Member
        Q4                              // Member

    Time-PeriodHier                 // Hierarchy
        (All)                           // Level
            2006
                Q1
                Q2
                Q3
                Q4
            2007
                Q1
                Q2
                Q3
                Q4

        Year                            // Level
            2006                            // Member
            2007                            // Member

        Quarter                         // Level
            Q1 (having 2006 as a parent) // Member
            Q1 (having 2007 as a parent) // Member
            Q2 (having 2006 as a parent) // Member
            Q2 (having 2007 as a parent) // Member
            Q3 (having 2006 as a parent) // Member
            Q3 (having 2007 as a parent) // Member
            Q4 (having 2006 as a parent) // Member
            Q4 (having 2007 as a parent) // Member
```

Notice in this cube:

- The information for the quarter is added as a hierarchy under the TimeDim dimension, and as a level under the Time-PeriodHier hierarchy.
- The Quarter level under the Time-PeriodHier hierarchy contains multiple entries for each quarter. In this example, there is an entry for each quarter for each year.
- The order of the members, meaning the values along each dimension, is based on the order in which the member values appear in the flat data.

The reason for the multiple entries for a single quarter in the Quarter level under the Time-PeriodHier hierarchy is that a cube has to be able to return results for each quarter for each year. For example, this structure lets you write a query to return data aggregations for all quarters for all years, for all quarters for 2006, or for all quarters for 2007.

Since the ProductDim contains a single level, you can write queries for it in the same way as you did for a simple cube. See “Writing a query for a simple OLAP cube” on page 1471 for more information.

The following table shows the information returned for different ways to access the TimeDim by calling the `findAttribute()` method:

Reference to method and property	**Returns**
`findDimension("TimeDim").findAttribute("Year").children`	2006, 2007
`findDimension("TimeDim").findAttribute("Year").members`	(All), 2006, 2007
`findDimension("TimeDim").findMember("2006")`	2006
`findDimension("TimeDim").findAttribute("Quarter").children`	Q1, Q2, Q3, and Q4
`findDimension("TimeDim").findAttribute("Quarter").members`	(All), Q1, Q2, Q3, and Q4
`findDimension("TimeDim").findMember("Q2")`	Q2 having 2006 as a parent. This is the first instance of Q2 in the cube.

The following table shows the information returned for different ways to use the `OLAPDimension.findHierarchy()`, `OLAPHierarchy.findLevel()`, and `OLAPLevel.findMember()` methods:

Reference to method and property	**Returns**
`findDimension("TimeDim").findHierarchy("Time-PeriodHier").findLevel("Year").children`	2006, 2007
`findDimension("TimeDim").findHierarchy("Time-PeriodHier").findLevel("Year").members`	(All), 2006, 2007
`IOLAPElement(cube.findDimension("TimeDim").findHierarchy("Time-PeriodHier").findLevel("Year").findMember("2006").getItemAt(0))`	2006
`findDimension("QuarterDim").findHierarchy("QuarterHier").findLevel("Quarter").children`	Q1, Q2, Q3, and Q4
`findDimension("QuarterDim").findHierarchy("QuarterHier").findLevel("Quarter").members`	(All), Q1, Q2, Q3, and Q4
`findDimension("TimeDim").findHierarchy("Time-PeriodHier").findLevel("Quarter").findMember("Q1")`	All Q1 members
`IOLAPElement(cube.findDimension("QuarterDim").findHierarchy("QuarterHier").findLevel("Quarter").findMember("Q2").getItemAt(0))`	Q2 having 2006 as a parent. Cast the result to an instance of IOLAPElement because `getItemAt()` returns an Object.
`IOLAPElement(cube.findDimension("QuarterDim").findHierarchy("QuarterHier").findLevel("Quarter").findMember("Q2").getItemAt(1))`	Q2 having 2007 as a parent. Cast the result to an instance of IOLAPElement because `getItemAt()` returns an Object.

You could add a Month level to the TimeDim, as the following definition of TimeDim shows:

```
<mx:OLAPDimension name="TimeDim">
    <mx:OLAPAttribute name="Year" dataField="year"/>
    <mx:OLAPAttribute name="Quarter" dataField="quarter"/>
    <mx:OLAPAttribute name="Month" dataField="month"/>
    <mx:OLAPHierarchy name="Time-PeriodHier" hasAll="true">
        <mx:OLAPLevel attributeName="Year"/>
        <mx:OLAPLevel attributeName="Quarter"/>
        <mx:OLAPLevel attributeName="Month"/>
    </mx:OLAPHierarchy>
</mx:OLAPDimension>
```

For this example, the structure of the TimeDim dimension is:

```
TimeDim                     // Dimension
    Year                        // Hierarchy
        (All)                       // Member
        2006                        // Member
        2007                        // Member

    Quarter                     // Hierarchy
        (All)                       // Member
        Q1                          // Member
        Q2                          // Member
        Q3                          // Member
        Q4                          // Member

    Month                       // Hierarchy
        (All)                       // Member
        Jan                         // Member
        Feb                         // Member
        ...                         // Adiitional members for each month

    Time-PeriodHier             // Hierarchy
        (All)                       // Level
            2006
                Q1
                    Jan
                    Feb
                    Mar
                ...
            2007
                Q1
                    Jan
                    Feb
                    Mar
                ...

        Year                        // Level
            2006                        // Member
            2007                        // Member

        Quarter                     // Level
            Q1 (having 2006 as a parent) // Member
            Q1 (having 2007 as a parent) // Member
            Q2 (having 2006 as a parent) // Member
            Q2 (having 2007 as a parent) // Member
            Q3 (having 2006 as a parent) // Member
            Q3 (having 2007 as a parent) // Member
            Q4 (having 2006 as a parent) // Member
            Q4 (having 2007 as a parent) // Member

        Month                       // Level
            Jan (having Q1 having 2006 as a parent) // Member
            Feb (having Q1 having 2006 as a parent) // Member
            Jan (having Q1 having 2007 as a parent) // Member
            Feb (having Q1 having 2007 as a parent) // Member
            ...                                     // Additional members for each possible
                                                    // combination of month, quarter,
                                                    // and year
```

Notice in this cube:

- The Month level contains a value for each month, and for each quarter for each year. Therefore, there should be two entries for January; one for Q1 of 2006 and one for Q1 of 2007.

Creating a multidimensional axis in an OLAPDataGrid control

The OLAPDataGrid control displays information along two axes: row and column. However, limiting yourself to writing queries that return only two dimensions can restrict your ability to examine your data.

To allow you greater flexibility in displaying query results, the OLAPDataGrid control supports hierarchical display along its axis. The following image shows quarterly sales information, grouped by year, displayed in the columns of the OLAPDataGrid control.

	Year	Quarter						
Product	2006				2007			
	Q1	Q2	Q3	Q4	Q1	Q2	Q3	Q4
ColdFusion	770	125	375	215	715	175	410	215
Flex	210	760	210	430	210	670	100	300
DreamWeaver	470	175	840	320	510	175	1150	270
Flash	280	570	670	1010	370	620	420	1240

To create a multidimensional axis in the OLAPDataGrid control, you create two or more OLAPSet instances for the axis, and then combine the OLAPSet instances by doing a crossjoin or a union, as the following table describes:

Combination type	OLAPSet method	Description
Crossjoin	`crossJoin()`	Creates a crossjoin of two OLAPSet instances, where a crossjoin contains all possible combinations of the two sets. A crossjoin is also called a cross product of the members of the two different sets.
Union	`union()`	Creates a union of two OLAPSet instances.

In the following example, you create an OLAPSet instance for the year, and then crossjoin that set with the OLAPSet instance for quarter to create the OLAPDataGrid control shown in the previous image:

```
private function getQuery(cube:IOLAPCube):IOLAPQuery {
    var query:OLAPQuery = new OLAPQuery;

    var rowQueryAxis:IOLAPQueryAxis = query.getAxis(OLAPQuery.ROW_AXIS);
    var productSet:OLAPSet = new OLAPSet;
    productSet.addElements(
        cube.findDimension("ProductDim").findAttribute("Product").children);
    rowQueryAxis.addSet(productSet);

    var colQueryAxis:IOLAPQueryAxis = query.getAxis(OLAPQuery.COLUMN_AXIS);
    var yearSet:OLAPSet= new OLAPSet;
    yearSet.addElements(
        cube.findDimension("TimeDim").findAttribute("Year").children);
    var quarterSet:OLAPSet= new OLAPSet;
    quarterSet.addElements(
        cube.findDimension("TimeDim").findAttribute("Quarter").children);
    colQueryAxis.addSet(yearSet.crossJoin(quarterSet));

    return query;
}
```

Creating a slicer axis

An OLAP query can have three axes: row, column, and slicer. A slicer axis lets you reduce the size of the query results, often to reduce the dimensionality of the results from a dimension greater than two so that you can display the results. Another common use of a slicer axis is to aggregate data on a measure other than the default measure.

Creating a query using a nondefault measure

The following schema defines two measures for the points in the cube: Revenue and Cost. The first measure defined in the schema is the default measure, and it is the data that is aggregated by a query if you do not explicitly specify the measure.

```
<mx:OLAPCube name="FlatSchemaCube"
    dataProvider="{flatData}"
    id="myMXMLCube"
    complete="runQuery(event);">

    <mx:OLAPDimension name="ProductDim">
        <mx:OLAPAttribute name="Product" dataField="product"/>
        <mx:OLAPHierarchy name="ProductHier" hasAll="true">
            <mx:OLAPLevel attributeName="Product"/>
        </mx:OLAPHierarchy>
    </mx:OLAPDimension>

    <mx:OLAPDimension name="QuarterDim">
        <mx:OLAPAttribute name="Quarter" dataField="quarter"/>
        <mx:OLAPHierarchy name="QuarterHier" hasAll="true">
            <mx:OLAPLevel attributeName="Quarter"/>
        </mx:OLAPHierarchy>
    </mx:OLAPDimension>

    <mx:OLAPMeasure name="Revenue"
        dataField="revenue" aggregator="MAX"/>
    <mx:OLAPMeasure name="Cost"
        dataField="cost" aggregator="MIN"/>
</mx:OLAPCube>
```

To aggregate by the Cost measure, you create a slicer axis to explicitly specify the measure for the query, as the following example shows:

```
private function getQuery(cube:IOLAPCube):IOLAPQuery {
    // Create an instance of OLAPQuery to represent the query.
    var query:OLAPQuery = new OLAPQuery;

    // Get the row axis from the query instance.
    var rowQueryAxis:IOLAPQueryAxis = query.getAxis(OLAPQuery.ROW_AXIS);
    // Create an OLAPSet instance to configure the axis.
    var productSet:OLAPSet = new OLAPSet;
    productSet.addElements(
        cube.findDimension("ProductDim").findAttribute("Product").children);
    rowQueryAxis.addSet(productSet);

    var colQueryAxis:IOLAPQueryAxis = query.getAxis(OLAPQuery.COLUMN_AXIS);
    var quarterSet:OLAPSet= new OLAPSet;
    quarterSet.addElements(
        cube.findDimension("TimeDim").findAttribute("Month").children);
    colQueryAxis.addSet(quarterSet);

    // Create the slicer axis.
    var slicerQueryAxis:IOLAPQueryAxis = query.getAxis(OLAPQuery.SLICER_AXIS);
    // Create an OLAPSet instance to configure the axis.
    var costSet:OLAPSet= new OLAPSet;
    // Use OLAPDimension.findMember() to add the Cost measure.
    costSet.addElement(cube.findDimension("Measures").findMember("Cost"));
    slicerQueryAxis.addSet(costSet);

    return query;
}
```

In this example, you use the keyword `Measures` to identify the measure dimension, and then use the `OLAPDimension.findMember()` method to access the Cost measure.

Using a slicer axis to reduce the dimensionality of the query result

The OLAPDataGrid control displays information in two dimensions along its row and column axis. However, to display product sales by region and by month, you require a three-dimensional display: one dimension each for product, region, and month.

For example, your data has the following format:

```
data:Object = {
    customer:"IBM",
    country:"US",
    state:"MA",
    region:"NewEngland",
    product:"ColdFusion",
    year:2005,
    quarter:"Q1"
    month:"January",
    revenue: 12,575.00,
    cost: 500
}
```

The examples use the following OLAP schema to represent this data in an OLAP cube:

```
<mx:OLAPCube name="FlatSchemaCube"
    dataProvider="{flatData}"
    id="myMXMLCube"
    complete="runQuery(event);">

    <mx:OLAPDimension name="CustomerDim">
        <mx:OLAPAttribute name="Customer" dataField="customer"/>
        <mx:OLAPHierarchy name="CustomerHier"
            hasAll="true">
            <mx:OLAPLevel attributeName="Customer"/>
        </mx:OLAPHierarchy>
    </mx:OLAPDimension>

    <mx:OLAPDimension name="ProductDim">
        <mx:OLAPAttribute name="Product" dataField="product"/>
        <mx:OLAPHierarchy name="ProductHier"
            hasAll="true">
            <mx:OLAPLevel attributeName="Product"/>
        </mx:OLAPHierarchy>
    </mx:OLAPDimension>
    <mx:OLAPDimension name="TimeDim">
        <mx:OLAPAttribute name="Year" dataField="year"/>
        <mx:OLAPAttribute name="Quarter" dataField="quarter"/>
        <mx:OLAPAttribute name="Month" dataField="month"/>
        <mx:OLAPHierarchy name="Time-Period"
            hasAll="true">
            <mx:OLAPLevel attributeName="Year"/>
            <mx:OLAPLevel attributeName="Quarter"/>
            <mx:OLAPLevel attributeName="Month"/>
        </mx:OLAPHierarchy>
    </mx:OLAPDimension>
    <mx:OLAPDimension name="GeographyDim">
        <mx:OLAPAttribute name="Country" dataField="country"/>
        <mx:OLAPAttribute name="Region" dataField="region"/>
        <mx:OLAPAttribute name="State" dataField="state"/>
        <mx:OLAPHierarchy name="Country-Region-State"
            hasAll="true">
            <mx:OLAPLevel attributeName="Country"/>
            <mx:OLAPLevel attributeName="Region"/>
            <mx:OLAPLevel attributeName="State"/>
        </mx:OLAPHierarchy>
    </mx:OLAPDimension>
    <mx:OLAPMeasure name="Revenue"
        dataField="revenue"
        aggregator="SUM"/>
    <mx:OLAPMeasure name="Cost"
     dataField="cost"
     aggregator="SUM"/>
</mx:OLAPCube>
```

You can use a slicer axis to filter the results of a query for display in two dimensions. In this example, you set the row axis to the region and the column axis to the month. You then define a slicer axis to specify the product as Flex so that you end up with a two-dimensional table of sales by region and month for Flex.

```
private function getQuery(cube:IOLAPCube):IOLAPQuery {
    // Create an instance of OLAPQuery to represent the query.
    var query:OLAPQuery = new OLAPQuery;

    // Get the row axis from the query instance.
    var rowQueryAxis:IOLAPQueryAxis = query.getAxis(OLAPQuery.ROW_AXIS);
    // Create an OLAPSet instance to configure the axis.
    var productSet:OLAPSet = new OLAPSet;
    productSet.addElements(
        cube.findDimension("GeographyDim").findAttribute("Region").children);
    rowQueryAxis.addSet(productSet);

    var colQueryAxis:IOLAPQueryAxis = query.getAxis(OLAPQuery.COLUMN_AXIS);
    var quarterSet:OLAPSet= new OLAPSet;
    quarterSet.addElements(
        cube.findDimension("TimeDim").findAttribute("Month").children);
    colQueryAxis.addSet(quarterSet);

    // Create the slicer axis.
    var slicerQueryAxis:IOLAPQueryAxis = query.getAxis(OLAPQuery.SLICER_AXIS);
    // Create an OLAPSet instance to configure the axis.
    var flexSet:OLAPSet= new OLAPSet;
    flexSet.addElement(
        IOLAPElement(cube.findDimension("ProductDim").findHierarchy("ProductHier").
        findLevel("Product").findMember("Flex").getItemAt(0)));
    slicerQueryAxis.addSet(flexSet);

    return query;
}
```

You can specify more than one member for the slicer access. For example, if your cube contains information on different product such as Flex and Adobe® Flash®, you could create the two slicer axes as the following example shows:

```
// Create the slicer axis.
var slicerQueryAxis:IOLAPQueryAxis = query.getAxis(OLAPQuery.SLICER_AXIS);

// Create an OLAPSet instance to configure the axis.
var sliceSet:OLAPSet= new OLAPSet;
sliceSet.addElement(IOLAPElement(cube.findDimension("ProductDim").
    findHierarchy("ProductHier").findLevel("Product").findMember("Flex").getItemAt(0)));

sliceSet.addElement(IOLAPElement(cube.findDimension("ProductDim").
    findHierarchy("ProductHier").findLevel("Product").findMember("Flash").getItemAt(0)));

slicerQueryAxis.addSet(sliceSet);
```

In this example, your query result would show sales of Flex and Flash for each region and month.

Configuring the display of an OLAPDataGrid

To control the display of an OLAPDataGrid control, you can apply styles to the cells of the control by using a callback function, or use item renderers to control the display.

Styling cells of the OLAPDataGrid control by using a callback function

To control the styling of a cell by using a callback function, use the `OLAPDataGrid.styleFunction` property to specify the callback function. The callback function must have the following signature:

```
function_name(row:IOLAPAxisPosition, column:IOLAPAxisPosition, value:Number):Object
```

where `row` is the IOLAPAxisPosition associated with this cell on the row axis, `column` is the IOLAPAxisPosition associated with this cell on the column axis, and `value` is the cell value.

The function returns an Object that contains one or more *styleName:value* pairs to specify a style setting, or null. The *styleName* field contains the name of a style property, such as `color`, and the *value* field contains the value for the style property, such as 0x00FF00. For example, you could return two styles using the following syntax:

```
{color:0xFF0000, fontWeight:"bold"}
```

The OLAPDataGrid control invokes the callback function when it updates its display, such as when the control is first drawn on application start up, or when you call the `invalidateList()` method.

The following example modifies the example shown in the section "Example using the OLAPDataGrid control" on page 1460 to add a callback function to display all cells with a value greater than 1000 in green:

```
<fx:Script>
    <![CDATA[
        ...

        // Callback function that hightlights in green
        // all cells with a value greater than or equal to 1000.
        public function myStyleFunc(row:IOLAPAxisPosition, column:IOLAPAxisPosition,
            value:Number):Object
        {
            if (value >= 1000)
            return {color:0x00FF00};

            // Return null if value is less than 1000.
            return null;
        }
        ]]>
</fx:Script>

...

<mx:OLAPDataGrid id="myOLAPDG"
    width="100%" height="100%"
    styleFunction="myStyleFunc"/>
```

Using an item renderer with the OLAPDataGrid control

You customize the appearance and behavior of cells in an OLAPDataGrid control by creating custom item renderers.

For an introduction to item renderers and item editors, see "MX item renderers and item editors" on page 1006.

To use an item renderer with the OLAPDataGrid control, you assign the item renderer to the OLAPDataGrid control itself, not to a specific column, by using the `OLAPDataGrid.itemRendererProviders` property. The `itemRendererProviders` property contains an Array of OLAPDataGridItemRendererProvider instances, where each OLAPDataGridItemRendererProvider instance defines the characteristics for a single item renderer.

You can use the `OLAPDataGridRendererProvider.renderer` property to assign an item renderer to the OLAPDataGrid control, much in the way that you can by using the `AdvancedDataGrid.rendererProviders` property, or can use the `OLAPDataGridRendererProvider.formatter` property to assign a formatter class. The following example modifies the example shown in the section "Example using the OLAPDataGrid control" on page 1460 to add an item renderer that applies the CurrencyFormatter formatter to each cell in the control:

```
...
<mx:CurrencyFormatter id="usdFormatter" precision="2"
    currencySymbol="$" decimalSeparatorFrom="."
    decimalSeparatorTo="." useNegativeSign="true"
    useThousandsSeparator="true" alignSymbol="left"/>

...

<mx:OLAPDataGrid id="myOLAPDG"
    width="100%" height="100%">

    <mx:itemRendererProviders>
        <mx:OLAPDataGridItemRendererProvider
            uniqueName="[QuarterDim].[Quarter]"
            type="{OLAPDataGrid.OLAP_HIERARCHY}"
            formatter="{usdFormatter}"/>
    </mx:itemRendererProviders>
</mx:OLAPDataGrid>
```

To assign the item renderer, use the `uniqueName` and `type` properties of the OLAPDataGridItemRendererProvider class. The `uniqueName` property specifies the elements of the query, and therefore the corresponding cells of the OLAPDataGrid control, that you modify by using the item renderer. The `type` properly specifies the element type, such as dimension, hierarchy, or level of the element specified by the `uniqueName` property.

When assigning a formatter to the OLAPDataGridItemRendererProvider, you must specify a subclass of the mx.formatters.Formatter class; for example, the MX formatters such as CurrencyFormatter or NumberFormatter. The formatter cannot be a Spark formatter.

The function that defines the query for this example is shown below:

```
// Create the OLAP query.
private function getQuery(cube:IOLAPCube):IOLAPQuery {
    // Create an instance of OLAPQuery to represent the query.
    var query:OLAPQuery = new OLAPQuery;

    // Get the row axis from the query instance.
    var rowQueryAxis:IOLAPQueryAxis = query.getAxis(OLAPQuery.ROW_AXIS);
    // Create an OLAPSet instance to configure the axis.
    var productSet:OLAPSet = new OLAPSet;
    // Add the Product to the row to aggregate data
    // by the Product dimension.
    productSet.addElements(
        cube.findDimension("ProductDim").findAttribute("Product").children);
    // Add the OLAPSet instance to the axis.
    rowQueryAxis.addSet(productSet);

    // Get the column axis from the query instance, and configure it
    // to aggregate the columns by the Quarter dimension.
    var colQueryAxis:IOLAPQueryAxis = query.getAxis(OLAPQuery.COLUMN_AXIS);
    var quarterSet:OLAPSet= new OLAPSet;
    quarterSet.addElements(
        cube.findDimension("QuarterDim").findAttribute("Quarter").children);
    colQueryAxis.addSet(quarterSet);

    return query;
}
```

Notice that the axis for the QuarterDim creates a query for the Quarter hierarchy of the QuarterDim dimension. Therefore, you set the `uniqueName` property to `[QuarterDim].[Quarter]`, and set the type property to `OLAPDataGrid.OLAP_HIERARCHY`. For more information on the structure of the `OLAP` code for this example, see "Writing a query for a simple OLAP cube" on page 1471.

You can modify this example to drill down through the cube by specifying the query as shown below for the QuarterDim:

```
quarterSet.addElements(
    cube.findDimension("QuarterDim").findHierarchy("QuarterHier").
    findLevel("Quarter").members);
```

You therefore modify the `uniqueName` and `type` properties as shown below:

```
<mx:OLAPDataGrid id="myOLAPDG"
    width="100%" height="100%">

    <mx:itemRendererProviders>
        <mx:OLAPDataGridItemRendererProvider
            uniqueName="[QuarterDim].[QuarterHier].[Quarter]"
            type="{OLAPDataGrid.OLAP_LEVEL}"
            formatter="{usdFormatter}"/>
    </mx:itemRendererProviders>
</mx:OLAPDataGrid>
```

Notice in this example that the query for the QuarterDim specifies the dimension, hierarchy, and level of the OLAP cube. Therefore, you modify the `uniqueName` property to match this structure, and set the `type` property to `OLAPDataGrid.OLAP_LEVEL`.

Resolving item renderer conflicts

Each cell in an OLAPDataGrid control is a result of an intersection between the members along a row and the members along a column of the control. However, when you assign an item renderer to an OLAPDataGrid control, you only specify the `uniqueName` and `type` properties for one of the dimensions, either row or column. Therefore, you can create a situation where two different item renderers are assigned to the same cell of the control.

In case of a conflict between two or more item renderers, the OLAPDataGrid control applies the item renderer based on the following priorities:

1. `type` = `OLAPDataGrid.OLAP_MEMBER`
2. `type` = `OLAPDataGrid.OLAP_LEVEL`
3. `type` = `OLAPDataGrid.OLAP_HIERARCHY`
4. `type` = `OLAPDataGrid.OLAP_DIMENSION`

Therefore, if an item renderer with a `type` value of `OLAPDataGrid.OLAP_LEVEL` and an item renderer with a `type` value of `OLAPDataGrid.OLAP_HIERARCHY` are applied to the same cell, the OLAPDataGrid control applies the item renderer with a `type` value of `OLAPDataGrid.OLAP_LEVEL`.

If two item renderers have the same value for the `type` property, the OLAPDataGrid control determines which renderer more closely matches the item, and uses it.

Using an item renderer to apply styles to an OLAPDataGrid control

You can use an item renderer to apply styles to specific cells in the OLAPDataGrid control, as the following example shows:

```
<fx:Style>
    .cellStyle
    {
        color:#ff0000;
        fontWeight:"bold"
    }
</fx:Style>

    ...

<mx:OLAPDataGrid id="myOLAPDG"
    width="100%" height="100%">

    <mx:itemRendererProviders>
        <mx:OLAPDataGridItemRendererProvider
            uniqueName="[QuarterDim].[Quarter]"
            type="{OLAPDataGrid.OLAP_HIERARCHY}"
            formatter="{usdFormatter}"
            styleName="cellStyle"/>
    </mx:itemRendererProviders>
</mx:OLAPDataGrid>
```

In this example, you create a style definition, then apply it to the cells of the OLAPDataGrid control so that it applies to the same cells as the CurrencyFormatter formatter.

Chapter 6: Enhancing the user interface

Styles and themes

Styles are useful for defining the look and feel of your applications built with Adobe® Flex®. You can use them to change the appearance of a single component, or apply them across all components.

Flex 4 deemphasizes the use of style properties for some tasks. Instead of styling individual components, or classes of components, you can use custom skins to perform most operations that change the look and feel of your applications. This includes adding background colors and images, borders, and other properties that were styleable in Flex 3 applications. For more information on skinning, see "Spark Skinning" on page 1602.

Peter deHaan's blog, FlexExamples.com has many examples of using styles and themes in Flex.

About styles

You modify the appearance of components through style properties. In Flex, some styles are inherited by children from their parent containers, and across style types and classes. This means that you can define a style once, and then apply that style to all controls of a single type or to a set of controls. In addition, you can override individual properties for each control at a local, component, or global level, giving you great flexibility in controlling the appearance of your applications.

The style properties that you can set on a component depend on the component's architecture. For example, the components in the MX component set (mx.controls.* and mx.containers.* packages) take one set of styles. Components in the Spark component set (spark.components.* package) allow an entirely different set of styles.

This section introduces you to applying styles to controls. It also provides a primer for using Cascading Style Sheets (CSS), an overview of the style value formats (`Length`, `Color`, and `Time`), and describes style inheritance. Subsequent sections provide detailed information about different ways of applying styles in Flex.

Flex does not support controlling all aspects of component layout with CSS. Properties such as `x`, `y`, `width,` and `height` are properties, not styles, of the UIComponent class, and therefore cannot be set in CSS.

Using styles in Flex

There are many ways to apply styles in Flex. Some provide more granular control and can be approached programmatically. Others are not as flexible, but can require less computation and therefor be better for your application's performance.

For MX components, to determine if an object's properties can be styled by using CSS, check to see if the class or its parent implements the IStyleClient interface. If it does, you can set the values of the object's style properties with CSS. If it does not, the class does not participate in the styles subsystem and you therefore cannot set its properties with CSS. In that case, the properties are public properties of the class and not style properties.

For Spark components, many properties that were formerly available as styles are now properties that you set on the Spark component's skin. As a result, to do something like create a border around a container, you edit the container's skin class rather than add a style property. For more information about skinning Spark components, see "Spark Skinning" on page 1602.

When applying styles, you must be aware of which properties your theme supports. The default theme in Flex does not support all style properties. To determine if a style property is supported by the theme you are using, view the style's entry in ActionScript 3.0 Reference for the Adobe Flash Platform. If the style property is limited to a theme, the Theme property will appear in the style's description, with the name of the supported themes next to it. For more information, see "About supported styles" on page 1532.

External style sheets

Use CSS to apply styles to a document or across entire applications. You can point to a style sheet without invoking ActionScript. This is the most concise method of applying styles, but can also be the least flexible. Style sheets can define global styles that are inherited by all controls, or individual classes of styles that only certain controls use.

The following example applies the external style sheet myStyle.css to the current document:

```
<fx:Style source="myStyle.css"/>
```

For more information, see "Using external style sheets" on page 1533.

Flex includes global style sheets inside the spark.swc and framework.swc files. These files contain style definitions for the global class selector, and type selectors for most components. For more information about the defaults.css files, see "About the default style sheets" on page 1534.

Flex also includes several other style sheets that each provide a unique look and feel. For more information, see "About the included theme files" on page 1565.

Local style definitions

Use the `<fx:Style>` tag to define styles that apply to the current document and its children. You define styles in the `<fx:Style>` tag using CSS syntax and can define styles that apply to all instances of a control or to individual controls. The following example defines a new style and applies it to only the myButton control:

```
<?xml version="1.0"?>
<!-- styles/ClassSelectorAgain.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <fx:Style>
        .myFontStyle {
            fontSize: 15;
            color: #9933FF;
        }
    </fx:Style>
    <s:VGroup>
        <!-- This button has the custom style applied to it. -->
        <s:Button id="myButton" styleName="myFontStyle" label="Click Me"/>
        <!-- This button uses default styles. -->
        <s:Button id="myButton2" label="Click Me"/>
    </s:VGroup>
</s:Application>
```

The following example defines a new style that applies to all instances of the Button class in the Spark namespace:

```
<?xml version="1.0"?>
<!-- styles/TypeSelector.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Style>
        @namespace s "library://ns.adobe.com/flex/spark";
        s|Button {
            fontSize: 15;
            color: #9933FF;
        }
    </fx:Style>
    <s:VGroup>
        <s:Button id="myButton" label="Click Me"/>
        <s:Button id="myButton2" label="Click Me"/>
    </s:VGroup>
</s:Application>
```

For more information, see “Using local style definitions” on page 1535.

StyleManager class

Use the StyleManager class to apply styles to all classes or all instances of specified classes. You can access the top-level StyleManager by using the `styleManager` property of the Application object.

The following example sets the `fontSize` style to 15 and the `color` to `0x9933FF` on all Button controls in the Spark namespace:

```
<?xml version="1.0"?>
<!-- styles/StyleManagerExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp()">
    <fx:Script><![CDATA[
        public function initApp():void {

styleManager.getStyleDeclaration("spark.components.Button").setStyle("fontSize",15);

styleManager.getStyleDeclaration("spark.components.Button").setStyle("color",0x9933FF);
        }
    ]]></fx:Script>
    <s:VGroup>
        <s:Button id="myButton" label="Click Me"/>
        <s:Button id="myButton2" label="Click Me"/>
    </s:VGroup>
</s:Application>
```

You can also use the CSSStyleDeclaration object to build run-time style sheets, and then apply them with the StyleManager’s `setStyleDeclaration()` method.

For more information, see “Using the StyleManager class” on page 1537.

getStyle() and setStyle() methods

Use the setStyle() and getStyle() methods to manipulate style properties on instances of controls. Using these methods to apply styles requires a greater amount of processing power on the client than using style sheets but provides more granular control over how styles are applied.

The following example sets the `fontSize` to 15 and the `color` to `0x9933FF` on only the myButton instance:

```
<?xml version="1.0"?>
<!-- styles/SetStyleExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp()">
    <fx:Script><![CDATA[
        public function initApp():void {
            myButton.setStyle("fontSize",15);
            myButton.setStyle("color",0x9933FF);
        }
    ]]></fx:Script>
    <s:VGroup>
        <s:Button id="myButton" label="Click Me"/>
        <s:Button id="myButton2" label="Click Me"/>
    </s:VGroup>
</s:Application>
```

For more information, see “Using the setStyle() and getStyle() methods” on page 1540.

Inline styles

Use attributes of MXML tags to apply style properties. These properties apply only to the instance of the control. This is the most efficient method of applying instance properties because no ActionScript code blocks or method calls are required.

The following example sets the `fontSize` to `15` and the `color` to `0x9933FF` on the myButton instance:

```
<?xml version="1.0"?>
<!-- styles/InlineExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:VGroup>
        <!-- This button uses custom inline styles. -->
        <s:Button id="myButton" color="0x9933FF" fontSize="15" label="Click Me"/>
        <!-- This button uses default styles. -->
        <s:Button id="myOtherButton" label="Click Me"/>
    </s:VGroup>
</s:Application>
```

In an MXML tag, you must use the camel-case version of the style property. For example, you must use “`fontSize`” rather than “`font-size`” (the CSS convention) in the previous example. For more information on style property names, see “About selector names” on page 1506.

As with other style properties, you can bind inline style properties to variables.

For more information, see “Using inline styles” on page 1546.

Setting global styles

To set a global style that is inheritable, you set its value on the container. All children of that container, including other containers, inherit the value of that style property. For example, if you set the `color` of a Panel container to green, the labels for all buttons in the Panel container are also green, unless those buttons override that color.

To use CSS to apply a noninheritable style globally, you can use the `global` selector. For more information, see "Using the global selector" on page 1536.

When using Spark components, the easiest way to set global styles is to set the value of the style property on the Application class, as long as that style is inheritable. To do this, you use the `FlexGlobals.topLevelApplication.application` property to reference the class, and then call the `setStyle()` method on it. For more information, see "Using themes" on page 1562.

If you apply a noninheritable style to a parent container, only the container uses that style. Children of that container do not use the values of noninheritable styles.

By using global styles, you can apply noninheritable styles to all controls that do not explicitly override that style. Flex provides the following ways to apply styles globally:

- StyleManager `global` style
- CSS `global` selector

The StyleManager lets you apply styles to all controls using the `global` style. You can access the top-level StyleManager by using the `styleManager` property of the Application object. For more information, see "Using the StyleManager class" on page 1537.

You can also apply global styles using the `global` selector in your CSS style definitions. These are located either in external CSS style sheets or in an `<fx:Style>` tag. For more information, see "Using the global selector" on page 1536.

About style value formats

Style properties can be of types String or Number. They can also be Arrays of these types. In addition to a type, style properties also have a format (`Length`, `Time`, or `Color`) that describes the valid values of the property. Some properties appear to be of type Boolean (taking a value of `true` or `false`), but these are Strings that are interpreted as Boolean values. This section describes these formats.

Length format

The `Length` format applies to any style property that takes a size value, such as the size of a font (or `fontSize`). `Length` is of type Number.

The `Length` type has the following syntax:

```
length[length_unit]
```

The following example defines the `fontSize` property with a value of 20 pixels:

```
<?xml version="1.0"?>
<!-- styles/LengthFormat.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
  <fx:Style>
     .myFontStyle {
        fontSize: 20px;
        color: #9933FF;
     }
  </fx:Style>
  <s:Button id="myButton" styleName="myFontStyle" label="Click Here"/>
</s:Application>
```

If you do not specify a unit, the unit is assumed to be pixels. The following example defines two styles with the same font size:

```
<?xml version="1.0"?>
<!-- styles/LengthFormat2.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
  <fx:Style>
     .myFontStyle {
        fontSize: 20px;
        color: #9933FF;
     }
     .myOtherFontStyle {
        fontSize: 20;
        color: #9933FF;
     }
  </fx:Style>
  <s:Button id="myButton" styleName="myFontStyle" label="Click Here"/>
  <s:Button id="myButton2" styleName="myOtherFontStyle" label="Click Here"/>
</s:Application>
```

***Note:** Spaces are not allowed between the length value and the unit.*

The following table describes the supported `length` units:

Unit	Scale	Description
px	Relative	Pixels.
in	Absolute	Inches.
cm	Absolute	Centimeters.
mm	Absolute	Millimeters.
pt	Absolute	Points.
pc	Absolute	Picas.

***Note:** The numeric values specified for font size in Flex are actual character sizes in the chosen units. These values are not equivalent to the relative font size specified in HTML using the `<font>` tag.*

Flex does not support the em and ex units. You can convert these to px units by using the following scales:

1em = 10.06667px

1ex = 6px

In Flex, all lengths are converted to pixels prior to being displayed. In this conversion, Flex assumes that an inch equals 72 pixels. All other lengths are based on that assumption. For example, 1 cm is equal to 1/2.54 of an inch. To get the number of pixels in 1 cm, multiply 1 by 72, and divide by 2.54.

When you use inline styles, Flex ignores units and uses pixels as the default.

The `fontSize` style property allows a set of keywords in addition to numbered units. You can use the following keywords when setting the `fontSize` style property. The exact sizes are defined by the client browser:

- `xx-small`
- `x-small`
- `small`
- `medium`
- `large`
- `x-large`
- `xx-large`

The following example class selector defines the `fontSize` as `x-small`:

```
<?xml version="1.0"?>
<!-- styles/SmallFont.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

  <fx:Style>
     .smallFont {
        fontFamily: Arial, Helvetica, "_sans";
        fontSize: x-small;
     }
  </fx:Style>
  <s:Button id="myButton" styleName="smallFont" label="Click Here"/>
</s:Application>
```

Time format

You use the `Time` format for component properties that move or have built-in effects, such as the ComboBox component when it drops down and pops up. The `Time` format is of type Number and is represented in milliseconds. Do not specify the units when entering a value in the `Time` format.

The following example sets the `openDuration` style property of the myTree control to 1000 milliseconds. The default value is 0, so this example opens the tree nodes considerably more slowly than normal.

```
<?xml version="1.0"?>
<!-- styles/TimeFormat.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp()">
    <fx:Script><![CDATA[
        public function initApp():void {
            myTree.setStyle("openDuration", 1000);
            myTree.setStyle("paddingLeft", 50);
        }
    ]]></fx:Script>
    <fx:Declarations>
        <fx:XMLList id="treeData">
            <node label="Mail Box">
                <node label="Inbox">
                    <node label="Marketing"/>
                    <node label="Product Management"/>
                    <node label="Personal"/>
                </node>
                <node label="Outbox">
                    <node label="Professional"/>
                    <node label="Personal"/>
                </node>
                <node label="Spam"/>
                <node label="Sent"/>
            </node>
        </fx:XMLList>
    </fx:Declarations>
    <mx:Panel title="Tree Control Example" width="100%">
        <mx:Tree id="myTree" width="100%" labelField="@label" dataProvider="{treeData}"/>
    </mx:Panel>
</s:Application>
```

Color format

You define `Color` in several formats. You can use most of the formats only in the CSS style definitions. The following table describes the recognized `Color` formats for a style property:

Format	**Description**
hexadecimal	Hexadecimal colors are represented by a six-digit code preceded by either a zero and small x (`0x`) or a pound sign (#). The range of valid values is `0x000000` to `0xFFFFFF` (or `#000000` to `#FFFFFF`). You use the `0x` prefix when defining colors in calls to the `setStyle()` method and in MXML tags. You use the # prefix in CSS style sheets and in `<fx:Style>` tag blocks.

Format	**Description**
RGB	RGB colors are a mixture of the colors red, green, and blue, and are represented in percentages of the color's saturation. The format for setting RGB colors is `color:rgb(x%, y%, z%)`, where the first value is the percentage of red saturation, the second value is the percentage of green saturation, and the third value is the percentage of blue saturation. You can use the RGB format only in style sheet definitions.
8-bit octet RGB	The 8-bit octet RGB colors are red, green, and blue values from 1 to 255. The format of 8-bit octet colors is `[0-255],[0-255],[0-255]`. You can use the 8-bit octet RGB format only in style sheet definitions.
VGA color names	VGA color names are a set of 16 basic colors supported by all browsers that support CSS. The available color names are `Aqua`, `Black`, `Blue`, `Fuchsia`, `Gray`, `Green`, `Lime`, `Maroon`, `Navy`, `Olive`, `Purple`, `Red`, `Silver`, `Teal`, `White`, `Yellow`. You can use the VGA color names format in style sheet definitions and inline style declarations. VGA color names are not case-sensitive.

Color formats are of type Number. When you specify a format such as a VGA color name, Flex converts that String to a Number.

CSS style definitions and the `<fx:Style>` tag support the following color value formats:

```
<?xml version="1.0"?>
<!-- styles/ColorFormatCSS.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

  <fx:Style>
     .myStyle {
        themeColor: #6666CC;    /* CSS hexadecimal format */
        color: Blue;        /* VGA color name */
     }
  </fx:Style>

  <s:Button id="myButton" styleName="myStyle" label="Click Here"/>

</s:Application>
```

You can use the following color value formats when setting the styles inline or using the `setStyle()` method:

```
<?xml version="1.0"?>
<!-- styles/ColorFormatStyleManager.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp()">
  <fx:Script><![CDATA[
     public function initApp():void {
        styleManager.getStyleDeclaration("spark.components.Button").setStyle("color","Blue");
     }
     public function changeStyles(e:Event):void {
        // Check against "255" here, because that is the numeric value of "Blue".
        if (e.currentTarget.getStyle("color") == 255) {
            e.currentTarget.setStyle("color", "Red");
        } else {
            e.currentTarget.setStyle("color", "Blue");
        }
     }
  ]]></fx:Script>
  <s:Button id="myButton" label="Click Here"
        click="changeStyles(event)"/>
</s:Application>
```

Using Arrays for style properties

Some controls accept arrays of colors. For example, the Tree control's `depthColors` style property can use a different background color for each level in the tree. To assign colors to a property in an Array, add the items in a comma-separated list to the property's definition. The index is assigned to each entry in the order that it appears in the list.

The following example defines Arrays of colors for properties of the `Tree` type selector:

```
<?xml version="1.0"?>
<!-- styles/ArraysOfColors.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
  <fx:Style>
     @namespace mx "library://ns.adobe.com/flex/mx";
     mx|Tree {
        depthColors: #FFCC33, #FFCC99, #CC9900;
        alternatingItemColors: red, green;
     }
  </fx:Style>
    <fx:Declarations>
      <fx:XMLList id="treeData">
         <node label="Mail Box">
            <node label="Inbox">
               <node label="Marketing"/>
               <node label="Product Management"/>
               <node label="Personal"/>
            </node>
            <node label="Outbox">
               <node label="Professional"/>
               <node label="Personal"/>
            </node>
            <node label="Spam"/>
            <node label="Sent"/>
         </node>
      </fx:XMLList>
    </fx:Declarations>
  <s:Panel title="Tree Control Example" width="100%">
        <mx:Tree id="myTree" width="100%" labelField="@label" dataProvider="{treeData}"/>
  </s:Panel>
</s:Application>
```

In this example, only `depthColors` will be seen. The `alternatingItemColors` property is visible only if `depthColors` is not set. Both are presented here for illustrative purposes only.

You can define the Array in ActionScript by using a comma-separated list of values surrounded by braces, as the following example shows:

```
<?xml version="1.0"?>
<!-- styles/SetStyleArray.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp()"
    height="500">

  <fx:Script>
    <![CDATA[
     public function initApp():void {
        myTree.setStyle("depthColors",[0xFFCC33, 0xFFCC99, 0xCC9900]);
        myTree.setStyle("alternatingItemColors",["red", "green"]);
     }
    ]]>
  </fx:Script>
  <fx:Declarations>
      <fx:XMLList id="treeData">
         <node label="Mail Box">
            <node label="Inbox">
               <node label="Marketing"/>
               <node label="Product Management"/>
               <node label="Personal"/>
            </node>
            <node label="Outbox">
               <node label="Professional"/>
               <node label="Personal"/>
            </node>
            <node label="Spam"/>
            <node label="Sent"/>
         </node>
      </fx:XMLList>
  </fx:Declarations>
  <s:Panel title="Tree Control Example" width="100%">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <mx:Tree id="myTree"
           width="100%"
           labelField="@label"
           dataProvider="{treeData}"/>
        <mx:Tree id="myOtherTree"
           width="100%"
           labelField="@label"
           dataProvider="{treeData}"
           depthColors="[0xFFCC33, 0xFFCC99, 0xCC9900]"
           alternatingItemColors="['red', 'green']"/>
  </s:Panel>
</s:Application>
```

This example also shows that you can set the properties that use Arrays inline.

Finally, you can set the values of the Array in MXML syntax and apply those values inline, as the following example shows:

```
<?xml version="1.0"?>
<!-- styles/ArrayOfColorsMXML.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Declarations>
      <fx:Array id="myDepthColors">
         <fx:Object>0xFFCC33</fx:Object>
         <fx:Object>0xFFCC99</fx:Object>
         <fx:Object>0xCC9900</fx:Object>
      </fx:Array>
      <fx:Array id="myAlternatingRowColors">
         <fx:Object>red</fx:Object>
         <fx:Object>green</fx:Object>
      </fx:Array>
      <fx:XMLList id="treeData">
         <node label="Mail Box">
            <node label="Inbox">
               <node label="Marketing"/>
               <node label="Product Management"/>
               <node label="Personal"/>
            </node>
            <node label="Outbox">
               <node label="Professional"/>
               <node label="Personal"/>
            </node>
            <node label="Spam"/>
            <node label="Sent"/>
         </node>
      </fx:XMLList>
    </fx:Declarations>
  <s:Panel title="Tree Control Example" width="50%">
        <mx:Tree id="myTree"
           width="100%"
           labelField="@label"
           dataProvider="{treeData}"
           depthColors="{myDepthColors}"
           alternatingItemColors="{myAlternatingRowColors}"/>
  </s:Panel>
</s:Application>
```

Using Cascading Style Sheets

Cascading Style Sheets (CSS) are a standard mechanism for declaring text styles in HTML and most scripting languages. A style sheet is a collection of formatting rules for types of components or classes that include sets of components. Flex supports the use of CSS syntax and styles to apply styles to components.

The dremsus.com blog has several examples of using CSS with Flex.

In CSS syntax, each declaration associates a style name, or *selector*, with one or more style properties and their values. You define multiple style properties in each selector by separating each property with a semicolon. For example, the following style defines a selector named `myFontStyle`:

```
<?xml version="1.0"?>
<!-- styles/ClassSelector.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <fx:Style>
        .myFontStyle {
            fontSize: 15;
            color: #9933FF;
        }
    </fx:Style>
    <s:VGroup>
        <!-- This button has the custom style applied to it. -->
        <s:Button id="myButton" styleName="myFontStyle" label="Click Me"/>
        <!-- This button uses default styles. -->
        <s:Button id="myButton2" label="Click Me"/>
    </s:VGroup>
</s:Application>
```

In this example, `myFontStyle` defines a new class of styles, so it is called a *class selector*. In the markup, you can explicitly apply the `myFontStyle` style to a control or class of controls.

A *type selector* implicitly applies itself to all components of a particular type, as well as all subclasses of that type. If you use type selectors, then you must be sure to define namespaces with the `@namespace` directive in the CSS so that Flex. This is because classes in different packages often share the same class name.

The following example defines a type selector named `Button`:

```
<?xml version="1.0"?>
<!-- styles/TypeSelectorAgain.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Style>
        @namespace s "library://ns.adobe.com/flex/spark";
        s|Button {
            fontSize: 15;
            color: #9933FF;
        }
    </fx:Style>
    <s:VGroup>
        <s:Button id="myButton" label="Click Me"/>
        <s:Button id="myButton2" label="Click Me"/>
    </s:VGroup>
</s:Application>
```

Flex applies this style to all Button controls, and all subclasses of Button controls in the Spark namespace. If you define a type selector on a container, that style applies to all children of that container if the style is an inheriting style.

Flex also supports id, descendent, and pseudo selectors.

When discussing CSS in Flex, the *subject* of a selector is the right-most simple type selector in a potentially-complex selector expression. In the following example, the Button is the subject of the selectors:

```
VBox Panel Button#button12 {
    color: #DDDDDD;
}
VBox.special Button {
    color: #CCCCCC;
}
Button.special {
    color: #BBBBBB;
}
```

When determining styles for a new component instance, Flex examines all the parent classes looking for type selectors. Flex applies settings in all type selectors, not just the exact match. For example, suppose that class MyButton extends Button. For an instance of MyButton, Flex first checks for a MyButton type selector. Flex applies styles in the MyButton type selector, and then checks for a Button type selector. Flex applies styles in the Button selector, and then checks for a UIComponent type selector. Flex stops at UIComponent. Flex does not continue up the parent chain past UIComponent because Flex does not support type selectors for Sprite (the parent of UIComponent) or any of Sprite's parent classes, up to the base Object class.

***Note:** The names of class selectors cannot include hyphens in Flex. If you use a hyphenated class selector name, such as my-class-selector, Flex ignores the style.*

You can programmatically define new class and type selectors using the StyleManager class. You can access the top-level StyleManager by using the `styleManager` property of the Application object. For more information, see "Using the StyleManager class" on page 1537.

About selector names

When applying style properties with CSS in a `<fx:Style>` block or in an external style sheet, the best practice is to use camel-case without hyphens for the style property, as in `fontWeight` and `fontFamily` (rather than `font-weight` and `font-family`). This matches the convention of using camel-case property names in MXML.

To make development easier, however, Flex supports both the camel-case and hyphenated syntax in style sheets, as the following example shows:

```
<?xml version="1.0"?>
<!-- styles/CamelCase.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
     <s:layout>
        <s:VerticalLayout/>
     </s:layout>

    <fx:Style>
        .myFontStyle {
            fontSize: 15; /* Note the camelCase. */
        }
        .myOtherFontStyle {
            font-size: 15; /* Note the hyphen. */
        }
    </fx:Style>
    <s:Button id="myButton" styleName="myFontStyle" label="Click Me"/>
    <s:Button id="myButton2" styleName="myOtherFontStyle" label="Click Me"/>
</s:Application>
```

In ActionScript or an MXML tag, you cannot use hyphenated style property names, so you must use the camel-case version of the style property. For the style name in a style sheet, you cannot use a hyphenated name, as the following example shows:

```
.myClass { ... } /* Valid style name */
.my-class { ... } /* Not a valid style name */
```

About namespaces in CSS

Some Spark and MX components share the same local name. For example, there is a Spark Button component (in the spark.components.* package) and an MX Button component (in the mx.controls.* package). To distinguish between different components that share the same name, you specify namespaces in your CSS that apply to types.

For example, you can specify that a particular selector apply to all components in the Spark namespace only. To specify a namespace in CSS, you declare the namespace with the @namespace directive, followed by the namespace's library in quotation marks. The following example defines the Spark namespace and uses the "s" as an identifier:

```
@namespace s "library://ns.adobe.com/flex/spark";
```

The following are valid namespace directives in Flex 4 that refer to the manifests in the related SWC files:

- `library://ns.adobe.com/flex/spark`
- `library://ns.adobe.com/flex/mx`

If you do not use type selectors in your style sheets, then you are not required to use the @namespace rule.

After you specify a namespace's identifier, you can use it in CSS selectors. The following example uses the Spark namespace for the Button components and the MX namespace for the Box containers:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- styles/NamespaceIdentifierExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:myComps="*"
    >
     <s:layout>
        <s:VerticalLayout/>
     </s:layout>

     <fx:Style>
          @namespace s "library://ns.adobe.com/flex/spark";
          @namespace mx "library://ns.adobe.com/flex/mx";
          s|Button {
               fontSize:16;
          }

          mx|VBox {
               color:red;
          }
     </fx:Style>
     <mx:VBox>
          <!-- This Spark button is red, and has a fontSize of 16. -->
          <s:Button label="Click Me, Too"/>
      </mx:VBox>
</s:Application>
```

You can also specify that a particular selector apply to mixed nested namespaces. This is common if you are using descendant selectors. You can exclude an identifier, in which case the declared namespace becomes the default namespace. The following example uses the default namespace:

```
<fx:Style>
    @namespace "library://ns.adobe.com/flex/spark";
    Button {
        color: #990000;
    }
</fx:Style>
```

For custom components, you can define your own style namespace; that style namespace must match the component's namespace. For example, components in the myComponents package use the style namespace "myComponents.*", as the following example shows:

```
<?xml version="1.0"?>
<!-- styles/CustomComponentsNamespace.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:comps="myComponents.*">
    <fx:Style>
        @namespace comps "myComponents.*";

        comps|MyButton {
            color:green;
        }
    </fx:Style>
    <comps:MyButton label="Click Me"/>
</s:Application>
```

For custom components that are in the top level package, you can use an "*" for the namespace. However, you cannot use wildcard namespace prefixes, such as "*|" to match any namespace.

You can create your own namespace. This can be useful if you want to defines type selectors for custom components. The following example creates a new namespace for the classes in the mx.charts.chartClasses.* package. It then applies the new styles to just the DataTip class in that package:

```
<?xml version="1.0"?>
<!-- charts/DataTipStyles.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="srv.send()"
    height="600">
    <fx:Declarations>
        <!-- View source of the following page to see the structure of the data that Flex uses 
in this example. -->
         <mx:HTTPService id="srv" url="http://aspexamples.adobe.com/chart_examples/expenses-
xml.aspx"/>
         <!-- To see data in an HTML table, go to 
http://aspexamples.adobe.com/chart_examples/expenses.aspx -->
    </fx:Declarations>
    <fx:Style>
        @namespace chartClasses "mx.charts.chartClasses.*";
        chartClasses|DataTip {
            fontFamily: "Arial";
            fontSize: 12;
            fontWeight:bold;
            fontStyle:italic;
        }
    </fx:Style>

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:Panel title="Bar Chart">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
        <mx:BarChart id="myChart"
            dataProvider="{srv.lastResult.data.result}"
            showDataTips="true">
            <mx:verticalAxis>
                <mx:CategoryAxis categoryField="month"/>
            </mx:verticalAxis>
            <mx:series>
                <mx:BarSeries
                    yField="month"
                    xField="profit"
                    displayName="Profit"/>
                <mx:BarSeries
                    yField="month"
                    xField="expenses"
                    displayName="Expenses"/>
            </mx:series>
        </mx:BarChart>
        <mx:Legend dataProvider="{myChart}"/>
    </s:Panel>
</s:Application>
```

About inheritance in CSS

If you set an inheritable style property on a parent container, its children inherit that style property. For example, if you define `fontFamily` as `Times` for a Panel container, all children of that container will also use `Times` for `fontFamily`, unless they override that property. If you set a noninheritable style on a parent container, only the parent container uses that style; the children do not use that style. For more information on inheritable style properties, see "About style inheritance" on page 1526.

In general, color and text styles are inheritable, regardless of which theme they are in (Spark or Halo) or how they are set (by using style sheets or the setStyle() method).

The following are exceptions to the rules of inheritance:

- If you use the `global` selector in a CSS style definition, Flex applies those style properties to all controls, regardless of whether the properties are inheritable. For more information, see "Using the global selector" on page 1536.
- The values set in type selectors apply to the target class as well as its subclasses, even if the style properties are not inheritable. For example, if you define a Group type selector, Flex applies all styles in that selector to Group and VGroup controls because VGroup is a subclass of Group.

In general, you should avoid using type selectors for commonly-used base classes like Group. Group is a class that Spark skins are based on. Setting styles on the Group type selector might cause unexpected results because the skins will have styles applied that you might not oridinarily expect to apply.

The following example illustrates this issue. All labels and button labels are yellow, even though only one label and one button is explicitly in a group. The reason is that the LabelSkin and ButtonSkin classes that define the skins for the Label and Button components, are based on the SparkSkin class. The SparkSkin class is a subclass of Group.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- styles/TypeSelectorInheritance.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
     <s:layout>
        <s:VerticalLayout/>
     </s:layout>

     <fx:Style>
          @namespace s "library://ns.adobe.com/flex/spark";
          @namespace mx "library://ns.adobe.com/flex/mx";
          s|Group {
               color:#FFCC33;
          }

     </fx:Style>

     <s:VGroup>
        <s:Button label="This Button is in a VGroup and its label is yellow."/>
        <s:Label text="This Label is in a VGroup and its text is yellow."/>
     </s:VGroup>
     <s:Button label="This Button is not in a Group, but it is still yellow."/>
     <s:Label text="This Label is not in a Group, but it is still yellow."/>
</s:Application>
```

CSS differences

There are some major differences in Flex between support of CSS and the CSS specification:

- Flex supports subclassing selectors. For example, if you specify a Box type selector, Flex applies the styles to all subclasses of Box, including VBox and HBox. This applies to all classes in the Flex framework's class hierarchy below UIComponent. In this case, UIComponent is considered a "stop class."
- Flex supports a subset of the style properties that are available in CSS. Flex controls also have unique style properties that are not defined by the CSS specification.
- Flex controls only support styles that are defined by the current theme. If a theme does not use a particular style, applying that style to a control or group of controls has no effect. For more information, see "About themes" on page 1561.
- Flex style sheets can define skins for controls using the Embed keyword. For more information, see "Skinning MX components" on page 1655.
- The CSS 3 wildcard namespace prefix syntax of *| that matches any namespace (including no namespace) is not supported. For more information, see "Using Cascading Style Sheets" on page 1504.
- The universal selector scoped to a particular CSS namespace is not supported. Namespaces are not known at runtime in Flex and as such the universal selector remains universal no matter what namespace it is scoped to in CSS.
- If you apply multiple class selectors to a component, the order of preference that the styles is applied is the order in which they appear in the `styleName` property's space-delimited list, not the order in which they are defined in the CSS block or external style sheet.

- The implementation of the CSS Media Query feature in Flex supports only the “screen” type. No other media types are supported.

About class selectors

Class selectors define a set of styles (or a class) that you can apply to any component. You define the style class, and then point to the style class using the `styleName` property of the component’s MXML tag. All components that are a subclass of the UIComponent class support the `styleName` property.

The following example defines a new style `myFontStyle` and applies that style to a Button component by assigning the Button to the `myFontStyle` style class:

```
<?xml version="1.0"?>
<!-- styles/ClassSelector.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <fx:Style>
        .myFontStyle {
            fontSize: 15;
            color: #9933FF;
        }
    </fx:Style>
    <s:VGroup>
        <!-- This button has the custom style applied to it. -->
        <s:Button id="myButton" styleName="myFontStyle" label="Click Me"/>
        <!-- This button uses default styles. -->
        <s:Button id="myButton2" label="Click Me"/>
    </s:VGroup>
</s:Application>
```

You can apply multiple class selectors by separating them with a space in the `styleName` property. The order of preference that the styles is applied is the order in which they appear in the space-delimited list, not the order in which they are defined in the CSS block or external style sheet. The following example applies both class selectors to the first button:

```
<?xml version="1.0"?>
<!-- styles/MultipleStyleNames.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <fx:Style>
        .myFontStyle {
            fontSize: 22;
        }
        .myOtherFontStyle {
            color: #9933FF;
        }
    </fx:Style>
    <s:VGroup>
        <!-- This button has the custom style applied to it. -->
        <s:Button id="myButton"
            styleName="myFontStyle myOtherFontStyle"
            label="Click Me"/>
        <!-- This button uses default styles. -->
        <s:Button id="myButton2" label="Click Me"/>
    </s:VGroup>
</s:Application>
```

Class selector names must start with a period when you access them with the `getStyleDeclaration()` method, as the following example shows:

```
<?xml version="1.0"?>
<!-- styles/ClassSelectorStyleManager.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Style>
        .myFontStyle {
            fontSize: 15;
            color: #9933FF;
        }
    </fx:Style>
    <fx:Script>
        <![CDATA[
            public function changeStyles(e:Event):void {
                styleManager.getStyleDeclaration(".myFontStyle").setStyle("color",0x3399CC);
            }
        ]]>
    </fx:Script>
    <s:Button id="myButton" label="Click Here" styleName="myFontStyle"
click="changeStyles(event)"/>

</s:Application>
```

You do not precede the class selector with a period when you use the `styleName` property for inline styles.

About type selectors

Type selectors assign styles to all components of a particular type. When you define a type selector, you are not required to explicitly apply that style. Instead, Flex applies the style to all classes of that type. Flex also applies the style properties defined by a type selector to all subclasses of that type.

When you use type selectors, you are required to specify which namespace each type appears in with the `@namespace` directive.

The following example shows a type selector for Button controls:

```
<?xml version="1.0"?>
<!-- styles/TypeSelector.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Style>
        @namespace s "library://ns.adobe.com/flex/spark";
        s|Button {
            fontSize: 15;
            color: #9933FF;
        }
    </fx:Style>
    <s:VGroup>
        <s:Button id="myButton" label="Click Me"/>
        <s:Button id="myButton2" label="Click Me"/>
    </s:VGroup>
</s:Application>
```

In this example, Flex applies the `color` style to all Spark Button controls in the current document, and all Button controls in all the child documents. In addition, Flex applies the `color` style to all subclasses of the Spark Button class.

You can set the same style declaration for multiple component types by using a comma-separated list of components. The following example defines style information for all Spark Button, TextInput, and Label components:

```
<?xml version="1.0"?>
<!-- styles/MultipleTypeSelector.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
     <s:layout>
        <s:VerticalLayout/>
     </s:layout>

    <fx:Style>
        @namespace s "library://ns.adobe.com/flex/spark";
        s|Button, s|TextInput, s|Label {
            fontStyle: italic;
            fontSize: 24;
        }
    </fx:Style>
    <s:Button id="myButton" label="Click Here"/>
    <s:Label id="l1" text="My Label"/>
    <s:TextInput id="ti1" text="Input text here"/>
</s:Application>
```

You can use multiple type selectors of the same name at different levels to set different style properties. In an external CSS file, you can set all Spark Button components to use the Blue color for the fonts, as the following example shows:

```
/* assets/SimpleTypeSelector.css */
@namespace s "library://ns.adobe.com/flex/spark";
s|Button {
    fontStyle: italic;
    color: #99FF00;
}
```

Then, in a local style declaration, you can set all Buttons to use the font size 10, as the following example shows:

```
<?xml version="1.0"?>
<!-- styles/TypeSelectorWithExternalCSS.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
  <fx:Style source="../assets/SimpleTypeSelector.css"/>
  <fx:Style>
     @namespace s "library://ns.adobe.com/flex/spark";
     s|Button {
        fontSize: 15;
     }
  </fx:Style>
  <s:Button id="myButton" label="Click Here"/>
</s:Application>
```

The local style declaration does not interfere with external style declarations. Flex applies only the style properties that you specified. The result of this example is that Spark Label controls that are children of the current document use Blue for the color and 10 for the font size.

All styles are shared across all documents in an application and across all applications that are loaded inside the same application. For example, if you load two SWF files inside separate tabs in an MX TabNavigator container, both SWF files share the external style definitions.

When you assign styles to a type selector, all subclasses of that selector’s type (the class) are affected by the styles. For example, if you create a type selector for Group, the styles are also applied to VGroup and HGroup instances because those classes are subclasses of Group.

Using compound selectors

You can mix class and type selectors to create compound style declarations. For example, you can define the color in a class selector and the font size in a type selector, and then apply both to a component:

```
<?xml version="1.0"?>
<!-- styles/CompoundSelectors.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
  <fx:Style>
     @namespace s "library://ns.adobe.com/flex/spark";

     s|Label {
        fontSize: 10pt;
     }
     .myLabel {
        color: Blue;
     }
  </fx:Style>
  <s:Label styleName="myLabel" text="This Label is 10pt Blue"/>
</s:Application>
```

If you later remove one of the selectors (for example, call the StyleManager class' `clearStyleDeclaration()` method on the type or class selector), the other selector's style settings remain.

Using id selectors

Flex supports using an id selector. Flex applies styles to a component whose id matches the id selector in the CSS. To define an id selector, specify the id of the component with a pound sign (#) followed by the id string. The id selector can be qualified by the type or by itself.

The following example shows two ways to use an id selector:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- styles/CSSIDSelectorExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
     <s:layout>
        <s:HorizontalLayout/>
     </s:layout>

     <fx:Style>
          @namespace s "library://ns.adobe.com/flex/spark";
          @namespace mx "library://ns.adobe.com/flex/mx";
          s|Button {
               fontSize:16;
          }

          #myButton2 {
               color:red;
          }

          s|Button#myButton3 {
               color:blue;
          }
     </fx:Style>

     <s:Button id="myButton1" label="Click Me"/>
     <s:Button id="myButton2" label="Click Me, Too"/>
     <s:Button id="myButton3" label="Click Me, Three"/>
</s:Application>
```

Using descendant selectors

Descendant selectors are applied to components in a document, depending on their relationship to other components in the document. A descendant selector lets you apply styles to a component based on whether they descend (are children, grandchildren, or great grandchildren) from particular types of components.

When a component matches multiple descendant selectors, it adopts the style of the most closely-related ancestor. If there are nested descendant selectors, the component uses the styles defined by the selector that most closely matches its line of ancestors. For example, a Spark Button control within a VGroup within another VGroup matches a descendant selector for “s|VGroup s|VGroup s|Button” rather than a descendant selector for “s|VGroup s|Button”.

The following example shows four selectors. The first class selector applies to all Button instances. The first descendant selector applies to the second button, because that Button’s parent is a VGroup. The second descendant selector applies to the third Button, because that Button is a child of an HGroup and a VGroup. The last descendant select applies to the last Button, because that Button is a child of a VGroup within a VGroup.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- styles/CSSDescendantSelectorExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
     <s:layout>
        <s:VerticalLayout/>
     </s:layout>

     <fx:Style>
          @namespace s "library://ns.adobe.com/flex/spark";
          @namespace mx "library://ns.adobe.com/flex/mx";
          s|Button {
               fontSize:16;
          }

          s|VGroup s|Button {
               color:red;
          }

          s|VGroup s|HGroup s|Button {
               color: blue;
          }
          s|VGroup s|VGroup s|Button {
               color: green;
          }
     </fx:Style>
     <!-- This button has a fontSize of 16. -->
     <s:Button label="Click Me"/>
     <s:VGroup>
          <!-- This button is red, and has a fontSize of 16. -->
          <s:Button label="Click Me, Too"/>
      </s:VGroup>
     <s:VGroup>
          <s:HGroup>
               <!-- This button is blue, and has a fontSize of 16. -->
               <s:Button label="Click Me, Also"/>
          </s:HGroup>
     </s:VGroup>
     <s:VGroup>
          <s:VGroup>
               <!-- This button is green, and has a fontSize of 16. -->
               <s:Button label="Click Me, Click Me!"/>
          </s:VGroup>
     </s:VGroup>
</s:Application>
```

Styles are applied only to components that appear in the display list. Descendant selectors are only applied if the ancestors also appear in the display list.

Descendant selectors work with all classes that implement the IStyleClient interface.

A descendant selector applies to a component as long as any parent class of that component matches the descendant selector. The following example shows that two Spark Button controls inherit the styles of the Group descendant selector, because their parents (VGroup and HGroup) are both subclasses of Group.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- styles/CSSDescendantSelectorExample2.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:myComps="*">
     <s:layout>
        <s:VerticalLayout/>
     </s:layout>
     <fx:Style>
          @namespace s "library://ns.adobe.com/flex/spark";
          @namespace mx "library://ns.adobe.com/flex/mx";

          s|Group s|Button {
               color:red;
          }
     </fx:Style>
     <s:VGroup>
          <!-- This button is red, because VGroup is a subclass of Group. -->
          <s:Button label="Click Me"/>
     </s:VGroup>
     <s:HGroup>
          <!-- This button is also red, because HGroup is also a subclass of Group. -->
          <s:Button label="Click Me, Too"/>
     </s:HGroup>
</s:Application>
```

In general, you should avoid using the Group type selector in CSS. This is because all Spark skins use the SparkSkin class, which is a subclass of Group. As a result, Spark skins will inherit style properties from the Group type selectors, which might produce unexpected results.

Nested descendant selectors that set inheritable style properties also work for subcomponents. For example, a Label is a subcomponent of a Button control. It is responsible for rendering the text for the button’s label text.

The following example shows that the nested descendant selectors Button Label apply to a Button for inheritable style properties:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- styles/SubComponentDescendantSelector.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
     <s:layout>
        <s:VerticalLayout/>
     </s:layout>

     <fx:Style>
          @namespace s "library://ns.adobe.com/flex/spark";
          @namespace mx "library://ns.adobe.com/flex/mx";
          s|Button s|Label {
               backgroundColor:#FFCC33;
          }
     </fx:Style>

     <!-- This button has a fontSize of 16. -->
     <s:Button label="Click Me"/>
</s:Application>
```

Using pseudo selectors

Pseudo selectors let you apply styles to a component when that component is in a particular state. The following example uses a pseudo selector to change the appearance of the button when it is in the up, down, and over states:

```
<?xml version="1.0"?>
<!-- styles/PseudoSelectorExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:custom="*">
    <fx:Style>
        @namespace s "library://ns.adobe.com/flex/spark";
        @namespace mx "library://ns.adobe.com/flex/mx";

        s|Button:up {
            chromeColor: black;
            color: #FFFFFF;
        }
        s|Button:over {
            chromeColor: gray;
            fontWeight: "bold";
            color: #FFFFFF;
        }
        s|Button:down {
            chromeColor: blue;
            fontWeight: "bold";
            color: #FFFF66;
        }
    </fx:Style>
    <s:Button label="Click Me" x="10" y="35"/>
</s:Application>
```

For more information about states, see “View states” on page 1847.

About selector precedence

In general, the following rules apply when determining which styles are applied:

- Local styles override global styles (a style set inline takes precedence over a selector)
- When styles have equivalent precedence, the last one applied takes precedence
- The more specific style takes precedence over the more general style

The rules for determining precedence are complicated. The Flex rules follow the CSS rules that are defined by the W3C.

For more information, see CSS3 Selectors W3C specification.

Class selectors take precedence over type selectors. In the following example, the text for the first Button control (with the class selector) is red, and the text of the second Button control (with the implicit type selector) is yellow:

```
<?xml version="1.0"?>
<!-- styles/SelectorPrecedence.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <fx:Style>
        @namespace s "library://ns.adobe.com/flex/spark";
        .myclass {
            color: Red;
        }
        s|Button {
            fontSize: 10pt;
            color: Yellow;
        }
    </fx:Style>
    <s:VGroup width="500" height="200">
        <s:Button styleName="myclass" label="Red Button"/>
        <s:Button label="Yellow Button"/>
    </s:VGroup>
</s:Application>
```

The font size of both buttons is 10. When a class selector overrides a type selector, it does not override all values, just those that are explicitly defined.

Type selectors apply to a particular class, as well as its subclasses and child components. In the following example, the `color` property for a VGroup control is `blue`. This means that the `color` property for the Button and Label controls, which are direct children of the VGroup control, is blue.

```
<?xml version="1.0"?>
<!-- styles/BasicInheritance.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Style>
        @namespace s "library://ns.adobe.com/flex/spark";
        s|VGroup {
            color:blue
        }
    </fx:Style>
    <s:VGroup width="500" height="200">
        <s:Label text="This is a Label control."/>
        <s:Button label="Click Me"/>
    </s:VGroup>
</s:Application>
```

If the same style property is applied in multiple type selectors that apply to a class, the closest type to that class takes precedence. For example, the MX VBox class is a subclass of Box, which is a subclass of Container. If there were Box and Container type selectors rather than a VBox type selector, then the value of the VBox control's `color` property would come from the Box type selector rather than the Container type selector, as the following example shows:

```
<?xml version="1.0"?>
<!-- styles/ContainerInheritance.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Style>
        @namespace mx "library://ns.adobe.com/flex/mx";
        mx|Container {
            color:red
        }
        mx|Box {
            color:green
        }
    </fx:Style>
    <mx:VBox width="500" height="200">
        <mx:Label text="This is a green label."/>
        <mx:Button label="Click Me"/>
    </mx:VBox>
</s:Application>
```

Not all style properties are inheritable. For more information, see "About style inheritance" on page 1526.

Embedding resources in style sheets

You can use embedded resources in your `<fx:Style>` blocks. This is useful for style properties such as `backgroundImage`, which you can apply to an embedded resource such as an image file. The following example embeds an image in CSS:

```
<?xml version="1.0"?>
<!-- styles/EmbedInCSS.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Style>
        .style1 {
            backgroundImage: Embed("../assets/butterfly.gif");
            backgroundAlpha: .2;
        }
    </fx:Style>

    <s:Panel title="BorderContainer Component Example"
            width="75%" height="75%"
            horizontalCenter="0" verticalCenter="0">
        <s:BorderContainer
            left="10" right="10" top="10" bottom="10"
            styleName="style1">
            <s:layout>
                <s:VerticalLayout
                    paddingLeft="5" paddingRight="5"
                    paddingTop="5" paddingBottom="5"/>
            </s:layout>
            <s:HGroup>
                <s:Button label="Button 1"/>
                <s:Button label="Button 2"/>
                <s:Button label="Button 3"/>
                <s:Button label="Button 4"/>
            </s:HGroup>
            <s:HGroup>
                <s:Button label="Button 5"/>
                <s:Button label="Button 6"/>
                <s:Button label="Button 7"/>
                <s:Button label="Button 8"/>
            </s:HGroup>
            <s:HGroup>
                <s:Button label="Button 9"/>
                <s:Button label="Button 10"/>
                <s:Button label="Button 11"/>
                <s:Button label="Button 12"/>
            </s:HGroup>
        </s:BorderContainer>
    </s:Panel>
</s:Application>
```

For graphical Halo skins, you use the `Embed` statement directly in the style sheet, as the following example shows:

```
<?xml version="1.0"?>
<!-- skins/EmbedImagesTypeSelector.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Style>
        @namespace mx "library://ns.adobe.com/flex/mx";

        mx|Button {
            overSkin: Embed("../assets/orb_over_skin.gif");
            upSkin: Embed("../assets/orb_up_skin.gif");
            downSkin: Embed("../assets/orb_down_skin.gif");
        }
    </fx:Style>
    <mx:Button id="b1" label="Click Me"/>
</s:Application>
```

For programmatic Halo skins, you use the `ClassReference` statement, as the following example shows:

```
<?xml version="1.0"?>
<!-- skins/ApplyButtonStatesSkin.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <fx:Style>
        @namespace mx "library://ns.adobe.com/flex/mx";
        mx|Button {
            overSkin: ClassReference("ButtonStatesSkin");
            upSkin: ClassReference("ButtonStatesSkin");
            downSkin: ClassReference("ButtonStatesSkin");
        }
    </fx:Style>
    <mx:Button id="b1" label="Click Me"/>
</s:Application>
```

For more information about using the `Embed` keyword, see “Embedding assets” on page 1699.

For Spark controls, you edit the skin class to add images and behaviors for certain states. For more information about skinning Spark components, see “Spark Skinning” on page 1602.

For more information about skinning MX components, see “Skinning MX components” on page 1655.

Using document properties in CSS

You can use document properties in your CSS with the `PropertyReference` keyword. The property must be public, or it must be defined in the same document as the CSS. For example, you can use a private variable in an imported CSS file, as long as you imported that CSS file in the same document in which the variable is declared.

If you change the value of the document property, the component’s style property is not updated, even if the document property is bindable. Changing the value of the document property will not update the control’s appearance because styles are not reapplied unless you explicitly call the `setStyle()` method or trigger a reapplication of the styles in some other way.

The following example defines the mySize variable and uses it in the CSS:

```
<?xml version="1.0"?>
<!-- styles/PropertyReferenceExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
  <!-- You can declare a property using this method, too: -->
  <!--
  <fx:Declarations>
    <fx:Number id="mySize">20</fx:Number>
  </fx:Declarations>
  -->

  <fx:Script>
    [Bindable]
    private var mySize:Number = 20;
  </fx:Script>

  <fx:Style>
     @namespace s "library://ns.adobe.com/flex/spark";
     s|Button {
        fontSize: PropertyReference("mySize");
     }
  </fx:Style>
    <!--Notice that when you click the button, the value of mySize increases,
         but the size of the font on the button's label does not. Style properties
         must be explicitly set, even if the property is bindable. -->
  <s:Button id="myButton" label="{mySize.toString()}" click="mySize+=2"/>
</s:Application>
```

Using media queries

Flex includes partial support for CSS media queries. In Flex, media queries let you conditionally apply styles based on the DPI and OS of the target device. You typically use this feature if you are developing for mobile or tablet devices that have different target DPIs. For example, if a tablet has a DPI of 300, then you can set the font size to one value. If a tablet has a DPI of 200, then you can set the font size to a different value.

Media queries use the values of the `application-dpi` and `os-platform` CSS properties to determine which styles to apply.

The syntax for using media queries is as follows:

```
@media [media_type] [application-dpi:180|240|320] [and|not|only]
    [os-platform:"Android"|"IOS"|"Macintosh"|"Windows"|"Linux"]
```

The only supported value for the `media_type` property is `screen`. As a result, you do not need to specify the media type.

If you do not specify a value for the `application-dpi` or `os-platform` properties, then all are assumed. You can specify one or more resolutions or platforms by comma-separating their values.

The following example changes the font size and color based on the value of the `applicationDPI` property:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- styles/MediaQueryExample.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
     xmlns:s="library://ns.adobe.com/flex/spark"
     applicationDPI="320"
     creationComplete="initApp()">

    <fx:Style>
        @namespace s "library://ns.adobe.com/flex/spark";
        @namespace mx "library://ns.adobe.com/flex/mx";
        s|TextArea {
            fontSize: 12;
        }
      @media (application-dpi: 160) and (os-platform: "Windows"), (os-platform: "Macintosh"),
(os-platform: "Linux") {
            s|TextArea {
                fontSize: 12;
                color: red;
            }
        }
      @media (application-dpi: 240) and (os-platform: "Windows"), (os-platform: "Macintosh"),
(os-platform: "Linux") {
            s|TextArea {
                fontSize: 18;
                color: green;
            }
        }
      @media (application-dpi: 320) and (os-platform: "Windows"), (os-platform: "Macintosh"),
(os-platform: "Linux") {
            s|TextArea {
                fontSize: 24;
                color: blue;
            }
        }
    </fx:Style>

    <fx:Script>
        private function initApp():void {
            myTextArea.text = "OS: " + Capabilities.os + "\n"
                + "MFR: " + Capabilities.manufacturer + "\n"
                + "DPI: " + applicationDPI;
        }
    </fx:Script>

    <s:TextArea id="myTextArea" width="100%"/>

</s:Application>
```

For more information and examples on using media queries in applications, see Support multiple screen sizes and DPI values in a mobile application.

About style inheritance

If you define a style in only one place in a document, Flex uses that definition to set a property's value. However, an application can have several style sheets, local style definitions, external style properties, and style properties set directly on component instances. In such a situation, Flex determines the value of a property by looking for its definition in all these places in a specific order.

Lower-level styles take precedence over higher-level or external styles. If you set a style on an instance, and then set the style globally, the global style does not override the local style, even if you set it after you set the local style.

Style inheritance order

The order in which Flex looks for styles is important to understand so that you know which style properties apply to which controls.

Flex looks for a style property that was set inline on the component instance. If no style was set on the instance using an inline style, Flex checks if a style was set using an instance's setStyle() method. If it did not directly set the style on the instance, Flex examines the `styleName` property of the instance to see if a style declaration is assigned to it.

If you did not assign the `styleName` property to a style declaration, Flex looks for the property on type selector style declarations. If there are no type selector declarations, Flex checks the `global` selector. If all of these checks fail, the property is undefined, and Flex applies the default style.

In the early stages of checking for a style, Flex also examines the control's parent container for style settings. If the style property is not defined and the property is inheritable, Flex looks for the property on the instance's parent container. If the property isn't defined on the parent container, Flex checks the parent's parent, and so on. If the property is not inheritable, Flex ignores parent container style settings.

The order of precedence for style properties, from first to last, is as follows:

- Inline
- Class selector
- Type selectors (most immediate class takes precedence when multiple selectors apply the same style property)
- Ancestor class's type selector
- Parent chain (inheriting styles only)
- Theme defaults.css file
- `global` selector

If you later call the `setStyle()` method on a component instance, that method takes precedence over all style settings, including inline.

Style definitions in `<fx:Style>` tags, external style sheets, and the defaults.css style sheet follow an order of precedence. The same style definition in defaults.css is overridden by an external style sheet that is specified by an `<fx:Style source="`*stylesheet*`"/>` tag, which is overridden by a style definition within an `<fx:Style>` tag.

The following example defines a type selector for Panel that sets the `fontFamily` property to `Times` and the `fontSize` property to 24. As a result, all controls inside the Panel container, as well as all subclasses such as Button and TextArea, inherit those styles. However, button2 overrides the inherited styles by defining them inline. When the application renders, button2 uses Arial for the font and 12 for the font size.

```
<?xml version="1.0"?>
<!-- skins/MoreContainerInheritance.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
  <fx:Style>
        @namespace s "library://ns.adobe.com/flex/spark";
        s|Panel {
             fontFamily: Times, "_serif";
             fontSize: 24;
          }
  </fx:Style>
  <s:Panel title="My Panel">
     <s:Button id="button1" label="Button 1"/>
     <s:Button id="button2" label="Button 2" fontFamily="Arial" fontSize="12"/>
     <s:TextArea text="Flex has is own set of style properties which are
        extensible so you can add to that list when you create a custom
        component." width="425" height="400"/>
  </s:Panel>
</s:Application>
```

Subcomponent styles

Some Flex controls are made up of other components. For example, the DateField control includes a DateChooser subcomponent, the calendar that pops up when you click on the DateField's icon. The DateChooser subcomponent itself contains Button subcomponents for navigation and TextField subcomponents for labels.

The following table lists some of the most commonly used Spark components and their subcomponents:

Spark component	Subcomponents
Button	Label
ComboBox	Button, Label
HScrollBar/VScrollBar	Button
HSlider/VSlider	Button, Label
NumericStepper	Button, TextInput
RadioButton	Label
TextArea	RichEditableText
TextInput	RichEditableText
TitleWindow	Button, Label
VideoPlayer	Button, Label

Inheritable styles are passed from the parent control to the subcomponent. These include text styles like `color` and `textDecoration`. If you set the `color` style property on a DateField control, Flex applies that `color` to the text in the DateChooser subcomponent, too.

If a style property is explicitly set on the subcomponent (such as in its skin class), then you cannot override it by setting it in CSS. You must edit the skin class or override the style property value in some other way. For example, the Spark HSlider control has a Label subcomponent that defines the appearance of the slider's labels. The `color` style property is set on this Label control explicitly in the HSliderSkin class:

```
<!-- From HSliderSkin.mxml -->
<s:Label id="labelDisplay" text="{data}"
    horizontalCenter="0" verticalCenter="1"
    left="5" right="5" top="5" bottom="5"
    textAlign="center" verticalAlign="middle"
    fontWeight="normal" color="white" fontSize="11">
</s:Label>
```

If you define a Label type selector and specify the color, your CSS setting does not override the explicit setting in the HSlider control's skin class. In this case, you must create a custom skin class for the HSlider control to change the color of the label's text.

If you do not want an inheritable style property to be applied to the subcontrol, you can override the parent's style by defining a custom class selector. For example, to apply styles to the subcomponents of a ComboBox control, you can use the `dropdownStyleName` or `textInputStyleName` style properties to define custom selectors.

Most controls that have subcomponents have custom class selectors that apply styles to their subcomponents. In some cases, controls have multiple custom class selectors so that you can set style properties on more than one subcomponent.

The following example sets the `color` style property on the DateField control. To prevent this color from being applied to the DateChooser subcomponent, the DCStyle custom class selector overrides the value of the `color` style property. This custom class selector is applied to the DateField control with the `dateChooserStyleName` property.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- styles/SubComponentStylesSelector.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
     <s:layout>
        <s:VerticalLayout/>
     </s:layout>

    <fx:Style>
        .DCStyle {
            color:blue;
        }
    </fx:Style>
    <s:VGroup>
        <s:Label text="Overrides the color property of the subcontrol:"/>
        <mx:DateField
            id="dateField1"
            yearNavigationEnabled="true"
            color="red"
            dateChooserStyleName="DCStyle"/>
    </s:VGroup>
    <mx:HRule width="200" height="1"/>
    <s:VGroup>
        <s:Label text="Applies the color property to the subcontrol:"/>
        <mx:DateField
            id="dateField2"
            yearNavigationEnabled="true"
            color="red"/>
    </s:VGroup>
</s:Application>
```

Noninheritable style properties are not passed from the parent component to the subcomponent. In some cases, the parent control provides a property that lets you access the subcomponent. For example, to access the RichEditableText control that is a subcontrol of the Spark TextArea and TextInput controls, you use the `textDisplay` property.

There are some exceptions to noninheritable styles. For example, the `verticalAlign`, `lineBreak`, and `paddingBottom/Left/Right/Top` style properties are noninheritable. You can set these properties, which are defined on the RichEditableText control, directly on the TextArea control because the TextAreaSkin class passes them through to the subcomponent.

The following example sets styles on the RichEditableText subcomponent with the `textDisplay` property, and also sets the values of some noninheriting style properties that are not normally accessible:

```
<?xml version="1.0"?>
<!-- styles/TextAreaStyles.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    creationComplete="initApp()">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            /*
            Non-inheriting styles you must set on textDisplay:
                columnCount
                columnGap
                columnWidth

            Non-inheriting styles that you can set on TextArea because
            they are passed to the subcomponent through the TextAreaSkin class:
                lineBreak
                paddingTop/Bottom/Left/Right
                verticalAlign
            */
            import spark.components.RichEditableText;

            private function initApp():void {
                RichEditableText(ta1.textDisplay).setStyle("columnCount", 3);
                RichEditableText(ta1.textDisplay).setStyle("columnWidth", 100);
                RichEditableText(ta1.textDisplay).setStyle("columnGap", 15);
            }
        ]]>
    </fx:Script>
    <s:TextArea id="ta1" height="100" width="400" verticalAlign="bottom" paddingBottom="20">
        This is a text area control. Because the text rendering is done by a RichEditableText
subcontrol,
      you have to use the textDisplay property to set the values of some non-inheriting styles.
       Other non-inheriting styles are defined in the skin class and are passed through to the
        subcomponent.
        For inheriting styles, they are inherited by the RichEditableText subcontrol.
    </s:TextArea>
</s:Application>
```

Some controls use filters to determine which style properties are passed to subcontrols. For example, if you customize the value of the `cornerRadius` property on a MX DateChooser control, the property does not affect the buttons that are subcomponents of the calendar. To pass that value to the subcomponent in MX components, you can modify the control's filter. Filters specify which style properties to pass to their subcomponents. A filter is an Array of objects that define the style properties that the parent control passes through to the subcomponent. Inheritable style properties are always passed; they cannot be filtered.

Most MX components with subcomponents have at least one filter. For example, the ComboBox subcontrol has a `dropDownStyleFilters` property that defines which style properties the ComboBox passes through to the drop down List subcomponent.

Some MX controls with subcomponents have multiple filters. For example, the DateChooser control has separate filters for each of the buttons on the calendar: the previous month button (`prevMonthStyleFilters`), the next month button (`nextMonthStyleFilters`), the previous year button (`prevYearStyleFilters`), and the next year button (`nextYearStyleFilters`).

The filters properties are read-only, but you can customize them by subclassing the control and adding or removing objects in the filter Array.

The following example includes two DateField controls. The first DateField control does not use a custom filter. The second DateField control is a custom class that uses two custom filters (one for the properties of the next month button and one for the properties of the previous month button).

```
<?xml version="1.0" encoding="utf-8"?>
<!-- versioning/StyleFilterOverride.mxml -->
<!-- Compile this example by setting the theme argument to use the Halo theme. -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:comps="*">
     <s:layout>
        <s:HorizontalLayout/>
     </s:layout>
    <s:VGroup>
        <s:Label width="200"
           text="Standard DateChooser control. Does not pass the cornerRadius property to the
button subcomponents:"/>
        <mx:DateChooser cornerRadius="10"/>
    </s:VGroup>
    <s:VGroup>
        <s:Label width="200"
            text="Custom DateChooser control. Passes the cornerRadius property to the button
subcomponents:"/>
        <comps:MyDateChooser cornerRadius="10"/>
    </s:VGroup>
</s:Application>
```

To compile this example, you cannot use the Spark theme. You must set `theme` compiler option to the Halo theme file. To use a background image on a container with the Spark theme, you must create a custom skin class.

The following class extends the DateChooser class and defines custom filters Arrays for two of the button subcomponents:

```
// styles/MyDateChooser.as
package {
    import mx.controls.DateChooser;

    public class MyDateChooser extends DateChooser {
        private static var myNextMonthStyleFilters:Object = {
             "highlightAlphas" : "highlightAlphas",
             "nextMonthUpSkin" : "nextMonthUpSkin",
             "nextMonthOverSkin" : "nextMonthOverSkin",
             "nextMonthDownSkin" : "nextMonthDownSkin",
             "nextMonthDisabledSkin" : "nextMonthDisabledSkin",
             "nextMonthSkin" : "nextMonthSkin",
             "repeatDelay" : "repeatDelay",
             "repeatInterval" : "repeatInterval",
             "cornerRadius" : "cornerRadius"  // This property is not normally included.
        }

       override protected function get nextMonthStyleFilters():Object {
            return myNextMonthStyleFilters;
       }

       private static var myPrevMonthStyleFilters:Object = {
            "highlightAlphas" : "highlightAlphas",
            "prevMonthUpSkin" : "prevMonthUpSkin",
            "prevMonthOverSkin" : "prevMonthOverSkin",
            "prevMonthDownSkin" : "prevMonthDownSkin",
            "prevMonthDisabledSkin" : "prevMonthDisabledSkin",
            "prevMonthSkin" : "prevMonthSkin",
            "repeatDelay" : "repeatDelay",
            "repeatInterval" : "repeatInterval",
            "cornerRadius" : "cornerRadius"
        }

        override protected function get prevMonthStyleFilters():Object {
            return myPrevMonthStyleFilters;
        }
    }
}
```

The custom filters each include the following additional entry in the Array:

```
"cornerRadius" : "cornerRadius"
```

The `cornerRadius` property is not normally listed in the `nextMonthStyleFilters` and `myPrevMonthStyleFilters` Arrays. By adding it to these filter Arrays, you ensure that the property is passed from the parent control to the subcontrol, and is applied to the previous month and next month buttons.

You can also use filters to exclude properties that are normally passed through the subcomponent. You do this by removing those properties from the filter Array in the subclass.

Inheritance exceptions for styles

Not all styles are inheritable, and not all styles are supported by all components and themes. In general, color and text styles are inheritable, regardless of how they are set (using CSS or style properties). All other styles are not inheritable unless otherwise noted.

A style is inherited only if it meets the following conditions:

- The style is inheritable. You can see a list of inherited style for each control by viewing that control's entry in the *ActionScript 3.0 Reference for the Adobe Flash Platform*. You can programmatically determine if a style is inheritable using the static `isInheritingStyle()` or `isInheritingTextFormatStyle()` methods on the StyleManager class. You can access the top-level StyleManager by using the `styleManager` property of the Application object.
- The style is supported by the theme. To determine if a style property is supported by the theme you are using, view the style's entry in the *ActionScript 3.0 Reference for the Adobe Flash Platform*. If the style property is limited to a theme, the `Theme` property will appear in the style's description, with the name of the supported theme next to it. If the style requires a different theme, you can use the `theme` compiler option to change the theme. If the *ActionScript 3.0 Reference for the Adobe Flash Platform* does not specify a theme for a particular style property, then that property should work with all themes.
- The style is supported by the control. For information about which controls support which styles, see the control's description in the *ActionScript 3.0 Reference for the Adobe Flash Platform*.
- The style is set on the control's parent container or the container's parent. A style is not inherited from another class, unless that class is a parent container of the control, or a parent container of the control's parent container. (The exception to this condition is if you use type selectors to apply the style property. In that case, Flex applies properties of the class's type selector, as well as any properties set in the base class's type selector.)
- The style is not overridden at a lower level. For example, if you define a style type selector (such as `Button { color:red }`), but then set an instance property on a control (such as `<mx:Button color="blue"/>`), the type selector style will not override the style instance property even if the style is inheritable.

You can apply noninheritable styles to all controls by using the `global` selector. For more information, see "Using the global selector" on page 1536.

About supported styles

All themes support the inheritable and noninheritable text styles, but not all styles are supported by all themes. If you try to set a style property on a control but the current theme does not support that style, Flex does not apply the style.

To determine if a style property is supported by the theme you are using, view the style's entry in the *ActionScript 3.0 Reference for the Adobe Flash Platform*. If the style property is limited to a theme, the Theme property will appear in the style's description, with the name of the supported theme next to it. If there is no theme specified for a particular style property, then the style property should be supported by all themes.

Some styles are only used by skins in the theme, while others are used by the component code itself.

The display text of components is not skinnable, so support for text styles is theme-independent.

For more information, "About themes" on page 1561.

About the themeColor property

Many assets in the Halo theme support a property called `themeColor`. You can set this property on the MX Application tag, and the color is applied throughout the application on component assets, such as the MX Button control's border, the headers of an Accordion control, and the default shading of a ToolTip control's background.

In addition to color values such as 0xCCCCCC (for silver) or 0x0066FF (for blue), the following values for the `themeColor` property are valid:

- `haloOrange`
- `haloBlue`
- `haloSilver`

- haloGreen

The default value is `haloBlue`. The following example sets the value of `themeColor` to `haloOrange`:

```
<?xml version="1.0"?>
<!-- styles/ThemeColorExample.mxml -->
<!-- Compile this example by setting the theme compiler argument to Halo.swc. -->
<mx:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    themeColor="haloOrange">

    <fx:Script>
        <![CDATA[
            import mx.core.FlexGlobals;
            import mx.collections.ArrayCollection;
            [Bindable]
            public var themes:ArrayCollection = new ArrayCollection(
                [ "haloOrange", "haloBlue", "haloSilver", "haloGreen"]);

            private function closeHandler(e:Event):void {
                FlexGlobals.topLevelApplication.setStyle("themeColor",
ComboBox(e.target).selectedItem);
            }
        ]]>
    </fx:Script>
    <mx:ComboBox dataProvider="{themes}" width="150" close="closeHandler(event);"/>
    <mx:Button id="myButton" label="Click Me" toolTip="Click me"/>
</mx:Application>
```

To compile this example, you must use the Halo theme. For information on using themes, see “Using themes” on page 1562.

To achieve functionality similar to the themeColor property in a Spark application, you can use the `chromeColor` style property. This property is supported only by the Spark theme.

Using external style sheets

Flex supports external CSS style sheets. You can declare the location of a local style sheet or use the external style sheet to define the styles that all applications use. To apply a style sheet to the current document and its child documents, use the `source` property of the `<fx:Style>` tag.

***Note:** You should try to limit the number of style sheets used in an application, and set the style sheet only at the top-level document in the application (the document that contains the `Application` tag). If you set a style sheet in a child document, unexpected results can occur.*

The following example points to the MyStyleSheet.css file in the *flex_app_root*/assets directory:

```
<?xml version="1.0"?>
<!-- styles/ExternalCSSExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Style source="../assets/SimpleTypeSelector.css"/>
    <s:Button id="myButton" label="Click Me"/>
</s:Application>
```

The value of the `source` property is the URL of a file that contains style declarations. When you use the `source` property, the contents of that `<fx:Style>` tag must be empty. You can use additional `<fx:Style>` tags to define other styles. Do not add `<fx:Style>` tags to your included file; it should follow standard CSS file syntax.

The external style sheet file can contain both type and class selectors.

If you are using Adobe® Flash® Builder™, you can generate style sheets from existing component definitions by using the Convert to CSS button in the Style pop-up menu in the Flex Properties view. You can export a custom style sheet for a single component type or class of components, or use that component's style properties to create a global style sheet.

You can also compile CSS files into SWF files and load them at run time. For more information, see "Loading style sheets at run time" on page 1547.

You can specify a CSS file as an argument to the `source-path` compiler argument. This lets you toggle among style sheets with that compiler argument.

About the default style sheets

Flex includes defaults.css style sheets in the following SWC files:

- spark.swc (Spark theme style sheet)
- frameworks.swc (default framework style sheet)

All applications use the framework style sheet. All Spark applications use the Spark style sheet, as well, or another style sheet if a new theme is applied.

The defaults.css style sheet in the frameworks.swc file applies default styles to all components. It uses a combination of global CSS style settings and embedded symbols from the Assets.swf file to apply default styles to your applications.

The defaults.css style sheet in the spark.swc file applies default styles to the Spark components. It provides the look and feel of the Spark theme. The Spark default style sheet is much simpler than the framework style sheet. It applies skin classes to the Spark components, and sets a limited number of style properties on the global selector. For more information about themes, see "About themes" on page 1561.

The framework style sheet is applied first, followed by the Spark style sheet. The result is that the Spark style sheet takes precedence where overlapping style definitions occur because the styles are applied after the framework styles.

Flex implicitly loads the default style sheet and Spark theme style sheet during compilation. You can explicitly point to other files by using the `defaults-css-url` compiler option. You can also rename the defaults.css files or remove them from the SWC files to disable them. You typically do not edit the default style sheets in the SWC files (and then recompile those SWC files) to change the default style values. Instead, you set new values on the global selector or create a new theme. For more information, see "Using the global selector" on page 1536.

The default style sheets define the look and feel for all components. If you apply additional themes or CSS files to your application, Flex still uses the styles in default style sheets, but only for the properties that your custom styles do not override. To completely eliminate the default styles from Flex, you must remove or override all styles defined in default style sheets.

Flex also includes other style sheets that let you apply a theme quickly and easily. For more information, see "About the included theme files" on page 1565.

Using local style definitions

The `<fx:Style>` tag contains style sheet definitions that adhere to the CSS syntax. These definitions apply to the current document and all children of the current document. You must also specify a namespace in the `<fx:Style>` tag if you use type selectors that might have ambiguous names.

The `<fx:Style>` tag uses the following syntax to define local styles:

```
<fx:Style>
    @namespace namespace_identifiernamespace_string;
    selector_name {
        style_property: value;
        [...]
    }
</fx:Style>
```

The following example defines a class and a type selector in the `<fx:Style>` tag:

```
<?xml version="1.0"?>
<!-- styles/CompoundLocalStyle.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Style>
        @namespace s "library://ns.adobe.com/flex/spark";
        .myFontStyle {
            fontSize: 15;
            color: #9933FF;
        }
        s|Button {
            fontStyle: italic;
        }
    </fx:Style>
    <s:Button id="myButton" styleName="myFontStyle" label="Click Me"/>
</s:Application>
```

Using the Application type selector

The Application container is the top-most container in an application. Styles defined on the Application type selector that are inheritable are inherited by all of the container's children as well as the container's subclasses. Styles that are not inheritable are only applied to the Application container itself and not its children.

Inheritable styles can be overriden at a lower level; for example, if you set the color style property on a container that has another container and a Button as children, but then set the color on the inner container, the Button control inherits the color from the inner container.

To use CSS to apply a noninheritable style globally, you can use the `global` selector. For more information, see "Using the global selector" on page 1536.

Use the following syntax to define styles for the Application type selector:

```
<fx:Style>
    @namespace_declaration
    namespace|Application { style_definition }
</fx:Style>
```

You can use the MX Application type selector to set the background image and other display settings that define the way the application appears in a browser. You can only do this if you apply the Halo theme to the application when you compile it. The following Halo example aligns the application to the left, removes margins, and sets the background image to be empty:

```
<?xml version="1.0"?>
<!-- styles/ApplicationTypeSelector.mxml -->
<!-- Compile this with theme=halo.swc -->
<mx:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <fx:Style>
        @namespace mx "library://ns.adobe.com/flex/mx";
        mx|Application {
            paddingLeft: 0px;
            paddingRight: 0px;
            paddingTop: 0px;
            paddingBottom: 0px;
            horizontalAlign: "left";
            backgroundColor: #FFFFFF; /* Change color of background to white. */
            backgroundImage: " "; /* The empty string sets the image to nothing. */
        }
    </fx:Style>
    <mx:Button id="myButton" styleName="myFontStyle" label="Click Me"/>
</mx:Application>
```

When the background image is set to the empty string, Flex does not draw the default gray gradient for an MX Application.

For the Spark Application class, you edit its skin class to set a background image and set padding properties. You can set the background color on the Spark Application class with the `backgroundColor` style property, just as you would set it on the MX Application class. For more information about skinning Spark components, see “Spark Skinning” on page 1602.

You can programmatically define values in the Application type selector using the StyleManager class. You can access the top-level StyleManager by using the `styleManager` property of the Application object. For more information, see “Using the StyleManager class” on page 1537.

Using the global selector

Flex includes a `global` selector that you can use to apply styles to all controls. Properties defined by a `global` selector apply to every control unless that control explicitly overrides it. Because the `global` selector is like a type selector, you do not preface its definition with a period in CSS.

The following example defines `fontSize` and `textDecoration` to the `global` selector:

```
<?xml version="1.0"?>
<!-- styles/GlobalTypeSelector.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <fx:Style>
        global {
            fontSize:22;
            textDecoration: underline;
        }
    </fx:Style>
     <s:layout>
        <s:VerticalLayout/>
     </s:layout>
    <s:Button id="myButton" label="Click Me"/>
    <s:Label id="myLabel" text="This is a Label control."/>
</s:Application>
```

You can also use the `getStyleDeclaration()` method to apply the styles with the global selector, as the following example shows:

```
<?xml version="1.0"?>
<!-- styles/GlobalTypeSelectorAS.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp(event)">
     <s:layout>
        <s:VerticalLayout/>
     </s:layout>

    <fx:Script><![CDATA[
        public function initApp(e:Event):void {
            styleManager.getStyleDeclaration("global").setStyle("fontSize", 22);
          styleManager.getStyleDeclaration("global").setStyle("textDecoration", "underline");
        }
    ]]></fx:Script>
    <s:Button id="myButton" label="Click Me"/>
    <s:Label id="myLabel" text="This is a Label control."/>
</s:Application>
```

Class selectors, type selectors, and inline styles all override the `global` selector.

Using the StyleManager class

The StyleManager class lets you access class selectors and type selectors in ActionScript. It also lets you apply inheritable and noninheritable properties globally. Using the StyleManager, you can define new CSS style declarations and apply them to controls in your applications.

You can access the top-level StyleManager by using the `styleManager` property of the Application object.

Setting styles with the StyleManager

To set a value using the StyleManager, use the following syntax:

```
styleManager.getStyleDeclaration(style_name).setStyle("property", value);
```

The `styleManager` property refers to the top level StyleManager object for the application.

The *`style_name`* can be the literal `global`, a type selector such as Button or TextArea, or a class selector that you define in either the `<fx:Style>` tag or an external style sheet. Global styles apply to every object that does not explicitly override them.

The `getStyleDeclaration()` method is useful if you apply a noninheritable style to many classes at one time. This property refers to an object of type CSSStyleDeclaration. Type selectors and external style sheets are assumed to already be of type CSSStyleDeclaration. Flex internally converts class selectors that you define to this type of object.

The following examples illustrate applying style properties to the `Button`, `myStyle`, and `global` style names:

```
<?xml version="1.0"?>
<!-- styles/UsingStyleManager.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp(event)">
    <fx:Style>
        .myStyle {
            color: red;
        }
    </fx:Style>
     <s:layout>
        <s:VerticalLayout/>
     </s:layout>
    <fx:Script><![CDATA[
        /* To get a reference to the top-level StyleManager, use the Application object's
           styleManager property. */

        public function initApp(e:Event):void {
            /* Type selector; applies to all Buttons and subclasses of Button. */

styleManager.getStyleDeclaration("spark.components.Button").setStyle("fontSize",24);
            /* Class selector; applies to controls using the style
               named myStyle. Note that class selectors must be prefixed
               with a period. */
            styleManager.getStyleDeclaration(".myStyle").setStyle("color",0xCC66CC);
            /* Global style: applies to all controls. */
            styleManager.getStyleDeclaration("global").setStyle("fontStyle","italic");
        }
    ]]></fx:Script>
    <s:Button id="myButton" label="Click Me" styleName="myStyle"/>
    <s:Label id="myLabel" text="This is a Label control." styleName="myStyle"/>
</s:Application>
```

***Note:** If you set either an inheritable or noninheritable style to the `global` style, Flex applies it to all controls, regardless of their location in the hierarchy.*

Accessing selectors with the StyleManager

You can access a list of all the class and type selectors that are currently registered with the StyleManager by using the StyleManager's `selectors` property. You can access the top-level StyleManager by using the `styleManager` property of the Application object. The selectors listed include the global selector, default selectors, and all user-defined selectors. This property is a read-only property.

You can use the name of a selector as the argument to the StyleManager's `getStyleDeclaration()` method.

The following example stores the names of all the selectors that are registered with the StyleManager in an Array. It then iterates over that Array and displays values for another Array of style properties by passing the selector name to the `getStyleDeclaration()` method.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- styles/SelectorsTest.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Style>
        .unusedStyleTest {
            fontSize:17;
            color:green;
        }
    </fx:Style>
     <s:layout>
        <s:VerticalLayout/>
     </s:layout>

    <fx:Script>
        <![CDATA[
            private var stylesList:Array = [
                'fontSize', 'color', 'fontWeight', 'fontFamily', 'fontStyle'
            ];

            public function showSelectors():void {
                msg.text = "List all selectors, and show when they explicitly define the
following:\n";
                msg.text += stylesList.toString();
                var selectors:Array = styleManager.selectors;
                for (var i:int = 0; i < selectors.length; i++) {
                    msg.text += "\n\n" + selectors[i] + " {"
                    for (var j:int = 0; j < stylesList.length; j++) {
                        var s:String =
CSSStyleDeclaration(styleManager.getStyleDeclaration(selectors[i])).getStyle(stylesList[j]);
                        if (s != null) {
                            msg.text += "\n    " + stylesList[j] + ":" + s + ";";
                        }
                    }
                    msg.text += "\n}";
                }
            }
        ]]>
    </fx:Script>
    <s:Button label="Show Selectors" click="showSelectors()"/>
    <s:TextArea id="msg" width="100%" height="100%"/>
</s:Application>
```

Creating style declarations with the StyleManager

You can create CSS style declarations by using ActionScript with the CSSStyleDeclaration class. This lets you create and edit style sheets at run time and apply them to classes in your applications. To change the definition of the styles or to apply them during run time, you use the setStyle() method.

The following example creates a new CSSStyleDeclaration object for the Spark and MX Button controls:

```
<?xml version="1.0"?>
<!-- styles/StyleDeclarationTypeSelector.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp()">
     <s:layout>
        <s:VerticalLayout/>
     </s:layout>
  <fx:Script><![CDATA[
     private var mySparkDynStyle:CSSStyleDeclaration;
     private var myHaloDynStyle:CSSStyleDeclaration;
     private function initApp():void {
        /* These CSSStyleDeclaration objects replace
           all style properties for their types, causing potentially unwanted
           results. */
        var mySparkDynStyle:CSSStyleDeclaration  = new CSSStyleDeclaration();
        var myMXDynStyle:CSSStyleDeclaration  = new CSSStyleDeclaration();
        myMXDynStyle.setStyle('color', 'blue');
        myMXDynStyle.setStyle('fontFamily', 'georgia');
        myMXDynStyle.setStyle('fontSize', 24);
        mySparkDynStyle.setStyle('color', 'blue');
        mySparkDynStyle.setStyle('fontFamily', 'georgia');
        mySparkDynStyle.setStyle('fontSize', 24);
        styleManager.setStyleDeclaration("mx.controls.Button", myMXDynStyle, true);
        styleManager.setStyleDeclaration("spark.components.Button", mySparkDynStyle, true);
    }
  ]]></fx:Script>
  <s:Button id="mySparkButton" label="Spark Button"/>
  <mx:Button id="myHaloButton" label="MX Button"/>
</s:Application>
```

When you set a new CSSStyleDeclaration on a type selector, you are replacing the entire existing type selector with your own selector. All style properties that you do not explicitly define in the new CSSStyleDeclaration are set to `null`. This can remove skins, borders, padding, and other properties that are defined in the default style sheet (defaults.css in the frameworks.swc file), default theme (defaults.css in the spark.swc file) or other style sheet that you may have applied already.

Using the setStyle() and getStyle() methods

You cannot get or set style properties directly on a component as you can with other properties. Instead, you set style properties at run time by using the getStyle() and setStyle() ActionScript methods. When you use the `getStyle()` and `setStyle()` methods, you can access the style properties of instances of objects or of style sheets.

Every component exposes these methods. When you are instantiating an object and setting the styles for the first time, you should try to apply style sheets rather than use the `setStyle()` method because it is computationally expensive. This method should be used only when you are changing an object’s styles during run time. For more information, see “Improving performance with the setStyle() method” on page 1545.

Setting styles

You use the `getStyle()` method in the following way:

```
var:return_type componentInstance.getStyle(property_name)
```

The *return_type* depends on the style that you access. Styles can be of type String, Number, Boolean, or, in the case of skins, Class. The *property_name* is a String that indicates the name of the style property—for example, `fontSize`.

The `setStyle()` method is used like this:

```
componentInstance.setStyle(property_name, property_value)
```

The *property_value* sets the new value of the specified property. To determine valid values for properties, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

The following example uses the `getStyle()` and `setStyle()` methods to change the Button's `fontSize` style and display the new size in the TextInput:

```
<?xml version="1.0"?>
<!-- styles/SetSizeGetSize.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp();">

  <fx:Script><![CDATA[
    import mx.controls.Alert;

    [Bindable]
    private var curSize:int = 10;

    private function initApp():void {
        ip1.setStyle("fontSize", curSize);
        b1.setStyle("fontSize", curSize);
        b2.setStyle("fontSize", curSize);
    }

    public function showStyles():void {
        Alert.show("Font size is " + ip1.getStyle("fontSize") + ".");
     }

     public function setNewStyles():void {
        curSize = Number(ip2.text);

        ip1.setStyle("fontSize", curSize);
        b1.setStyle("fontSize", curSize);
        b2.setStyle("fontSize", curSize);
```

```
      }
   ]]></fx:Script>
   <s:VGroup id="vb">
      <s:TextInput id="ip1"
         styleName="myClass"
         text="This is a TextInput control."
         width="400"
      />
      <s:Label id="lb1" text="Current size: {curSize}" width="400"/>
      <s:Button id="b1" label="Get Style" click="showStyles();"/>
      <s:Form>
         <s:FormItem label="Enter new size:">
             <s:HGroup>
                 <s:TextInput text="{curSize}" id="ip2" width="50"/>
                 <s:Button id="b2" label="Set Style" click="setNewStyles();"/>
             </s:HGroup>
         </s:FormItem>
      </s:Form>
   </s:VGroup>
</s:Application>
```

You can use the `getStyle()` method to access style properties regardless of how they were set. If you defined a style property as a tag property inline rather than in an `<fx:Style>` tag, you can get and set this style. You can override style properties that were applied in any way, such as in an `<fx:Style>` tag or in an external style sheet.

The following example sets a style property inline, and then reads that property with the `getStyle()` method:

```
<?xml version="1.0"?>
<!-- styles/GetStyleInline.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script><![CDATA[
        private function readStyle():void {
            myLabel.text = "Label style is: " + myLabel.getStyle("fontStyle");
        }
    ]]></fx:Script>

    <s:VGroup width="500" height="200">
        <s:Button id="b1" click="readStyle()" label="Get Style"/>
        <s:Label id="myLabel" fontStyle="italic"/>
    </s:VGroup>
</s:Application>
```

When setting color style properties with the `setStyle()` method, you can use the hexadecimal format or the VGA color name, as the following example shows:

```
<?xml version="1.0"?>
<!-- styles/ColorFormatStyleManager.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp()">
  <fx:Script><![CDATA[
     public function initApp():void {
        styleManager.getStyleDeclaration("spark.components.Button").setStyle("color","Blue");
     }
     public function changeStyles(e:Event):void {
        // Check against "255" here, because that is the numeric value of "Blue".
        if (e.currentTarget.getStyle("color") == 255) {
            e.currentTarget.setStyle("color", "Red");
        } else {
            e.currentTarget.setStyle("color", "Blue");
        }
     }
  ]]></fx:Script>
  <s:Button id="myButton" label="Click Here"
        click="changeStyles(event)"/>
</s:Application>
```

When you get a `color` style property with the `getStyle()` method, Flex returns an integer that represents the hexadecimal value of the style property. To convert this to its hexadecimal format, you use the color variable's `toString()` method and pass it the value 16 for the radix (or base):

```
<?xml version="1.0"?>
<!-- styles/ColorFormatNumericValue.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="initApp()">
  <fx:Style>
     @namespace s "library://ns.adobe.com/flex/spark";
     s|Button {
        color: #66CCFF;
     }
  </fx:Style>
  <fx:Script><![CDATA[
     [Bindable]
     private var n:Number;
     private function initApp():void {
        n = myButton.getStyle("color");
     }
     public function changeStyles(e:Event):void {
        if (myButton.getStyle("color").toString(16) == "ff0000") {
           myButton.setStyle("color", 0x66CCFF);
        } else {
           myButton.setStyle("color", "Red");
        }

        n = myButton.getStyle("color"); // Returns 16711680
     }
  ]]></fx:Script>
    <s:VGroup>
        <s:Button id="myButton" label="Click Me" click="changeStyles(event)"/>
        <s:Label id="myLabel" text="0x{n.toString(16).toUpperCase()}"/>
    </s:VGroup>

</s:Application>
```

When you use the `setStyle()` method to change an existing style (for example, to set the `color` property of a Button control to something other than 0x000000, the default), Flex does not overwrite the original style setting. You can return to the original setting by setting the style property to `null`. The following example toggles the color of the Button control between blue and the default by using this technique:

```
<?xml version="1.0"?>
<!-- styles/ResetStyles.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
     <s:layout>
        <s:VerticalLayout/>
     </s:layout>
    <fx:Script>
        <![CDATA[
        public function toggleStyle():void {
            if (cb1.selected == true) {
                b1.setStyle("color","blue");
                b1.setStyle("fontSize", 8);
            } else {
                b1.setStyle("color", null);
                b1.setStyle("fontSize", null);
            }
        }
        ]]>
    </fx:Script>

    <fx:Style>
        @namespace s "library://ns.adobe.com/flex/spark";
        s|Button {
            color: red;
            fontSize: 25;
        }
    </fx:Style>
    <s:Button id="b1" label="Click Me"/>
    <s:CheckBox id="cb1" label="Set Style/Unset Style"
        click="toggleStyle()" selected="false" color="Black"/>
</s:Application>
```

Improving performance with the setStyle() method

Run-time cascading styles are very powerful, but you should use them sparingly and in the correct context. Dynamically setting styles on an instance of an object means accessing the UIComponent’s `setStyle()` method. The `setStyle()` method is one of the most resource-intensive calls in the Flex framework because the call requires notifying all the children of the newly styled object to do another style lookup. The resulting tree of children that must be notified can be quite large.

A common mistake that impacts performance is overusing or unnecessarily using the `setStyle()` method. In general, you need the `setStyle()` method only when you want to change styles on existing objects. Do not use it when setting up styles for an object for the first time. Instead, set styles in an `<fx:Style>` block, through an external CSS style sheet, or as global styles. It is important to initialize your objects with the correct style information if you do not expect these styles to change while your program executes (whether it is your application, a new view in a navigator container, or a dynamically created component).

Some applications must call the `setStyle()` method during the application or object instantiation. If this is the case, call the `setStyle()` method early in the instantiation phase. Early in the instantiation phase means setting styles from the component or application's `preinitialize` event, instead of the `creationComplete` or other event. By setting the styles as early as possible during initialization, you avoid unnecessary style notification and lookup.

For more information about the component startup life cycle, see “Improving startup performance” on page 2333.

Using inline styles

You can set style properties as properties of the component in the MXML tag. Inline style definitions take precedence over any other style definitions. The following example defines a type selector for Button components, but then overrides the `color` with an inline definition:

```
<?xml version="1.0"?>
<!-- styles/InlineOverride.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
     <s:layout>
        <s:VerticalLayout/>
     </s:layout>

  <fx:Style>
     @namespace s "library://ns.adobe.com/flex/spark";
     s|Button {
        fontSize: 10pt;
        fontStyle: italic;
        color: #FF0000;
     }
  </fx:Style>

  <s:Button label="Button Type Selector Color"/>
  <s:Button color="0x999942" label="Inline Color"/>
</s:Application>
```

When setting style properties inline, you must adhere to the ActionScript style property naming syntax rather than the CSS naming syntax. For example, you can set a Button control's `fontSize` property as `font-size` or `fontSize` in an `<fx:Style>` declaration, but you must set it as `fontSize` in a tag definition:

```
<?xml version="1.0"?>
<!-- styles/CamelCase.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
     <s:layout>
        <s:VerticalLayout/>
     </s:layout>

    <fx:Style>
        .myFontStyle {
            fontSize: 15; /* Note the camelCase. */
        }
        .myOtherFontStyle {
            font-size: 15; /* Note the hyphen. */
        }
    </fx:Style>
    <s:Button id="myButton" styleName="myFontStyle" label="Click Me"/>
    <s:Button id="myButton2" styleName="myOtherFontStyle" label="Click Me"/>
</s:Application>
```

When setting color style properties inline, you can use the hexadecimal format or the VGA color name, as the following example shows:

```
<?xml version="1.0"?>
<!-- styles/ColorFormatInline.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
     <s:layout>
        <s:VerticalLayout/>
     </s:layout>
    <s:Button id="myButton" color="Blue" label="Click Here"/>
    <s:Button id="myButton2" color="0x6666CC" label="Click Here"/>
</s:Application>
```

You can remove an inline style definition by using the `clearStyle()` method.

You can bind inline style properties to variables, as long as you tag the variable as `[Bindable]`. The following example binds the value of the `backgroundColor` property of the HBox controls to the value of the `colorValue` variable:

```
<?xml version="1.0"?>
<!-- styles/PropertyBinding.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
     <s:layout>
        <s:VerticalLayout/>
     </s:layout>

      <fx:Script><![CDATA[
         [Bindable]
         public var colorValue:int = 0x333999;
         public function changeHBoxStyle():void {
            colorValue = cp.selectedColor;
         }
      ]]></fx:Script>
      <mx:HBox width="100" height="100" backgroundColor="{colorValue}"/>
      <mx:ColorPicker id="cp" showTextField="true" change="changeHBoxStyle()"
selectedColor="0x333999"/>
</s:Application>
```

Binding a style property can be a computationally expensive operation. You should use this method of applying style properties only when absolutely necessary. You can also use the `getStyle()` method in a data binding expression.

Loading style sheets at run time

You can load style sheets at run time by using the StyleManager. You can access the top-level StyleManager by using the `styleManager` property of the Application object. These style sheets take the form of SWF files that are dynamically loaded while your application runs.

By loading style sheets at run time, you can load images (for graphical skins), fonts, type and class selectors, and programmatic skins into your application without embedding them at compile time. This lets skins and fonts be partitioned into separate SWF files, away from the main application. As a result, the application's SWF file size is smaller, which reduces the initial download time.

However, the first time a run-time style sheet is used, it takes longer for the styles and skins to be applied than if you load styles by using the `<fx:Style>` tag or set the styles inline. This is because Flex must download the necessary CSS-based SWF file while the application is starting up or running.

Loading style sheets at run time is a three-step process:

1 Write a CSS file for your application.

2 Compile the CSS file into a SWF file.

3 Call the `styleManager.loadStyleDeclarations()` method in your application. This method loads the CSS-based SWF file into your application. When this method executes, Flex loads the new CSSStyleDeclarations into the top-level StyleManager.

You can load multiple style sheets that define the same styles in the same application. After you set a style, subsequent style sheets can overwrite previous ones if they have common selectors. Styles loaded with run-time style sheets do not completely replace compile-time styles, however. They just override them until the run-time style sheets are unloaded. At that point, Flex reverts to the compile-time style settings. Compile-time style settings include any default styles sheets that were loaded at compile time, theme files loaded by using the `theme` compiler option, and styles set by using the `<fx:Style>` block inside an MXML file.

You cannot load an uncompiled CSS file into your application at run time. You must compile it into a SWF file before loading it.

Creating a run-time style sheet

To load style sheets at run time, you must first create a style sheet that is compiled into a SWF file. A run-time style sheet is like any other style sheet. It can be a simple style sheet that sets basic style properties, as the following example shows:

```
/* ../assets/BasicStyles.css */
@namespace s "library://ns.adobe.com/flex/spark";
s|Button {
    fontSize:    24;
    color: #FF9933;
}
s|Label {
    fontSize:    24;
    color: #FF9933;
}
```

Or the style sheet can be a complex style sheet that embeds programmatic and graphical skins, fonts, and other style properties, and uses type and class selectors, as the following example shows:

```
/* assets/ComplexStyles.css */
@namespace mx "library://ns.adobe.com/flex/mx";
mx|Application {
    backgroundImage: "greenBackground.gif";
    theme-color: #9DBAEB;
}
mx|Button {
    fontFamily: Tahoma;
    color: #000000;
    fontSize: 11;
    fontWeight: normal;
    text-roll-over-color: #000000;
    upSkin: Embed(source="orb_up_skin.gif");
    overSkin: Embed(source="orb_over_skin.gif");
    downSkin: Embed(source="orb_down_skin.gif");
}
.noMargins {
    margin-right: 0;
    margin-left: 0;
    margin-top: 0;
    margin-bottom: 0;
    horizontal-gap: 0;
    vertical-gap: 0;
}
```

To create a new style sheet in Flash Builder, you select File > New > CSS File. Create the CSS file in the project's main directory or another subdirectory that is not the bin directory. You should not create the CSS file in the bin directory. Flash Builder will compile the SWF file to the bin directory for you.

Compiling the CSS-based SWF file

Before you can load a style sheet at run time, you must compile the style sheet into a SWF file. The style sheet that you compile into a SWF file must use a .css filename extension.

To compile the CSS file into a SWF file, you use the mxmlc command-line compiler or Flash Builder's compiler. The default result of the compilation is a SWF file with the same name as the CSS file, but with the .swf extension.

The following example produces the BasicStyles.swf file by using the mxmlc command-line compiler:

```
mxmlc BasicStyles.css
```

To compile the SWF file with Flash Builder, right-click the CSS file and select Compile CSS to SWF. Flash Builder saves the SWF file in the project's bin directory. If the original CSS file is in the bin directory, you cannot compile it into a SWF file. You must move it to a different directory before you can compile it.

When you compile your application, the compiler does not perform any compile-time link checking against the CSS-based SWF files used by the application. This means that you are not required to create the SWF file before you compile your main application. This also means that if you mistype the name or location of the SWF file, or if the SWF file does not exist, the application will fail silently. The application will not throw an error at run time.

Loading the style sheets

You load a CSS-based SWF file at run time by using the StyleManager's `loadStyleDeclarations()` method. You can access the top-level StyleManager by using the `styleManager` property of the Application object.

The following example shows loading a style sheet SWF file:

```
styleManager.loadStyleDeclarations("../assets/MyStyles.swf");
```

The first parameter of the `loadStyleDeclarations()` method is the location of the style sheet SWF file to load. The location can be local or remote.

The second parameter is `update`. You set this to `true` or `false`, depending on whether you want the style sheets to immediately update in the application. For more information, see "Updating CSS-based SWF files" on page 1551.

The next parameter, `trustContent`, is optional and obsolete. If you do specify a value, set this to `false`.

The final two parameters are `applicationDomain` and `securityDomain`. These parameters specify the domains into which the style sheet SWF file is loaded. In most cases, you should accept the default values (`null`) for these parameters. The result is that the style sheet's SWF file is loaded into child domains of the current domains. For information on when you might use something other than the default for these parameters, see "Using run-time style sheets with modules and sub-applications" on page 1554.

The following example loads a style sheet when you click the button:

```
<?xml version="1.0"?>
<!-- styles/BasicApp.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
        public function applyRuntimeStyleSheet():void {
            styleManager.loadStyleDeclarations("assets/BasicStyles.swf")
        }
        ]]>
    </fx:Script>
    <s:VGroup>
        <s:Label text="Click the button to load a new CSS-based SWF file."/>
        <s:Button id="b1" label="Click Me" click="applyRuntimeStyleSheet()"/>
    </s:VGroup>

</s:Application>
```

Loading a remote style sheet typically requires a crossdomain.xml file that gives the loading application permission to load the SWF file. You can do without a crossdomain.xml file if your application is in the local-trusted sandbox, but this is usually restricted to SWF files that have been installed as applications on the local machine.

For more information about crossdomain.xml files, see "Using cross-domain policy files" on page 125.

Also, to use remote style sheets, you must compile the loading application with network access (have the `use-network` compiler property set to `true`, the default). If you compile and run the application on a local file system, you might not be able to load a remotely accessible SWF file.

The `loadStyleDeclarations()` method is asynchronous. It returns an instance of the IEventDispatcher class. You can use this object to trigger events based on the success of the style sheet's loading. You have access to the `StyleEvent.PROGRESS`, `StyleEvent.COMPLETE`, and `StyleEvent.ERROR` events of the loading process.

The following application calls a method when the style sheet finishes loading:

```
<?xml version="1.0"?>
<!-- styles/StylesEventApp.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="init()">

    <fx:Script>
        <![CDATA[
        import mx.events.StyleEvent;

        public function init():void {
            var myEvent:IEventDispatcher =
styleManager.loadStyleDeclarations("../assets/ACBStyles.swf");
            myEvent.addEventListener(StyleEvent.COMPLETE, getImage);
        }
        private function getImage(event:StyleEvent):void {
            map1.source = acb.getStyle("dottedMap");
        }
        ]]>
    </fx:Script>

    <mx:ApplicationControlBar id="acb" width="100%">
        <s:Image id="map1"/>
    </mx:ApplicationControlBar>

</s:Application>
```

The style sheet used in this example embeds a PNG file:

```
/* assets/ACBStyles.css */
@namespace mx "library://ns.adobe.com/flex/mx";
mx|ApplicationControlBar {
    borderStyle:      "solid";
    cornerRadius:     10;
    backgroundColor: #FF9933;
    alpha:            1;
    dottedMap:        "beige_dotted_map.png";
}
```

Updating CSS-based SWF files

You can force an immediate update of all styles in the application when you load a new CSS-based SWF file. You can also delay the update if you want.

The second parameter of the `loadStyleDeclarations()` method is `update`. Set the `update` parameter to `true` to force an immediate update of the styles. Set it to `false` to avoid an immediate update of the styles in the application. The styles are updated the next time you call this method or the `unloadStyleDeclarations()` method with the `update` property set to `true`.

Each time you call the `loadStyleDeclarations()` method with the `update` parameter set to `true`, Adobe® Flash Player and Adobe AIR™ reapply all styles to the display list, which can degrade performance. If you load multiple CSS-based SWF files at the same time, you should set the `update` parameter to `false` for all but the last call to this method. As a result, Flash Player and AIR apply the styles only once for all new style SWF files rather than once for each new style SWF.

The following example loads three style SWF files, but does not apply them until the third one is loaded:

```
<?xml version="1.0"?>
<!-- styles/DelayUpdates.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="init()">
     <s:layout>
        <s:VerticalLayout/>
     </s:layout>

    <fx:Script>
        <![CDATA[
        import mx.events.StyleEvent;

        public function init():void {
            styleManager.loadStyleDeclarations("assets/ButtonStyles.swf", false);
            var myEvent:IEventDispatcher =
              styleManager.loadStyleDeclarations("assets/LabelStyles.swf", false);
            myEvent.addEventListener(StyleEvent.COMPLETE, doUpdate);
        }
        public function doUpdate(event:StyleEvent):void {
            styleManager.loadStyleDeclarations("assets/ACBStyles.swf", true);
        }
        ]]>
    </fx:Script>

    <s:Label text="This is a Label control."/>
    <mx:ApplicationControlBar id="acb" width="100%">
        <s:Button label="Submit"/>
    </mx:ApplicationControlBar>

</s:Application>
```

Unloading style sheets at run time

You can unload a style sheet that you loaded at run time. You do this by using the StyleManager’s `unloadStyleDeclarations()` method. You can access the top-level StyleManager by using the `styleManager` property of the Application object. The result of this method is that all style properties set by the specified style SWF files are returned to their defaults.

The following example loads and unloads a style SWF when you toggle the check box:

```
<?xml version="1.0"?>
<!-- styles/UnloadStyleSheets.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

  <s:layout>
     <s:VerticalLayout/>
  </s:layout>
    <fx:Script>
        <![CDATA[
        public function toggleStyleSheet():void {
            if (cb1.selected == true) {
                styleManager.loadStyleDeclarations("assets/ButtonStyles.swf", true);
                styleManager.loadStyleDeclarations("assets/LabelStyles.swf", true);
            } else {
                styleManager.unloadStyleDeclarations("assets/ButtonStyles.swf", true);
                styleManager.unloadStyleDeclarations("assets/LabelStyles.swf", true);
            }
        }
        ]]>
    </fx:Script>
    <s:Button id="b1" label="Submit"/>

    <s:Label id="l1" text="This is a Label control."/>

    <s:CheckBox id="cb1" label="Load style sheet"
        click="toggleStyleSheet()" selected="false"/>
</s:Application>
```

The `unloadStyleDeclarations()` method takes a second parameter, `update`. As with loading style sheets, Flash Player and AIR do not reapply the styles (in this case, reapply default styles when the loaded styles are unloaded) if you set the value of the `update` parameter to `false`. For more information about the `update` parameter, see "Loading the style sheets" on page 1549.

Using run-time style sheets in custom components

You can use run-time style sheets in custom components. To do this, you generally call the `loadStyleDeclaration()` method after the component is initialized. If the style sheet contains class selectors, you then apply them by setting the `styleName` property.

The following example defines style properties and skins in a class selector named `specialStyle`:

```
/* ../assets/CustomComponentStyles.css */
.specialStyle {
    fontSize:    24;
    color: #FF9933;
    upSkin: Embed(source="SubmitButtonSkins.swf", symbol="MyUpSkin");
    overSkin: Embed(source="SubmitButtonSkins.swf", symbol="MyOverSkin");
    downSkin: Embed(source="SubmitButtonSkins.swf", symbol="MyDownSkin");
}
```

The following example custom component loads this style sheet and applies the `specialStyle` class selector to itself during initialization:

```
// styles/MyButton.as -->
package {
    import mx.controls.Button;
    import mx.events.*;

    public class MyButton extends Button {

        public function MyButton() {
            addEventListener(FlexEvent.INITIALIZE, initializeHandler);
        }
         // Gets called when the component has been initialized
        private function initializeHandler(event:FlexEvent):void {
            styleManager.loadStyleDeclarations("assets/CustomComponentStyles.swf");
            this.styleName = "specialStyle";
        }
    }
}
```

The following sample application uses this custom button:

```
<?xml version="1.0"?>
<!-- styles/MyButtonApp.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:custom="*">

    <custom:MyButton/>

</s:Application>
```

Using theme SWC files as run-time style sheets

If you have an existing theme SWC file, you can use it as a run-time style sheet. To do this, you must extract the CSS file from the theme SWC file. You then compile the style SWF file by passing the remaining SWC file as a library.

The following steps show this process using the command line:

1 Extract the CSS file from the SWC file using PKZip or similar archiving utility, as the following example shows:

```
$ unzip halo.swc defaults.css
```

2 (Optional) Rename the CSS file to a meaningful name. This is the name of your style SWF file. The following example renames the defaults.css file to halo.css:

```
$ mv defaults.css halo.css
```

3 Compile the style SWF file. Add the theme SWC file to the style SWF file by using the `include-libraries` option, as the following example shows:

```
$ mxmlc -include-libraries=halo.swc halo.css
```

If you have multiple CSS files inside a theme SWC file, you must extract all of them before compiling the style SWF file.

Using run-time style sheets with modules and sub-applications

When loading run-time style sheets with modules and sub-applications, consider the following factors:

- The application domain into which you load the style SWF file

- The StyleManager that loads the style SWF file

Selecting the application domain that you load the style SWF file into determines where the classes are loaded. You typically load a style SWF file into the module's *current application domain*. You do not typically load it into a child application domain of the current module or application.

The StyleManager that loads the style SWF file is equally important. Because each module and application has its own StyleManager, you can load a style SWF file with the root application's StyleManager or any module's StyleManager. Which StyleManager you choose determines which applications or modules in the chain use those styles.

To load the style sheet into the current application domain of the module, set the *`applicationDomain`* parameter to `ApplicationDomain.currentDomain` in the `loadStyleDeclarations()` method. The following example loads the Style.swf file in the module into the current application domain:

```
styleManager.loadStyleDeclaration("Style.swf",true,false, ApplicationDomain.currentDomain)
```

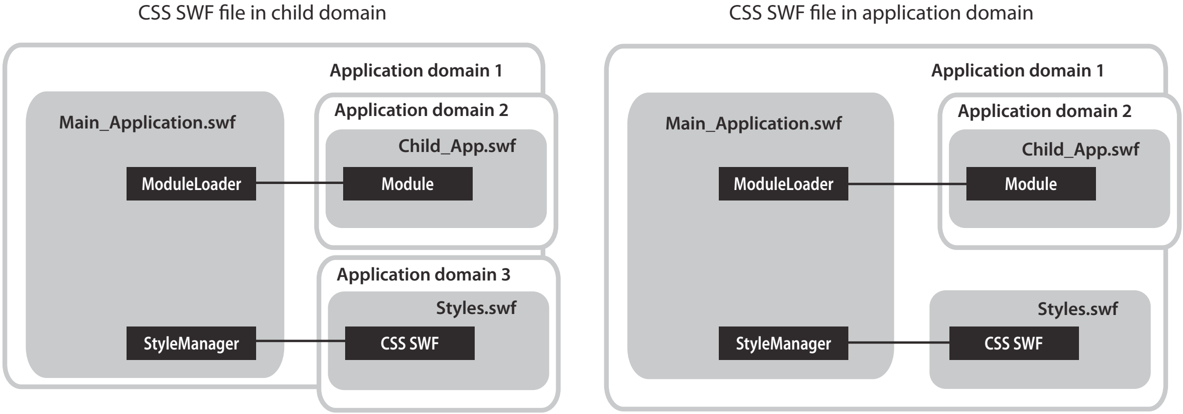
If you leave the *`applicationDomain`* parameter blank, then the default is to load the SWF file into a child domain of the main application. The result is a style SWF that is in a sibling application domain of modules and sub-applications.

Each module and the main application have their own instances of type IStyleManager2. If you want a style SWF file to be used by all modules, load it with the main application's StyleManager. If you want a style SWF file to be used by a module and its children, load the style SWF file with the module's StyleManager.

If you load the style SWF file into the main application's StyleManager, then all child modules and sub-applications will merge their styles with it when they are loaded. If you load the style SWF file into a module or sub-application's StyleManager, then only the children of that module or sub-application will merge their styles with it.

To load a style SWF file with the current module or application's StyleManager, use the `styleManager` property. In general, you should not load a style SWF file into a StyleManager of another module or application from one module or application.

Even when loading a style SWF file into the main application, you should specify the current application domain rather than a child application domain to avoid class conflicts. The following example illustrates loading the run-time style sheet into a child application domain and the current application domain of the main application:



In the first approach, the module and the run-time style sheet are loaded into separate child application domains (application domains 2 and 3). Because the style SWF file and the module are in sibling application domains, the classes referenced in the style module (such as skins) might cause class conflicts with the classes in the module.

The second approach loads the module into a child application domain and the style SWF file into the same domain as the main application. In this case, no class conflicts should occur.

The disadvantage of loading a style SWF file into the current application domain is that you cannot unload it, even when the module is unloaded.

"Using styles with modules" on page 143

Using filters

You can use filters to apply style-like effects to MX and Spark components. You can apply filters to any visual component that is derived from UIComponent. Filters are not styles; you cannot apply them with a style sheet or the `setStyle()` method. The result of a filter, such as a drop shadow, is often thought of as a style.

Filters are in the spark.filters.* package, and include the DropShadowFilter, GlowFilter, and BlurFilter classes. There are equivalent filter classes in the mx.filters.* package. These filters are mapped to the spark.filters.* package by the compiler.

To apply a filter to a component with MXML, you add the filter class to the component's `filters` Array. The `filters` Array contains any number of filters you want to apply to the component.

You wrap the filter class in an `<mx:filters>` or `<s:filters>` tag to define the array of filters applied to that control. If the control is an MX control, you use the `<mx:filters>` tag. If the control is a Spark control, you use the `<s:filters>` tag.

The following example applies a drop shadow to Label controls by using expanded MXML syntax and inline syntax:

```
<?xml version="1.0"?>
<!-- styles/ApplyFilterInline.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:VGroup>
        <!-- Apply filter using MXML syntax to set properties. -->
        <s:Label text="DropShadowFilter" fontSize="20">
            <s:filters>
                <s:DropShadowFilter distance="10" angle="45"/>
            </s:filters>
        </s:Label>
        <!-- Apply filter and set properties inline. -->
        <s:Label text="DropShadowFilter (inline)"
            fontSize="20"
            filters="{[new DropShadowFilter(10, 45)]}"/>
    </s:VGroup>
</s:Application>
```

You can apply filters in ActionScript. You do this by importing the spark.filters.* package, and then adding the new filter to the `filters` Array of the Flex control. The following example toggles a shadow filter on the Label control when the user clicks the button:

```
<?xml version="1.0"?>
<!-- styles/ApplyFilterAS.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <fx:Script><![CDATA[
        import spark.filters.*;
        private var dsf:DropShadowFilter;
        public function toggleFilter():void {
            trace(label1.filters.length);
            if (label1.filters.length == 0) {
                /*
                    The first four properties of the DropShadowFilter constructor are
                    distance, angle, color, and alpha.
                */
                dsf = new DropShadowFilter(5,30,0x000000,.8);
                label1.filters = [dsf];
            } else {
                label1.filters = null;
            }
        }
    ]]></fx:Script>

    <s:VGroup>
        <s:Label id="label1" text="ActionScript-applied filter."/>
        <s:Button id="b1" label="Toggle Filter" click="toggleFilter()"/>
    </s:VGroup>
</s:Application>
```

You cannot bind the filter properties to other values.

If you change a filter, you must reassign it to the component so that the changes take effect. The following example changes the color of the filters when you click the button:

```
<?xml version="1.0"?>
<!-- styles/FilterChange.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="createFilters()"
    height="700">

  <fx:Script><![CDATA[
     import spark.filters.*;
     import flash.filters.BitmapFilterQuality;
     import flash.filters.BitmapFilterType;

     private var myBlurFilter:BlurFilter;
     private var myGlowFilter:GlowFilter;
     private var myBevelFilter:BevelFilter;
     private var myDropShadowFilter:DropShadowFilter;

     private var color:Number = 0xFF33FF;
     public function createFilters():void {

        myBlurFilter = new BlurFilter(4, 4, 1);
        myGlowFilter = new GlowFilter(color, .8, 6, 6, 2, 1,
            false, false);
        myDropShadowFilter = new DropShadowFilter(15, 45,
            color, 0.8, 8, 8, 0.65, 1, false, false);
        myBevelFilter = new BevelFilter(5, 45, color, 0.8, 0x333333,
            0.8, 5, 5, 1, BitmapFilterQuality.HIGH, BitmapFilterType.INNER,
            false);

        applyFilters();
     }

     public function applyFilters():void {
        rte1.filters = [myGlowFilter];
        b1.filters = [myDropShadowFilter];
        dc1.filters = [myBevelFilter];
        hs1.filters = [myBlurFilter];
     }
     public function changeFilters():void {
        color = 0x336633;
        createFilters();
     }
  ]]></fx:Script>
    <s:VGroup>
        <mx:RichTextEditor id="rte1"/>
        <mx:DateChooser id="dc1"/>
        <mx:HSlider id="hs1"/>
        <mx:Button id="b1" label="Click me" click="changeFilters()"/>
    </s:VGroup>
</s:Application>
```

Clearing filters

You can remove filters by setting the filters Array to an empty Array, as the following example shows:

```
<s:filters>
    <fx:Array/>
</s:filters>
```

Using the dropShadowEnabled property

Some MX containers and controls have a `dropShadowEnabled` property. You can use this property instead of applying a filter if you are using the Halo theme. This property is more efficient than using a filter.

To use the `dropShadowEnabled` property, set it to `true` on the component. However, when you use this property, the component draws its own drop shadow by using the RectangularDropShadow class. It copies the edges of the target and then draws the shadow onto a bitmap, which is then attached the target. If the target component is rotated, the drop shadow might appear jagged because of the way rotated vectors are rendered.

To avoid this and have smooth drop shadow filters on rotated components, you use the DropShadowFilter class.

The following example shows the difference between drawing a filter with the `dropShadowEnabled` property and using the DropShadowFilter class. This example was compiled with the Halo theme:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- styles/SmoothFilter.mxml -->
<!-- Compile this example by setting theme=halo.swc for a compiler argument. -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    backgroundColor="0xFFFFFF">
    <fx:Style>
        @namespace mx "library://ns.adobe.com/flex/mx";
        mx|Canvas {
            borderStyle:solid;
            cornerRadius:10;
            borderColor:#000000;
            backgroundColor:#FFFFFF;
        }
    </fx:Style>
    <fx:Script>
        <![CDATA[
            import spark.filters.*;
            import flash.filters.BitmapFilterQuality;
            private function getBitmapFilter():DropShadowFilter {
                var distance:Number = 3;
                var angle:Number = 90;
                var color:Number = 0x000000;
                var alpha:Number = 1;
                var blurX:Number = 8;
                var blurY:Number = 8;
                var strength:Number = 0.65;
                var quality:Number = BitmapFilterQuality.LOW;
                var inner:Boolean = false;
                var knockout:Boolean = false;
                return new DropShadowFilter(distance, angle, color, alpha,
                    blurX, blurY, strength, quality, inner, knockout);
            }
        ]]>
    </fx:Script>
    <s:HGroup>
        <!-- This rotated canvas applies a filter using the dropShadowEnabled
            property. As a result, the filter's edges are slightly jagged. -->
        <mx:Canvas id="canvas1"
            dropShadowEnabled="true"
            creationComplete="canvas1.rotation=-10"
            x="50" y="80"
            width="200"
            height="200"/>
        <!-- This rotated canvas applies a bitmap filter. As a result,
            the edges are smoother. -->
        <mx:Canvas id="canvas2"
            filters="{[getBitmapFilter()]}"
            creationComplete="canvas2.rotation=-10"
            x="50" y="450"
            width="200"
            height="200"/>
    </s:HGroup>
</s:Application>
```

Using Animated filters

The spark.effects.AnimateFilter class is a more generic version of what effects such as the BlurFilter and GlowFilter classes do. It lets you apply any filter and optionally animate the filter during the context of a Spark component's effect or transition.

The AnimateFilter class extends the Animate class, and provides an additional input property `bitmapFilter`, of type IBitmapFilter. It lets you animate an arbitrary set of properties of the filter between values, as specified by the `propertyValuesList`.

The AnimateFilter class applies the associated filter when the effect begins, and removes it when the effect finishes.

The primary difference between the Animate class and the AnimateFilter class, is that the properties that the effect is animating apply not to the target of the effect, but to the associated filter instead. As a result, for example, the extents of a drop shadow can be animated during an effect sequence.

The following example defines a BlurFilter and the animation on that filter. It then plays the animation when the user moves the mouse pointer over the Button control, and stops the animation when the user moves the mouse away from the Button control.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- styles/AnimateFilterExample.mxml -->
<s:Application backgroundColor="0xFFFFFF"
     xmlns:fx="http://ns.adobe.com/mxml/2009"
     xmlns:mx="library://ns.adobe.com/flex/mx"
     xmlns:s="library://ns.adobe.com/flex/spark"
     creationComplete="initApp();">
     <fx:Script>
          <![CDATA[
               import spark.effects.*;
               import spark.filters.BlurFilter;
               import spark.effects.animation.*;

               private var blurFilter:BlurFilter;
               private var blurAnim:AnimateFilter;
               private var smpX:SimpleMotionPath;
               private var smpY:SimpleMotionPath;

               private function initApp():void {
                    blurFilter = new BlurFilter();
                    blurAnim = new AnimateFilter(btn1, blurFilter);
                    smpX = new SimpleMotionPath("blurX",0,20);
                    smpY = new SimpleMotionPath("blurY",0,20);
                    blurAnim.motionPaths = Vector.<MotionPath>([smpX,smpY]);
               }

               private function doBlurSample():void {
                    blurAnim.repeatCount = 0;
                    blurAnim.repeatBehavior = RepeatBehavior.REVERSE;
                    blurAnim.play();
               }

               private function stopAnimation():void {
                    blurAnim.stop();
               }
          ]]>
     </fx:Script>
      <s:Button id="btn1" label="Blur"
           mouseOver="doBlurSample();"
           mouseOut="stopAnimation();"/>
</s:Application>
```

About themes

A *theme* defines the look and feel of an application's visual components. A theme can define something as simple as the color scheme or common font for an application, or it can be a complete reskinning of all the components used by the application.

The default theme for Flex 4 components is Spark. All controls in an application built with Flex 4 use the Spark theme. Even MX controls have a Spark look and feel in a Flex 4 application.

The Spark theme is a combination of styles and skin classes that define the appearance of the components in the spark.components package. This theme is defined in the defaults.css style sheet in the spark.swc file. Spark components use the skin classes in the spark.skins.spark.* package. MX components use the skin classes in the mx.skins.spark.* package.

For Flex 3, the default theme was called Halo. The components that used the Halo theme are in the mx.controls.* package. They are typically referred to as MX components. In Flex 4, however, the MX components use the Spark theme to define their appearance by default. This is set in the defaults.css file in the framework.swc file.

To use the Halo theme in a Flex 4 application, you can use the `theme` compiler option to point to the Halo theme SWC file, or you can set the `compatibility-version` compiler option to 3.0.0. If you use the Halo theme, then the Halo theme is applied only to MX components in your application. The Spark components continue to use the Spark theme unless you specifically override them.

Themes usually take the form of a SWC file. However, themes can also be a CSS file and embedded graphical resources, such as symbols from a SWF file. Theme SWC files can also be compiled into style SWF files so that they can be loaded at run time. For more information, see "Using theme SWC files as run-time style sheets" on page 1554.

To apply a theme SWC file to your application, use the instructions in "Using themes" on page 1562. To create your own theme, use the instructions in "Creating a theme SWC file" on page 1565.

Flex also includes several other predefined themes that you can apply to your applications. For more information, see "About the included theme files" on page 1565.

Using themes

Themes generally take the form of a theme SWC file. These SWC files contain style sheets and skinning assets. You use the assets inside theme SWC files for programmatic skins or graphical assets, such as SWF, GIF, or JPEG files. Themes can also contain just stand-alone CSS files.

Packaging a theme as a SWC file rather than as a loose collection of files has the following benefits:

- SWC files are easier to distribute.
- SWC files cannot be modified and reapplied to the application without recompiling.
- SWC files are precompiled. This reduces application compile time, compared to compile time for skin classes that are not in a SWC file.

You apply a theme to your application by specifying the SWC or CSS file with the `theme` compiler option. The following example uses the mxmlc command-line compiler to compile an application that uses the BullyBuster theme SWC file:

```
mxmlc -theme theme/BullyBuster.swc MainApp.mxml
```

When compiling an application by using options in the flex-config.xml file, you specify the theme as follows:

```
<compiler>
    <theme>
        <filename>c:/theme/BullyBuster.swc</filename>
    </theme>
</compiler>
```

When you add a SWC file to the list of themes, the compiler adds the classes in the SWC file to the application's `library-path`, and applies any CSS files contained in the SWC file to your application. The converse is not true, however. If you add a SWC file to the `library-path`, but do not specify that SWC file with the `theme` option, the compiler does not apply CSS files in that SWC file to the application.

For more information, see "Flex compilers" on page 2164.

Themes are additive. You can specify more than one theme file to be applied to the application. If there are no overlapping styles, both themes are applied completely. The ordering of the theme files is important, though. If you specify the same style property in more than one theme file, Flex uses the property from the last theme in the list. In the following example, style properties in the Wooden.css file take precedence, but unique properties in the first two theme files are also applied:

```
<compiler>
    <theme>
        <filename>../themes/Institutional.css</filename>
        <filename>../themes/Ice.css</filename>
        <filename>../themes/Wooden.css</filename>
    </theme>
</compiler>
```

On the command line, you can use the `+=` operator with the `theme` compiler option to apply themes additively. The following example applies the BullyBuster.swc theme, in addition to the default theme:

```
mxmlc -theme+=themes/BullyBuster.swc MainApp.mxml
```

Creating color schemes

One common way to use themes is to create a color scheme for your application. This color scheme can be used to blend your application into its surrounding website, or define its overall look and feel.

In Spark applications, most styles are inheritable styles. This means that you can set any style on any level of the containment hierarchy. The inheritable styles will be inherited by all controls that are within the container that you set it on. One common use of this is to set styles on the Application tag so that the entire application uses those styles.

The following table describes the color styles that you use most often to create a color scheme in Spark applications:

Property	Description
`backgroundColor`	The background color of the application.
`chromeColor`	The base color of the component. The default skins are based on various shades of gray. The `chromeColor` style is applied as a color transformation (tinting), which preserves all of the visual fidelity of the default appearance. Items colorized by other color style values are not affected by `chromeColor`.
`color`	The color of text in a component.
`contentBackgroundColor`	The color of the content area of components that contain content.
`focusColor`	The color of the focus glow.
`rollOverColor`	The background color of items when the mouse is positioned over the item.
`selectionColor`	The background color of selected items in a drop down list.
`symbolColor`	The color of symbols or glyphs. For example, the arrows on a scroll bar or the check mark in a CheckBox control.

The following example lets you toggle between two color schemes. It shows that the colors are inherited by all Spark controls in that application.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- styles/SparkThemeColorExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
            import mx.core.FlexGlobals;
            import mx.events.IndexChangedEvent;

            private function changeStyleSettings(e:Event):void {
                if (e.currentTarget.selectedItem == "Gray") {
           FlexGlobals.topLevelApplication.setStyle("backgroundColor", 0x333333);
                    FlexGlobals.topLevelApplication.setStyle("chromeColor", 0x4C4C4C);
                    FlexGlobals.topLevelApplication.setStyle("color", 0xCCCCCC);
                FlexGlobals.topLevelApplication.setStyle("contentBackgroundColor", 0x555555);
                    FlexGlobals.topLevelApplication.setStyle("symbolColor", 0xFFFFFF);
                    FlexGlobals.topLevelApplication.setStyle("rollOverColor", 0x666666);
                    FlexGlobals.topLevelApplication.setStyle("selectionColor", 0x999999);
                    FlexGlobals.topLevelApplication.setStyle("focusColor", 0xEEEEEE);
                } else {
        FlexGlobals.topLevelApplication.setStyle("backgroundColor",0xCCCC99);
                    FlexGlobals.topLevelApplication.setStyle("chromeColor", 0x999966);
                    FlexGlobals.topLevelApplication.setStyle("color", 0x996600);
                FlexGlobals.topLevelApplication.setStyle("contentBackgroundColor", 0xFFFFCC);
                    FlexGlobals.topLevelApplication.setStyle("symbolColor", 0x663300);
                    FlexGlobals.topLevelApplication.setStyle("rollOverColor", 0xFFEE88);
                    FlexGlobals.topLevelApplication.setStyle("selectionColor", 0xFFCC66);
              FlexGlobals.topLevelApplication.setStyle("focusColor", 0xCC9900);
                }
            }
        ]]>
    </fx:Script>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:Button label="Button"/>
    <s:ToggleButton label="Toggle Button"/>
    <s:CheckBox label="CheckBox" selected="true"/>
    <s:RadioButton label="RadioButton" selected="true"/>
    <s:NumericStepper/>
    <s:TextInput/>
    <s:TextArea/>
    <s:DropDownList id="myDropDown" selectedIndex="0"
        change="changeStyleSettings(event);">
        <s:dataProvider>
            <s:ArrayList source="[Gray,Brown]"/>
        </s:dataProvider>
    </s:DropDownList>
</s:Application>
```

You can affect the general coloring of MX components without creating a new theme or changing many of the style properties in the Halo theme. You do this with the `themeColor` property. For more information, see “Creating a Halo theme” on page 1661.

A useful utility for developing color schemes is Kuler. This utility helps users create new color schemes and share them with other users. For more information, see the Kuler online application at http://kuler.adobe.com/.

About the included theme files

Flex includes several themes that you can use. Some are for version compatibility, some are for testing, and some are purely for visual appearance. Most themes are located in the *sdk_install_dir*/frameworks/themes directory for the SDK. For Flash Builder, the themes are located in the *flash_builder_install_dir*/sdks/*sdk_version*/frameworks/themes directory. Other themes are in the /*sdk_version*/samples/themes directory.

The following table describes these themes:

Theme	Description
Aeon Graphical	Contains the AeonGraphical.css file and the AeonGraphical.swf file. This is the graphical version of the Halo theme, which is only used by MX components. The source FLA file for the graphical assets is in the AeonGraphical Source directory. You change the graphical assets in this file by using the Flash IDE. You must ensure that you export the SWF file, which is used by the theme in Flex.
Halo	The Halo theme uses the halo.swc theme file and the classes in the mx.skins.halo package. For more information about the default theme assets, see "About the default style sheets" on page 1534.
Ice	Contains the Ice.css file.
Institutional	Contains the Institutional.css file.
Mobile	Contains the defaults.css file for mobile applications. For more information, see Mobile theme.
Sample themes	The themes in the samples/themes directory include arcade, cobalt, and graphite. These theme files should be considered sample quality. Before you use them in production applications, be sure to test them thoroughly.
Smoke	Contains the Smoke.css file and a background JPEG file.
Wireframe	An alternate theme for the Spark components. This theme gives a simple, wireframe appearance to an application. It might be appropriate to use it when developing a prototype or "proof of concept" application. This theme is also useful as a starting point to write custom skins, particularly if they are not styleable. This is because the skin classes in the Wireframe theme file are simpler than their Spark counterparts.
Wooden	Contains the Wooden.css file and a background JPEG file.

To apply a theme to an application, you use the `theme` compiler option, as the following example shows:

```
mxmlc -theme=c:\Flex\frameworks\themes\Halo\halo.swc MyApp.mxml
```

In addition to the basic themes, Flex also includes the MXFTEText.css theme file. This file is located in the frameworks directory. You use this theme if you want to use embedded fonts with MX controls in your Flex 4 applications. For more information, see "Embedding fonts with MX components" on page 1592.

Another theme file, MXCharts.css, is meant to be used with MX-only applications that contain charting components.

Creating a theme SWC file

To build a theme SWC file, you create a CSS file, and include that file plus the graphical and programmatic assets in the SWC file. To do this, you use the `include-file` option of the compc utility.

A good starting point for creating a new theme is to customize the default CSS files for the Spark and MX components. For Spark components, customize the defaults.css file in the spark.swc file. For MX components, customize the defaults.css file in the framework.swc file. The following sections describe these steps in detail.

Creating a theme style sheet

A theme typically consists of a style sheet and any assets that the style sheet uses. These assets can be graphic files or programmatic skin classes. For the Spark theme, the assets are skin classes that use a combination of MXML and FXG syntax to draw the skin. For the Halo theme, the assets are typically ActionScript class files that extend Halo skin classes.

To add MXML skins to a Spark theme file, you use a `ClassReference` statement to specify the class name (not the file name) for each component. You must also specify a namespace and the Spark skin class for that component. The following is a typical CSS file that defines a small Spark theme:

```
@namespace s "library://ns.adobe.com/flex/spark";
s|Button {
    skinClass: ClassReference("ButtonTransitionSkin");
}
s|CheckBox {
    skinClass: ClassReference("CheckBoxTransitionSkin");
}
```

To add programmatic skin classes to a Halo theme's CSS file, you specify a class for each of the component's states, as the following example shows:

```
@namespace mx "library://ns.adobe.com/flex/mx";
mx|Button {
    upSkin:ClassReference('myskins.ButtonSkin');
    downSkin:ClassReference('myskins.ButtonSkin');
    overSkin:ClassReference('myskins.ButtonSkin');
}
```

For information about creating custom Spark skins, see “Spark Skinning” on page 1602. For information about creating custom Halo skins, see “Creating programmatic skins for MX components” on page 1674.

To add graphic files to the theme's CSS file, which is a common task for the Halo theme, you use the `Embed` statement. The following example defines new graphical skins for the Button class:

```
@namespace mx "library://ns.adobe.com/flex/mx";
mx|Button {
    upSkin: Embed("upIcon.jpg");
    downSkin: Embed("downIcon.jpg");
    overSkin: Embed("overIcon.jpg");
}
```

The name you provide for the `Embed` keyword is the same name that you use for the skin asset when compiling the SWC file.

The CSS file can include any number of class selectors, as well as type selectors. Style definitions for your theme do not have to use skins. You can simply set style properties in the style sheet, as the following example shows:

```
@namespace mx "library://ns.adobe.com/flex/mx";
mx|ControlBar {
    color:red;
}
```

For more information about the default style sheets, see “About the default style sheets” on page 1534.

Compiling a theme SWC file

You compile a theme SWC file by using the `include-file` and `include-classes` options of the component compiler. This is the same compiler that creates component libraries and Runtime Shared Libraries (RSLs).

You invoke the component compiler either with the compc command line utility or when creating a Library Project in Adobe Flash Builder.

You use the `include-file` option to add the CSS file and graphics files to the theme SWC file. You use the `include-classes` option to add programmatic skin classes to the theme SWC file.

To simplify the commands for compiling theme SWC files, you can use configuration files. For more information, see "Using a configuration file to compile theme SWC files" on page 1568.

Using the include-file option to compile theme SWC files

The `include-file` option takes two arguments: a name and a path. The name is the name that you use to refer to that asset as in the CSS file. The path is the file system path to the asset. When using `include-file`, you are not required to add the resources to the source path. The following command line example includes the upIcon.jpg asset in the theme SWC file:

```
-include-file upIcon.jpg c:/myfiles/themes/assets/upIcon.jpg
```

You also specify the CSS file as a resource to include in the theme SWC file. You must include the .css extension when you provide the name of the CSS file; otherwise, Flex does not recognize it as a style sheet and does not apply it to your application.

You use the component compiler to compile theme assets, such as a style sheet and graphical skins, into a SWC file. The following example compiles a theme by using the compc command-line compiler:

```
compc -include-file mycss.css c:/myfiles/themes/mycss.css
    -include-file upIcon.jpg c:/myfiles/themes/assets/upIcon.jpg
    -include-file downIcon.jpg c:/myfiles/themes/assets/downIcon.jpg
    -include-file overIcon.jpg c:/myfiles/themes/assets/overIcon.jpg
    -o c:/myfiles/themes/MyTheme.swc
```

You cannot pass a list of assets to the `include-file` option. Each pair of arguments must be preceded by `-include-file`. Most themes use many skin files and style sheets, which can be burdensome to enter each time you compile. To simplify this, you can use the `load-config` option to specify a file that contains configuration options, such as multiple `include-file` options. For more information, see "Using a configuration file to compile theme SWC files" on page 1568.

Using the include-classes option to compile theme SWC files

The `include-classes` option takes a single argument: the name of the class to include in the SWC file. You pass the class name and not the class filename (for example, MyButtonSkin rather than MyButtonSkin.as). The class must be in your source path when you compile the SWC file.

The following command-line example compiles a theme SWC file that includes the CSS file and a single programmatic skin class, MyButtonSkin, which is in the themes directory:

```
compc -source-path c:/myfiles/flex/themes
    -include-file mycss.css c:/myfiles/flex/themes/mycss.css
    -include-classes MyButtonSkin -o c:/myfiles/flex/themes/MyTheme.swc
```

You can pass a list of classes to the `include-classes` option by space-delimiting each class, as the following example shows:

```
-include-classes MyButtonSkin MyControlBarSkin MyAccordionHeaderSkin
```

For more information about creating skin classes, see "Skinning MX components" on page 1655.

Using a configuration file to compile theme SWC files

Using a configuration file is generally more verbose than passing options on the command line, but it can make the component compiler options easier to read and maintain. For example, you could replace a command line with the following entries in a configuration file:

```
<?xml version="1.0"?>
<flex-config>
    <output>MyTheme.swc</output>
    <include-file>
        <name>mycss.css</name>
        <path>c:/myfiles/themes/mycss.css</path>
    </include-file>
    <include-file>
        <name>upIcon.jpg</name>
        <path>c:/myfiles/themes/assets/upIcon.jpg</path>
    </include-file>
    <include-file>
        <name>downIcon.jpg</name>
        <path>c:/myfiles/themes/assets/downIcon.jpg</path>
    </include-file>
    <include-file>
        <name>overIcon.jpg</name>
        <path>c:/myfiles/themes/assets/overIcon.jpg</path>
    </include-file>
    <include-classes>
        <class>MyButtonSkin</class>
        <class>MyAccordionHeaderSkin</class>
        <class>MyControlBarSkin</class>
    </include-classes>
</flex-config>
```

You can use the configuration file with compc by using the `load-config` option, as the following example shows:

```
compc -load-config myconfig.xml
```

You can also pass a configuration file to the Flash Builder component compiler. For more information on using the component compilers, see “Flex compilers” on page 2164.

Fonts

You can include fonts in your Adobe® Flex® applications. Although it is easier and more efficient to use the default device fonts, you can embed other fonts so that you can apply special effects to text-based controls, such as rotating and fading.

About fonts

When you compile an application in Flex, the application stores the names of the fonts that you used to create the text. Adobe® Flash® Player uses the font names to locate identical or similar fonts on the user’s system when the application runs. You can also embed fonts in the application so that the exact font is used, regardless of whether the client’s system has that font.

You define the font that appears in each of your components by using the `fontFamily` style property. You can set this property in an external style sheet, an `<fx:Style>` block, or inline. This property can take a list of fonts, as the following example shows:

```
.myClass {
    fontFamily: Arial, Helvetica;
    color: Red;
    fontSize: 22;
    fontWeight: bold;
}
```

If the client's system does not have the first font in the list, Flash Player attempts to find the second, and so on, until it finds a font that matches. If no fonts match, Flash Player makes a best guess to determine which font the client uses.

Fonts are inheritable style properties. So, if you set a font style on a container, all controls inside that container inherit that style, as the following example shows:

```
<?xml version="1.0"?>
<!-- fonts/InheritableExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    width="600">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <fx:Style>
    @namespace s "library://ns.adobe.com/flex/spark";

     s|VGroup {
        fontFamily: Helvetica;
        fontSize: 13pt;
     }

     s|HGroup {
        fontFamily: Times;
        fontSize: 13pt;
     }
  </fx:Style>
  <s:Panel title="Styles Inherited from VGroup Type Selector">
     <s:VGroup>
        <s:Button label="This Button uses Helvetica"/>
        <s:Label text="This Label control is in Helvetica."/>
        <s:RichText height="75" width="200">
```

```
            <s:text>
            The text in this RichText control uses the Helvetica font
            because it is inherited from the VGroup style.
            </s:text>
        </s:RichText>
    </s:VGroup>
  </s:Panel>
  <s:Panel title="Styles Inherited from HGroup Type Selector">
    <s:HGroup>
        <s:Button label="This Button uses Times"/>
        <s:Label text="This Label control is in Times."/>
        <s:RichText height="75" width="200">
            <s:text>
            The text in this RichText control uses the Times font
            because it is inherited from the HGroup style.
            </s:text>
        </s:RichText>
    </s:HGroup>
  </s:Panel>
</s:Application>
```

This example defines the HGroup and VGroup type selectors' `fontSize` and `fontFamily` properties. Flex applies these styles to all components in the container that support those properties; in these cases, the Button, Label, and RichText controls.

Controls that support FTE have limited font fallback. What this means is that when you try to use a special character that is not available in a font, Flash Player attempts to use a character from another font if possible.

Using device fonts

You can specify any font for the `fontFamily` property. However, not all systems have all font faces, which can result in an unexpected appearance of text in your application. The safest course when specifying font faces is to include a device font as a default at the end of the font list. *Device fonts* do not export font outline information and are not embedded in the SWF file. Instead, Flash Player uses whatever font on the client's local computer most closely resembles the device font.

Flash Player supports three device fonts. The following table describes these fonts:

Font name	Description
`_sans`	The `_sans` device font is a sans-serif typeface; for example, Helvetica or Arial.
`_serif`	The `_serif` device font is a serif typeface; for example, Times Roman.
`_typewriter`	The `_typewriter` device font is a monospace font; for example, Courier.

The following example specifies the device font `_sans` to use if Flash Player cannot find either of the other fonts on the client machine:

```
<?xml version="1.0"?>
<!-- fonts/DeviceFont.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <!-- Use a vertical layout -->
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

  <fx:Style>
      @namespace s "library://ns.adobe.com/flex/spark";
     .myClass {
        fontFamily: Arial, Helvetica, "_sans";
        color: Red;
        fontSize: 12;
        fontWeight: bold;
     }
  </fx:Style>
  <s:Panel title="myClass Class Selector with Device Font">
     <s:VGroup styleName="myClass">
        <s:Button label="Click Me"/>
        <s:Label text="This is a Label control."/>
        <s:RichText width="200">
            <s:text>
            The text in the RichText control uses the myClass class selector.
            </s:text>
        </s:RichText>
     </s:VGroup>
  </s:Panel>
</s:Application>
```

***Note:** You must surround device font names with quotation marks when defining them with style declarations.*

Using device fonts does not affect the size of the SWF file because the fonts reside on the client. However, using device fonts can affect performance of the application because it requires that Flash Player interact with the local operating system. Also, if you use only device fonts, your selection is limited to three fonts.

Embed fonts

Rather than rely on a client machine to have the fonts you specify, you can embed fonts in your application. This means that the font is always available to Flash Player when the application is running, and you do not have to consider the implications of a missing font.

Spark components by default use the new Text Layout Framework (TLF) engine and require CFF embedded fonts. Renaun Erickson demonstrates (video) how to embed fonts for both TLF and non-TLF based components.

Peter DeHaan’s FlexExamples blog includes several examples of embedding fonts in Flex 4.

Cameron Yule explains how how embedding fonts in Flex 4 uses Text Layout Framework (TLF).

Supported file types include TrueType fonts (*.ttf), OpenType fonts (*.otf), as well as TrueType Collections (*.ttc), Mac Data Fork Fonts (*.dfont), and Mac Resource Fork TrueType Suitcases (which do not have a file extension).

***Note:** Check your font licenses before embedding any font files in your applications. Fonts might have licensing restrictions that preclude them from being stored as vector information.*

Benefits of embedded fonts

Embedded fonts have the following benefits:

- Client environment does not need the font to be installed.
- Embedded fonts can be rotated and faded.
- Embedded fonts are anti-aliased, which means that their edges are smoothed for easier readability. This is especially apparent when the text size is large.
- Embedded fonts provide smoother playback when zooming.
- Text appears exactly as you expect when you use embedded fonts.
- When you embed a font, you can use the advanced anti-aliasing information that provides clear, high-quality text rendering in SWF files. Using advanced anti-aliasing greatly improves the readability of text, particularly when it is rendered at smaller font sizes. For more information about advanced anti-aliasing, see "Using advanced anti-aliasing with non-CFF based fonts" on page 1579.

Drawbacks of using embedded fonts

Using embedded fonts is not always the best solution, however. Embedded fonts have the following limitations and drawbacks:

- Embed only TrueType or OpenType fonts and related "collection" formats. To embed other font types such as Type 1 PostScript fonts, embed that font in a SWF file that you create in Flash or with the fontswf utility, and then embed that SWF file in your application. For information about using the fontswf utility, see "Using the fontswf utility" on page 1584.
- Embedded fonts increase the file size of your application, because the document must contain font outlines for the text. This can result in longer download times for your users.
- In some cases, the text that is rendered by embedded fonts is truncated when they are used in visual components. This can happen, for example, when you explicitly set the width of a control. In these cases, you might be required to change the padding properties of the component by using style properties or subclassing it. This only occurs with some fonts.
- If you use MX controls in a Flex 4 application, you might have to add additional code to make the MX control use the embedded font. For more information, see "Embedding fonts with MX components" on page 1592.

Embed fonts with CSS

You typically use Cascading Style Sheets (CSS) syntax for embedding fonts in applications. You use the `@font-face` "at-rule" declaration to specify the source of the embedded font and then define the name of the font by using the `fontFamily` property. You typically specify the `@font-face` declaration for each face of the font for the same family that you use (for example, plain, bold, and italic).

Embed fonts with ActionScript

You can also embed fonts in ActionScript by using the `[Embed]` metadata tag. As with the `@font-face` declaration, you must specify a separate `[Embed]` tag for each font face.

Finding fonts

If you attempt to embed a font that the Flex compiler cannot find, Flex throws an error and your application does not compile. As a result, be sure to include directories that contain your fonts in the source path, or use absolute paths to the font file.

Embedded font syntax

To embed TrueType or OpenType fonts, you use the following syntax in your style sheet or `<fx:Style>` tag:

```
@font-face {
    src: url("location");
    fontFamily: alias;
    [fontStyle: normal | italic | oblique] ;
    [fontWeight: normal | bold | heavy] ;
    [embedAsCFF:true | false] ;
    [advancedAntiAliasing: true | false];
}
```

The following table describes the properties for the `@font-face` rule:

Property	Description
`src`	Specifies the file path location of a font. In Flex 4 and later, you cannot embed a font by its local name only. If you specify a relative location, the location is relative to the file in which the `@font-face` rule appears.
`fontFamily`	Sets the alias for the font that you use to apply the font in style sheets. This property is required. If you embed a font with a family name that matches the family name of a system font, the Flex compiler gives you a warning. You can disable this warning by setting the `show-shadows-system-font-warnings` compiler option to `false`.
`fontStyle`	Set the style type face value for the font. This property is optional, unless you are embedding a face that requires it. The default value is `normal`. Valid values are `normal`, `italic`, and `oblique`.

Property	Description
`fontWeight`	Set the weight type face value for the font. This property is optional, unless you are embedding a face that requires it. The default value is `normal`. Valid values are `normal`, `bold`, and `heavy`.
`embedAsCFF`	Indicates whether to embed an FTE-enabled font for components. Flash Text Engine (FTE) is a library that provides text controls with a rich set of formatting options. For Flex 4 and later, the default value is `true`. If you set the `compatibility-version` compiler option to 3.0.0, then the default value is `false`. If you set the `embedAsCFF` property to `true`, then you can use the advanced formatting features of FTE such as bidirectional text, kerning, and ligatures. If you set the value of `embedAsCFF` to `false`, then the embedded font does not support FTE, and works only with the MX text components. For information on using FTE-based classes for text rendering in your MX text controls, see "Embedding fonts with MX components" on page 1592.
`advancedAntiAliasing`	Determines whether to include the advanced anti-aliasing information when embedding the font. This property is optional and only used for legacy fonts. This property is ignored if you embed a font with the `embedAsCFF` property set to `true`. You cannot use this option when embedding fonts from a SWF file because this option requires access to the original, raw font file to pre-calculate anti-aliasing information at compile time. For more information on using advanced anti-aliasing, see "Using advanced anti-aliasing with non-CFF based fonts" on page 1579.

Example of @font-face rule

The following example embeds the MyriadWebPro.ttf font file:

```
@font-face {
    src: url("../assets/MyriadWebPro.ttf");
    fontFamily: myFontFamily;
    embedAsCFF: true;
}
```

After you embed a font with an `@font-face` declaration, you can use the value of the `fontFamily` property, or *alias*, in a selector's property declarations. The following example uses `myFontFamily`, the value of the `fontFamily` property, as the font in the VGroup type selector:

```
<?xml version="1.0"?>
<!-- fonts/EmbeddedFontFace.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <fx:Style>
     @namespace s "library://ns.adobe.com/flex/spark";
     @font-face {
        src:url("../assets/MyriadWebPro.ttf");
        fontFamily: myFontFamily;
        embedAsCFF: true;
     }

     s|VGroup {
        fontFamily: myFontFamily;
        fontSize: 15;
     }
  </fx:Style>
  <s:Panel title="Embedded Font Applied With Type Selector">
     <s:VGroup>
        <!-- This MX button tries to use a system font. -->
        <mx:Button label="Click Me"/>
        <!-- This Spark button uses the font of the VGroup container. -->
        <s:Button label="Click Me"/>
        <s:Label text="This is a Label control."/>
        <s:RichText width="250">
            <s:text>
                The text in this RichText control uses the
                font set on the VGroup.
            </s:text>
        </s:RichText>
     </s:VGroup>
  </s:Panel>
  <!-- This button uses the default font because it is not in the VGroup. -->
  <s:Button label="Click Me"/>

</s:Application>
```

Considerations when using the MX Button control

When you run this example, you might notice that the label on the MX Button (in the “mx” namespace) disappears. This is because the default style of an MX Button control’s label uses a bold typeface. However, the embedded font’s typeface (Myriad Web Pro) does not contain a definition for the bold typeface.

The Spark Button (in the “s” namespace) control’s label renders with the embedded font because it does not require a bold faced font.

To ensure that the MX Button control’s label uses the proper typeface, you can:

- Apply the MXFTEText.css theme if you mix MX and Spark components and use embedded fonts. In this case, you should embed both the plain and bold faces of the embedded font in separate `@font-face` rules. For more information, see “Using FTE in MX controls” on page 1594. This theme sets `embedAsCFF` to `false`.
- Add `fontWeight:bold` to the `@font-face` rule. This will render the MX Button label’s text, but with a device font.

- Embed a bold typeface so that the label of an MX Button control is rendered with the correct font. For information on embedding bold typefaces, see “Using multiple typefaces” on page 1585.
- Change the MX Button control’s label typeface to be non-bold. You can do this by creating a custom skin for the MX Button control.

Apply embedded font inline

You can also apply the embedded font inline by specifying the alias as the value of the control’s `fontFamily` property, as the following example shows:

```
<?xml version="1.0"?>
<!-- fonts/EmbeddedFontFaceInline.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <fx:Style>
     @font-face {
        src:url("../assets/MyriadWebPro.ttf");
        fontFamily: myFontFamily;
        embedAsCFF: true;
     }
  </fx:Style>
  <s:Panel title="Embedded Font Applied Inline">
     <s:VGroup fontFamily="myFontFamily">
        <s:Button label="Click Me"/>
        <s:Label text="This is a Label."/>
        <s:RichText width="200" fontFamily="myFontFamily">
            <s:text>The text in the RichText control is Myriad Web Pro.</s:text>
        </s:RichText>
     </s:VGroup>
  </s:Panel>
</s:Application>
```

Locating embedded fonts

The `src` property in the `@font-face` declaration specifies the location of the font family. You use the `src` property to embed a TrueType or OpenType font by location by specifying a valid URI to the font. The URI can be relative (for example, ../fontfolder/akbar.ttf) or absolute (for example, c:/myfonts/akbar.ttf). The URI can also point to a SWF file that has embedded fonts within it, such as a SWF file created with the fontswf utility. For information about using the fontswf utility, see “Using the fontswf utility” on page 1584.

You must specify the `url` of the `src` property in the `@font-face` declaration. All other properties are optional.

Embedding fonts in ActionScript

You can embed TrueType or OTF font files by location by using the `[Embed]` metadata tag in ActionScript. To embed a font by location, you use the `source` property in the `[Embed]` metadata tag.

The `[Embed]` metadata tag takes the same properties that you set as the @font-face rule. You separate them with commas. For the list of properties, see “Embedded font syntax” on page 1573

The following examples embed fonts by location by using the `[Embed]` tag syntax:

```
<?xml version="1.0"?>
<!-- fonts/EmbeddedFontFaceActionScriptByLocation.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    width="700">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <fx:Style>
     .mystyle1 {
        fontFamily:myMyriadFont;
        fontSize: 32pt;
     }
     .mystyle2 {
        fontFamily:myBoldMyriadFont;
        fontSize: 32pt;
        fontWeight: bold;
     }
  </fx:Style>

  <fx:Script>
     /*
      * Embed a font by location.
      */
     [Embed(source='../assets/MyriadWebPro.ttf',
        fontName='myMyriadFont',
        mimeType='application/x-font',
        embedAsCFF='true'
     )]
     // You do not use this variable directly. It exists so that
     // the compiler will link in the font.
     private var font1:Class;

     /*
      * Embed a font with bold typeface by location.
      */
     [Embed(source='../assets/MyriadWebPro-Bold.ttf',
        fontWeight='bold',
        fontName='myBoldMyriadFont',
        mimeType='application/x-font',
        embedAsCFF='true'
     )]
     private var font2:Class;

  </fx:Script>
  <s:Panel title="Embedded Fonts Using ActionScript">
     <s:VGroup>
        <s:RichText
            width="100%"
            height="75"
            styleName="mystyle1"
            text="This text uses the MyriadWebPro font."
        />
        <s:RichText
            width="100%"
            height="75"
            styleName="mystyle2"
            text="This text uses the MyriadWebPro-Bold font."
        />
     </s:VGroup>
  </s:Panel>
</s:Application>
```

You use the value of the `fontName` property that you set in the `[Embed]` tag as the alias (`fontFamily`) in your style definition.

Note that specifying the `mimeType` is not necessary if your font uses a known file extension such as *.ttf.

To embed a font with a different typeface (such as bold or italic), you specify the `fontWeight` or `fontStyle` properties in the `[Embed]` statement and in the style definition. For more information on embedding different typefaces, see "Using multiple typefaces" on page 1585.

You can specify a subset of the font's character range by specifying the `unicodeRange` parameter in the `[Embed]` metadata tag or the `@font-face` declaration. Embedding a range of characters rather than using the default of all characters can reduce the size of the embedded font and, therefore, reduce the final output size of your SWF file. For more information, see "Setting character ranges" on page 1588.

Embedding fonts in container formats

When the `@font-face src` property points to a file that is a "container" of several fonts (such as a *.ttc or *.dfont file), you use the `fontFamily` property to select the precise font face you want out of the collection. The value of the `fontFamily` property should be the full font name of the exact font face that you want to target.

The following example embeds and uses two different fonts from the same TTC file:

```
<?xml version="1.0"?>
<!-- fonts/TTCTest.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Style>
        @namespace s "library://ns.adobe.com/flex/spark";
        @font-face {
            src:url("../assets/CAMBRIA.TTC");
            fontFamily: "Cambria Math";
            embedAsCFF: true;
        }
        @font-face {
            src:url("../assets/CAMBRIA.TTC");
            fontFamily: "Cambria";
            embedAsCFF: true;
        }
        .useCambriaMath {
            fontFamily: "Cambria Math";
            fontSize:24;
        }
        .useCambria {
            fontFamily: "Cambria";
            fontSize:24;
        }
    </fx:Style>
    <s:HGroup>
        <s:Button label="Default Font" fontSize="24"/>
        <s:Button label="Cambria Math" styleName="useCambriaMath"/>
        <s:Button label="Cambria" styleName="useCambria"/>
    </s:HGroup>
</s:Application>
```

You can also use this technique when using the `[Embed]` syntax.

Using advanced anti-aliasing with non-CFF based fonts

Flex 3 components in the Halo theme use non-CFF fonts. The text in these components is rendered with the flash.text.TextField API (instead of the new Flash Text Engine (FTE).

When you embed non-CFF fonts (with the `embedAsCFF` property set to `false`), you can use advanced anti-aliasing to provide those fonts with additional information about the font. Non-CFF embedded fonts that use the advanced anti-aliasing information are typically clearer and appear sharper at smaller font sizes. CFF fonts have this information by default.

By default, non-CFF fonts that you embed in applications use the advanced anti-aliasing information. This default is set by the `fonts.advanced-anti-aliasing` compiler option in the flex-config.xml file (the default value is `true`). You can override this default value by setting the value in your style sheets or changing it in the configuration file. To disable advanced anti-aliasing in style sheets, you set the `advancedAntiAliasing` style property to `false` in your `@font-face` rule, as the following example shows:

```
@font-face {
    src:url("../assets/MyriadWebPro.ttf");
    fontFamily: myFontFamily;
    advancedAntiAliasing: false;
    embedAsCFF: false;
}
```

Using advanced anti-aliasing can degrade the performance of your compiler. This is not a run-time concern, but can be noticeable if you compile your applications frequently or use the web-tier compiler. Using advanced anti-aliasing can also cause a slight delay when you load SWF files. You notice this delay especially if you are using several different character sets, so be aware of the number of fonts that you use. The presence of advanced anti-aliasing information may also cause an increase in the memory usage in Flash Player and Adobe® AIR™. Using four or five fonts, for example, can increase memory usage by approximately 4 MB.

When you embed non-CFF fonts that use advanced anti-aliasing in your applications, the fonts function exactly as other embedded fonts. They are anti-aliased, you can rotate them, and you can make them partially or wholly transparent.

Font definitions that use advanced anti-aliasing support several additional styles properties: `fontAntiAliasType`, `fontGridFitType`, `fontSharpness`, and `fontThickness`. These properties are all inheriting styles, but they are applied on the component being styled. They are not relevant to the actual font embedding process (and thus must not be specified in the `@font-face` rule).

Because the advanced anti-aliasing-related style properties are CSS styles, you can use them in the same way that you use standard style properties, such as `fontFamily` and `fontSize`. For example, a text-based component could use subpixel-fitted advanced anti-aliasing of New Century 14 at sharpness 50 and thickness -35, while all Button controls could use pixel-fitted advanced anti-aliasing of Tahoma 10 at sharpness 0 and thickness 0. These styles apply to all the text in a TextField control; you cannot apply them to some characters and not others.

The default values for the advanced anti-aliasing styles properties are defined in the defaults.css file. If you replace this file or use another style sheet that overrides these properties, Flash Player and AIR use the standard font renderer to render the fonts that use advanced anti-aliasing. If you embed fonts that use advanced anti-aliasing, you must set the `fontAntiAliasType` property to `advanced`, or you lose the benefits of the advanced anti-aliasing information.

The following table describes these properties:

Style property	Description
fontAntiAliasType	Sets the antiAliasType property of internal TextField controls. The valid values are normal and advanced. The default value is advanced, which enables advanced anti-aliasing for the font. Set this property to normal to prevent the compiler from using advanced anti-aliasing. This style has no effect for system fonts or fonts embedded without the advanced anti-aliasing information.
fontGridFitType	Sets the gridFitType property of internal TextField controls. The valid values are none, pixel, and subpixel. The default value is pixel. For more information, see the TextField and GridFitType classes in the *ActionScript 3.0 Reference for the Adobe Flash Platform*. This property has the same effect as the gridFitType style property of the TextField control for system fonts, only it applies when you embed fonts with advanced anti-aliasing. Changing the value of this property has no effect unless the fontAntiAliasType property is set to advanced.
fontSharpness	Sets the sharpness property of internal TextField controls. The valid values are numbers from -400 to 400. The default value is 0. This property has the same effect as the fontSharpness style property on the TextField control for system fonts, only it applies when you embed fonts with advanced anti-aliasing. Changing the value of this property has no effect unless the fontAntiAliasType property is set to advanced.
fontThickness	Sets the thickness property of internal TextField controls. The valid values are numbers from -200 to 200. The default value is 0. This property has the same effect as the fontThickness style property on the TextField control for system fonts, only it applies when you embed fonts with advanced anti-aliasing. Changing the value of this property has no effect unless the fontAntiAliasType property is set to advanced.

To use functionality similar to advanced anti-aliasing with CFF based fonts, you use the functionality of FTE that is built into Spark's text-based controls. For more information, see "Formatting Data" on page 2004.

Detecting embedded fonts

You can use the SystemManager class's isFontFaceEmbedded() method to determine whether the font is embedded or whether it has been registered globally with the register() method of the Font class. The isFontFaceEmbedded() method takes a single argument—the object that describes the font's TextFormat—and returns a Boolean value that indicates whether the font family you specify is embedded, as the following example shows:

```
<?xml version="1.0"?>
<!-- fonts/DetectingEmbeddedFonts.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
     creationComplete="determineIfFontFaceIsEmbedded()">

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

  <fx:Style>
     @font-face {
        src: url(../assets/MyriadWebPro.ttf);
        fontFamily: myPlainFont;
        embedAsCFF: true;
     }

     .myStyle1 {
        fontFamily: myPlainFont;
        fontSize:12pt
     }
  </fx:Style>

  <fx:Script><![CDATA[
     import mx.managers.SystemManager;
     import mx.core.FlexGlobals;
     import flash.text.TextFormat;

    [Bindable]
     private var b1:Boolean;
    [Bindable]
     private var b2:Boolean;

     public function determineIfFontFaceIsEmbedded():void {
        var tf1:TextFormat = new TextFormat();
        tf1.font = "myPlainFont";

        var tf2:TextFormat = new TextFormat();
        tf2.font = "Arial";

        b1 = FlexGlobals.topLevelApplication.systemManager.
           isFontFaceEmbedded(tf1);
        b2 = FlexGlobals.topLevelApplication.systemManager.
           isFontFaceEmbedded(tf2);
     }
  ]]></fx:Script>
  <s:Form>
     <s:FormItem label="isFontFaceEmbedded (myPlainFont):">
        <s:Label id="l1" text=" {b1}"/>
     </s:FormItem>
     <s:FormItem label="isFontFaceEmbedded (Arial):">
        <s:Label id="l2" text="{b2}"/>
     </s:FormItem>
  </s:Form>
</s:Application>
```

In this example, the font identified by the myPlainFont family name is embedded, but the Arial font is not.

You can use the Font class's `enumerateFonts()` method to output information about device or embedded fonts. The following example lists embedded fonts:

```
<?xml version="1.0"?>
<!-- fonts/EnumerateFonts.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="listFonts()">

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <fx:Style>
     @font-face {
        src:url("../assets/MyriadWebPro.ttf");
        fontFamily: myFont;
        embedAsCFF: true;
     }
     @font-face {
        src:url("../assets/MyriadWebPro-Bold.ttf");
        fontFamily: myFont;
        fontWeight: bold;
        embedAsCFF: true;
     }
     @font-face {
        src:url("../assets/MyriadWebPro-Italic.ttf");
        fontFamily: myFont;
        fontStyle: italic;
        embedAsCFF: true;
     }

     .myPlainStyle {
        fontSize: 20;
        fontFamily: myFont;
     }

     .myBoldStyle {
        fontSize: 20;
        fontFamily: myFont;
        fontWeight: bold;
     }
     .myItalicStyle {
        fontSize: 20;
        fontFamily: myFont;
        fontStyle: italic;
     }
  </fx:Style>
  <fx:Script><![CDATA[
     private function listFonts():void {
        var fontArray:Array = Font.enumerateFonts(true);
        ta1.text += "Fonts: \n";
        for(var i:int = 0; i < fontArray.length; i++) {
            var thisFont:Font = fontArray[i];
            ta1.text += "FONT " + i + ":: name: " + thisFont.fontName + "; typeface: " +
                thisFont.fontStyle + "; type: " + thisFont.fontType;
            if (thisFont.fontType == "embeddedCFF"||thisFont.fontType == "embedded") {
                ta1.text += "*";
            }
            ta1.text +=  "\n";

        }

    }
  ]]></fx:Script>
  <s:VGroup>
     <s:RichText text="Plain Label" styleName="myPlainStyle"/>
     <s:RichText text="Bold Label" styleName="myBoldStyle"/>
     <s:RichText text="Italic Label" styleName="myItalicStyle"/>
     <s:TextArea id="ta1" height="200" width="400"/>
     <s:RichText text="* Embedded" styleName="myItalicStyle"/>
  </s:VGroup>
</s:Application>
```

The following list shows the first few lines of sample output. This list will vary depending on the client's system.

```
FONT 0:: name: myFont; typeface: regular; type: embeddedCFF*
FONT 1:: name: myFont; typeface: bold; type: embeddedCFF*
FONT 2:: name: myFont; typeface: italic; type: embeddedCFF*
FONT 3:: name: Marlett; typeface: regular; type: device
FONT 4:: name: Arial; typeface: regular; type: device
FONT 5:: name: Arial CE; typeface: regular; type: device
```

The `enumerateFonts()` method takes a single Boolean argument: `enumerateDeviceFonts`. The default value of the `enumerateDeviceFonts` property is `false`, which means it returns an Array of embedded fonts by default.

If you set the `enumerateDeviceFonts` argument to `true`, the `enumerateFonts()` method returns an array of available device fonts on the client system, but only if the client's mms.cfg file sets the `DisableDeviceFontEnumeration` property to 0, the default value. If you set the `DisableDeviceFontEnumeration` property to 1, Flash Player cannot list device fonts on a client computer unless you explicitly configure the client to allow it. For more information about configuring the client with the mms.cfg file, see the Flash Player documentation.

Using the fontswf utility

The fontswf utility is a simple command line tool that converts a single font face from a font file into a SWF file. This SWF file can be used as the source of an embedded font in your applications. Supported font file types are *.ttf, *.otf, *.ttc, and *.dfont.

The fontswf utility is for users of the Mozilla Public License version of the Flex SDK. This version includes only open-source technology. Because the font managers are not open-source, this utility can be used in their place so that you can embed fonts in your applications.

The fontswf utility is in the *sdk_root*/bin directory of the Flex SDK. For Flash Builder, the fontswf utility is located in the sdks/4.6.0/bin directory. If you do not have the fontswf utility in your bin directory, you must get a more recent version of the SDK.

You use fontswf by invoking it from the command line, as the following example shows:

```
fontswf [options] font_input_file
```

For example:

```
c:\flex\bin> fontswf -4 -u U+0020-007F -bold -o c:/temp/myboldfont.swf
c:/assets/fonts/myboldfont.ttf
```

The following table describes the options for the fontswf utility:

Option	Description
`-a, -alias` ***`name`***	Sets the font’s alias. The default is the font’s family name.
`-b, -bold`	Embeds the font’s bold face.
`-i, -italic`	Embeds the font’s italic face.
`-o, -output` ***`file_path`***	Sets the output file path for the SWF file.
`-u, -unicode-range` ***`range`***	Sets the included character range. The default value is “*”, which includes all characters. For information on using character ranges, see “Setting character ranges” on page 1588.
`-3`	Generates a font SWF file for applications that use TextField-based text rendering. Use this option if you are creating a font SWF file for a Flex 3 application.
`-4`	Generates a font SWF file for applications that support CFF (Flex 4) with Flash Player 10. This is the default option.

Using multiple typefaces

Most fonts have four typeface styles: plain, bold, italic, and bold-italic. You can embed any number of these typeface styles for each font in your applications. If you embed only the bold typeface in your application, you cannot use the normal (or plain) typeface unless you also embed that typeface. For each typeface that you use, you must add a new `@font-face` declaration to your style sheet.

***Note:** Some Flex controls, such as the MX Button control, use the bold typeface style by default, rather than the plain style. If you use an embedded font for an MX Button’s label, you must either embed the bold font style for that font, or set the default typeface for the MX Button label to match a typeface that you embed.*

The following example embeds the bold, italic, and plain typefaces of the Myriad Web Pro font. After you define the font face, you define selectors for the font by using the same alias as the `fontFamily`. You define one for the bold, one for the italic, and one for the plain face. To apply the font styles, this example applies the class selectors to the Label controls inline:

```
<?xml version="1.0"?>
<!-- fonts/MultipleFaces.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <!-- Use a vertical layout -->
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <fx:Style>
     @font-face {
        src:url("../assets/MyriadWebPro.ttf");
        fontFamily: myFont;
        embedAsCFF: true;
     }
     @font-face {
        /* Note the different filename for boldface. */
        src:url("../assets/MyriadWebPro-Bold.ttf");
        fontFamily: myFont; /* Notice that this is the same alias. */
        fontWeight: bold;
        embedAsCFF: true;
     }
     @font-face {
        /* Note the different filename for italic face. */
        src:url("../assets/MyriadWebPro-Italic.ttf");
        fontFamily: myFont; /* Notice that this is the same alias. */
        fontStyle: italic;
        embedAsCFF: true;
     }

     .myPlainStyle {
        fontSize: 32;
        fontFamily: myFont;
     }

     .myBoldStyle {
        fontSize: 32;
        fontFamily: myFont;
        fontWeight: bold;
     }
     .myItalicStyle {
        fontSize: 32;
        fontFamily: myFont;
        fontStyle: italic;
     }
  </fx:Style>
  <s:VGroup>
     <s:Label text="Plain Text" styleName="myPlainStyle"/>
     <s:Label text="Italic Text" styleName="myItalicStyle"/>
     <s:Label text="Bold Text" styleName="myBoldStyle"/>
  </s:VGroup>
</s:Application>
```

Optionally, you can apply the bold or italic type to controls inline, as the following example shows:

```
<?xml version="1.0"?>
<!-- fonts/MultipleFacesAppliedInline.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <fx:Style>
     @font-face {
        src:url("../assets/MyriadWebPro.ttf");
        fontFamily: myFont;
        embedAsCFF: true;
     }
     @font-face {
        src:url("../assets/MyriadWebPro-Bold.ttf");
        fontFamily: myFont;
        fontWeight: bold;
        embedAsCFF: true;
     }
     @font-face {
        src:url("../assets/MyriadWebPro-Italic.ttf");
        fontFamily: myFont;
        fontStyle: italic;
        embedAsCFF: true;
     }

     .myStyle1 {
        fontSize: 32;
        fontFamily: myFont;
     }
  </fx:Style>
  <s:VGroup styleName="myStyle1">
     <s:Label text="Plain Text"/>
     <s:Label text="Italic Text" fontStyle="italic"/>
     <s:Label text="Bold Text" fontWeight="bold"/>
  </s:VGroup>
</s:Application>
```

If you use a bold-italic font, the font must have a separate typeface for that font. You specify both properties (`fontWeight` and `fontStyle`) in the `@font-face` and selector blocks, as the following example shows:

```
@font-face {
    src:url("../assets/KNIZIA-BI.TTF");
    fontStyle: italic;
    fontWeight: bold;
    fontFamily: myFont;
    embedAsCFF: true;
}
.myBoldItalicStyle {
    fontFamily:myFont;
    fontWeight:bold;
    fontStyle:italic;
    fontSize: 32;
}
```

In the `@font-face` definition, you can specify whether the font is bold or italic by using the `fontWeight` and `fontStyle` properties. For a bold font, you can set `fontWeight` to `bold` or an integer greater than or equal to 700. You can specify the `fontWeight` as `plain` or `normal` for a nonboldface font. For an italic font, you can set `fontStyle` to `italic` or `oblique`. You can specify the `fontStyle` as `plain` or `normal` for a nonitalic face. If you do not specify a `fontWeight` or `fontStyle`, Flex assumes you embedded the plain or regular font face.

You can also add any other properties for the embedded font, such as `fontSize`, to the selector, as you would with any class or type selector.

Some fonts with multiple faces are packaged as TTC (TrueType Collection) files. In these cases, you can use the `fontFamily` alias to embed the specific face in the TTC file that you want. For more information, see "Embedding fonts in container formats" on page 1578.

By default, Flex includes the entire font definition for each embedded font in the application, so you should limit the number of fonts that you use to reduce the size of the application. You can limit the size of the font definition by defining the character range of the font. For more information, see "Setting character ranges" on page 1588.

Setting character ranges

By specifying a range (or subset) of characters that compose the face of an embedded font, you reduce the size of an embedded font. Each character in a font that you use must be described; removing some of these characters reduces the overall size of the description information that Flex must include for each embedded font.

You can set the range of glyphs in the flex-config.xml file or in the `@font-face` declaration. You specify individual characters or ranges of characters using the Unicode values for the characters, and you can set multiple ranges for each font declaration.

The syntax for setting a character range is as follows:

```
U+[beginning of range]-[end of range];
```

For example:

```
U+0041-005A
```

You can also use wild cards Unicode range syntax; for example:

```
U+00??
```

This is the same as `U+0000-00FF`.

You can also refer to a single character without a range; for example:

```
U+0041
```

Finally, you can specify a list of ranges by using a comma separator; for example:

```
U+0041,U+0043-00FF,U+0045
```

If you use a character that is outside of the declared range, Flex displays a device font for that character (for FTE-based controls) or a blank character (for non-FTE-based controls). For more information on setting character ranges in applications built with Flex, see the CSS-2 Fonts specification at www.w3.org/TR/1998/REC-CSS2-19980512/fonts.html#descdef-unicode-range.

If you embed a font from a SWF file that you create with Flash or the fontswf utility, you should set the character range to include only those characters that you need to keep the size of the SWF file as small as possible. For information about using the fontswf utility, see "Using the fontswf utility" on page 1584.

Setting ranges in font-face declarations

You can set the range of embedded characters in an application by using the `unicodeRange` property of the `@font-face` declaration. The following example embeds the Myriad Web Pro font and defines the range of characters for the font in the `<fx:Style>` tag:

```
<?xml version="1.0"?>
<!-- fonts/EmbeddedFontCharacterRange.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <fx:Style>
      @namespace s "library://ns.adobe.com/flex/spark";
     @font-face {
        src:url("../assets/MyriadWebPro.ttf");
        fontFamily: myFontFamily;
        embedAsCFF: true;
        unicodeRange:
           U+0041-005A, /* Upper-Case [A..Z] */
           U+0061-007A, /* Lower-Case a-z */
           U+0030-0039, /* Numbers [0..9] */
           U+002E-002E; /* Period [.] */
     }
     s|RichText {
        fontFamily: myFontFamily;
        fontSize: 32;
     }
  </fx:Style>
  <s:Panel title="Embedded Font Character Range">
        <s:RichText width="400" height="150">
          <s:text>The Text Uses Only Some of Available Characters 0 1 2 3 4 5 6 7 8 9.</s:text>
        </s:RichText>
  </s:Panel>
</s:Application>
```

Setting language ranges in flex-config.xml

You can specify the language and character range for embedded fonts in the flex-config.xml file by using the `<language-range>` child tag. This lets you define the range once and use it across multiple `@font-face` blocks.

The following example creates named ranges in the flex-config.xml file:

```
<fonts>
    <languages>
        <language-range>
            <lang>englishRange</lang>
            <range>U+0020-007E</range>
        </language-range>
        <language-range>
            <lang>lowerCaseEnglish</lang>
            <range>U+0061-007A</range>
        </language-range>
    <languages>
</fonts>
```

In your style sheet, you point to the defined ranges by using the `unicodeRange` property of the `@font-face` declaration, as the following example shows:

```
@font-face {
    fontFamily: myPlainFont;
    src: url("../assets/MyriadWebPro.ttf");
    unicodeRange: "englishRange";
    embedAsCFF: true;
}
```

Flex includes a file that lists convenient mappings of the Flash UnicodeTable.xml character ranges for use in the Flex configuration file. For the Flex SDK, the file is located at *flex_install_dir*/frameworks/flash-unicode-table.xml. For Adobe LiveCycle Data Services ES, the file is located at *flex_app_root*/WEB-INF/flex/flash-unicode-table.xml.

The following example shows the predefined range Latin 1:

```
<language-range>
    <lang>Latin I</lang>
    <range>U+0020,U+00A1-00FF,U+2000-206F,U+20A0-20CF,U+2100-2183</range>
</language-range>
```

To make ranges listed in the flash-unicode-table.xml file available in your applications, copy the ranges from this file and add them to the flex-config.xml files.

Detecting available ranges

You can use the Font class to detect the available characters in an embedded font. You do this with the `hasGlyphs()` method.

The following example embeds the same font twice, each time restricting the font to different character ranges. The first font includes support only for the letters A and B. The second font family includes all 128 glyphs in the Basic Latin block.

```
<?xml version="1.0"?>
<!-- charts/CharacterRangeDetection.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    creationComplete="checkCharacterSupport();"
>
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Style>
        @font-face {
            font-family: myABFont;
            src:url("../assets/MyriadWebPro.ttf");
            /*
            * Limit range to the characters A and B.
            */
            unicodeRange: U+0041-0042;
            embedAsCFF: true;
        }
        @font-face {
            font-family: myWideRangeFont;
            src:url("../assets/MyriadWebPro.ttf");
            /*
            * Set range to the 128 characters in
            * the Basic Latin block.
            */
            unicodeRange: U+0041-007F;
            embedAsCFF: true;
        }
    </fx:Style>
    <fx:Script><![CDATA[
        public function checkCharacterSupport():void {
            var fontArray:Array = Font.enumerateFonts(false);
            for(var i:int = 0; i < fontArray.length; i++) {
                var thisFont:Font = fontArray[i];
                if (thisFont.hasGlyphs("DHARMA")) {
                    ta1.text += "The font '" + thisFont.fontName +
                        "' supports these glyphs.\n";
                } else {
                    ta1.text += "The font '" + thisFont.fontName +
                        "' does not support these glyphs.\n";
                }
            }
        }
    ]]></fx:Script>
    <s:VGroup>
        <s:RichText>
            <s:text>myABFont unicodeRange: U+0041-0042 (characters A and B)</s:text>
        </s:RichText>
        <s:RichText>
            <s:text>myWideRangeFont unicodeRange: U+0041-007F (Basic Latin chars)</s:text>
        </s:RichText>
        <s:Label text="Glyphs: DHARMA"/>
        <s:RichText id="ta1" height="150" width="300"/>
    </s:VGroup>
</s:Application>
```

Embedding multi-byte fonts

When using multi-byte fonts that have a large number of characters, such as those used in Asian languages, you should embed the smallest possible set of characters. If you embed a font's entire character set, the size of your application's SWF file can be very large. You can define sets of Unicode character ranges in the flex-config.xml file and then reference the name of that range in your style's `@font-face` declaration.

The Flex CookBook shows you how to limit character sets when embedding fonts.

Flex provides predefined character ranges for common multi-byte scripts such as Thai, Kanji, Hangul, and Hebrew in the flash-unicode-table.xml file. This file is not processed by Flex, but is included to provide you with ready definitions for various character ranges. For example, the following character range for Thai is listed in the flash-unicode-table.xml file:

```
<language-range>
    <lang>Thai</lang>
    <range>U+0E01-0E5B</range>
</language-range>
```

To use this language in your application, copy the character range to the flex-config.xml file or pass it on the command line by using the `fonts.languages.language-range` option. Add the full definition as a child tag to the `<languages>` tag, as the following example shows:

```
<flex-config>
    <compiler>
        <fonts>
            <languages>
                <language-range>
                    <lang>thai</lang>
                    <range>U+0E01-0E5B</range>
                </language-range>
            </languages>
        </fonts>
    </compiler>
    ...
</flex-config>
```

You can change the value of the `<lang>` element to anything you want. When you embed the font by using CSS, you refer to the language by using this value in the `unicodeRange` property of the `@font-face` declaration, as the following example shows:

```
@font-face {
    fontFamily:"Thai_font";
    src: url("../assets/THAN.TTF"); /* Embed from file */
    unicodeRange:"thai";
    embedAsCFF: true;
}
```

Embedding fonts with MX components

The `embedAsCFF` (Compact Font Format) property indicates whether to embed a font that supports the advanced text layout features used by the Flash Text Engine (FTE). This is sometimes referred to as DefineFont4. If you set the value of the `embedAsCFF` property to `true`, then you can only use that font with controls that support FTE. If you set the value of the `embedAsCFF` property to `false`, then the embedded font does not support FTE and you can only use that font with controls that do not have FTE support.

The implications of this appear when you try to use MX controls with a font that was embedded with FTE support. In those cases, the text does not appear, as the following example shows.

In the first panel, the embedded CFF font is applied to the Spark control and the embedded non-CFF font is applied to the MX control. The result is that the Button labels show correctly. In the second Panel, both Button labels use the CFF font. The result is that no text appears for the MX control in the second Panel because the MX control does not support CFF.

```
<?xml version="1.0"?>
<!-- fonts/CFFTest.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <fx:Style>
     @font-face {
        src:url("../assets/MyriadWebPro.ttf");
        fontFamily: myCFFFont;
        embedAsCFF: true;
     }
     @font-face {
        src:url("../assets/MyriadWebPro.ttf");
        fontFamily: myFontNoCFF;
        embedAsCFF: false;
     }

     .myCFFStyle {
        fontSize: 32;
        fontFamily: myCFFFont;
     }
     .myStyleNoCFF {
        fontSize: 32;
        fontFamily: myFontNoCFF;
     }
  </fx:Style>
  <s:Panel title="Using Correct Fonts">
    <s:VGroup>
        <s:Button label="Spark Button" styleName="myCFFStyle"/>
        <mx:Button label="MX Button" styleName="myStyleNoCFF"/>
    </s:VGroup>
  </s:Panel>
  <s:Panel title="Using Incorrect Fonts">
    <s:VGroup>
        <s:Button label="Spark Button" styleName="myCFFStyle"/>
        <!-- The Button label will not show up because it's a MX control that
        is attempting to use a Spark-compatible embedded font. -->
        <mx:Button label="MX Label" styleName="myCFFStyle"/>
    </s:VGroup>
  </s:Panel>
</s:Application>
```

As this example illustrates, if you mix MX and Spark controls inside the same application, you might not be able to use the same embedded font.

There are two possible remedies to this situation:

- Specify that the MX controls use FTE classes to render text, rather than their default text renderers.
- Embed both the non-CFF version of the font in addition to the CFF version of the font. This is the less-desireable approach because it increases the size of your SWF file.

The following sections describe each of these solutions.

More Help topics

"MX text controls" on page 805

Using FTE in MX controls

The controls that support FTE include all Spark components in the spark.components.* package. This includes the Spark text controls such as Label, RichText, and RichEditableText. This also includes Spark versions of the TextInput and TextArea controls. This does not include MX controls in the mx.controls.* package.

The reason that MX controls do not support FTE is that in previous versions of Flex, they used the UITextField subcomponent to render text. This subcomponent does not support FTE. Spark controls, on the other hand, use FTE-compatible classes to render text.

The Flex SDK provides the mx.core.UIFTETextField and mx.controls.MXFTETextInput classes that support FTE for MX text controls. You can use these classes in some MX controls so that those controls can use CFF versions of embedded fonts. As a result, those controls can use the same embedded fonts that you also use with the Spark controls. You do this by setting the `textFieldClass` and `textInputClass` styles to use these classes.

The easiest way to use the MXFTETextInput and UIFTETextField classes with your MX text controls is to apply the MXFTEText.css theme file to your application. This theme causes your MX controls to use the MXFTETextInput and UIFTETextField classes for text rendering. The MXFTEText.css theme file is a convenience theme that is set up to apply only FTE-supporting classes to MX controls.

The following excerpt from the MXFTEText.css theme file shows that the `textInputClass` and `textFieldClass` style properties are set to classes that support FTE:

```
DateField {
    textInputClass: ClassReference("mx.controls.MXFTETextInput");
}
Label {
    textFieldClass: ClassReference("mx.core.UIFTETextField");
}
```

On the command line, you specify the MXFTEText.css theme file by using the `theme` compiler option, as the following example shows:

```
mxmlc -theme+=frameworks/projects/spark/MXFTEText.css MyApp.mxml
```

Note that instead of setting `theme=`*`filename`*, this example uses `theme+=`*`filename`*. This is so that the MXFTEText.css file is used as a theme, *in addition* to the default themes, not as a replacement of the default themes.

In Flash Builder, you can use the MXFTEText.css theme file in your application by selecting Project > Properties > Flex Compiler. Then select the Use Flash Text Engine in MX Components option.

The following example is compiled with the the MXFTEText.css theme. Because this theme is used, the MX text controls can use the same embedded font as the Spark embedded font. If you compile this example without the `theme` option, the label for the MX Button does not render.

```
<?xml version="1.0"?>
<!-- fonts/UseTLFTextTheme.mxml -->
<!-- Compile this example by setting theme=MXFTEText.css for a compiler argument. -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
  <fx:Style>
     @font-face {
        src:url("../assets/MyriadWebPro.ttf");
        fontFamily: myCFFFont;
        embedAsCFF: true;
     }
     .myCFFStyle {
        fontSize: 32;
        fontFamily: myCFFFont;
     }
  </fx:Style>
  <s:Panel title="Spark and MX Buttons">
    <s:VGroup>
        <s:Button label="Spark Button" styleName="myCFFStyle"/>
        <mx:Button label="MX Button" styleName="myCFFStyle"/>
    </s:VGroup>
  </s:Panel>
</s:Application>
```

The MX DataGrid control has a special class, FTEDataGridItemRenderer, that you can use for custom item renderers. The MXFTEText.css theme file specifies it as follows:

```
defaultDataGridItemRenderer:
ClassReference("mx.controls.dataGridClasses.FTEDataGridItemRenderer");
```

Some controls are not affected by the MXFTEText.css theme. This is because some MX controls have Spark equivalents, such as Button or ComboBox. As a result, you should use the Spark version of the control instead of the MX version where possible.

Rather than use the MXFTEText.css theme file to add FTE support to your MX controls, you can manually replace the non-FTE classes with the FTE classes for text rendering on a MX control. You do this by setting the value of the control's `textFieldClass` or `textInputClass` style properties to the UIFTETextField or MXFTETextInput classes, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fonts/TextFieldClassExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout
            paddingLeft="20" paddingRight="20"
            paddingTop="20" paddingBottom="20" />
    </s:layout>
    <fx:Style>
        @namespace mx "library://ns.adobe.com/flex/mx";
        @namespace s "library://ns.adobe.com/flex/spark";
        @font-face {
            src:url("../assets/MyriadWebPro.ttf");
            fontFamily: cffFont;
            embedAsCFF: true;
        }
        mx|Label{
            fontFamily: cffFont;
            fontSize: 22;
            textFieldClass:ClassReference("mx.core.UIFTETextField");
        }
        s|Label{
            fontFamily: cffFont;
            fontSize: 22;
        }
    </fx:Style>
    <mx:Label text="Hello World 1234567890 [MX Label]" width="100%"/>
    <s:Label text="Hello World 1234567890 [Spark Label]" width="100%"/>
</s:Application>
```

You can also specify the value of the `textFieldClass` or `textInputClass` style properties inline, as the following example shows:

```
<mx:Label text="Hello World 1234567890 [Label]" width="100%"
textFieldClass="mx.core.UIFTETextField"/>
```

Do not use the `setStyle()` method to specify the value of these style properties in ActionScript.

The UIFTETextField class does not support editing, scrolling, selection, linking, or rich text. As a result, you can only use this class on MX controls that do not use these features. The MXFTETextInput class can be edited and is selectable.

The following MX controls support the UIFTETextField and MXFTETextInput classes, which means that you can use CFF fonts with them:

- Accordion
- Alert (the text is not selectable)
- Button
- ButtonBar
- CheckBox
- DateChooser
- FileSystemComboBox

- FileSystemHistoryButton
- FormHeading
- FormItem
- FormHeading
- FormItem
- HSlider (the labels follow the same rules as the MX Label control)
- LinkBar
- LinkButton
- Menu
- MenuBar
- Panel
- PopUpButton
- PopUpMenuButton
- PrintDataGrid
- ProgressBar
- RadioButton
- TabBar
- TabNavigator
- TitleWindow
- ToggleButtonBar
- ToolTip
- VSlider (the labels follow the same rules as the MX Label control)

Other MX controls have some limitations when it comes to using the UIFTETextField and MXFTETextInput classes. In some cases, you should use the Spark equivalents. In other cases, you can use the UIFTETextField and MXFTETextInput subcomponents with the MX control, as long as you avoid using advanced text features, such as editability or the `htmlText` property. The following table describes these limitations:

MX control	Description
List-based components (such as List, FileSystemList, HorizontalList, TileList, DataGrid, and Tree)	Some list-based components have Spark equivalents (including List, HorizontalList, and TileList). You can use the UIFTETextField and MXFTETextInput classes in the other components if you do not use selection, editability, HTML links, or scrolling. Otherwise, you should embed a non-CFF version of the font to support these controls.
Label and Text	Use Spark equivalents such as Label, RichText, and RichEditableText. You can use UIFTETextField with the Label and Text controls if the text is not selectable or you do not use the `htmlText` property to specify the content of the controls. Otherwise, you should embed a non-CFF version of the font to support these controls.
TextInput and TextArea	Use the Spark equivalents. Otherwise, you should embed a non-CFF version of the font to support these controls.
RichTextEditor	There is no equivalent class. In this case, you should embed a non-CFF version of the font to support this control.

MX control	Description
ColorPicker	There is no equivalent class. In this case, you should embed a non-CFF version of the font to support this control. However, the ColorPicker control only uses the font to display a color value, so in some cases, using an embedded font might not be necessary.
ComboBox	Use the Spark equivalent. If your ComboBox's text does not need to be editable, you can use the MXFTETextInput class. Otherwise, you should embed a non-CFF version of the font to support this control.
DateField	If you do not use editability, then you can use the MXFTETextInput class. Otherwise, you should embed a non-CFF version of the font to support this control.
NumericStepper	If you do not use editability, then you can use the MXFTETextInput class. Otherwise, you should embed a non-CFF version of the font to support this control.

Embedding non-CFF versions of fonts for MX components

To use MX controls with embedded fonts, you can embed the non-CFF version of the font instead of changing the properties of the control to use CFF fonts. You should do this only if your MX control:

- Has no Spark equivalent
- Does not support using the UIFTETextField and MXFTETextInput classes for text rendering
- Must use selection, scrolling, or HTML text
- Is editable

If you embed a non-CFF version of a font in addition to a CFF version of the font in your application, your SWF file will be larger than if you embedded only a single version of the font. As a result, only do this when absolutely necessary.

If you compile an application with the `compatibility-version` compiler option set to 3.0.0, then the non-CFF version of the font is embedded automatically.

The following example embeds both a non-CFF version and a CFF version of the font so that the Spark and MX Labels use embedded fonts. The reason this is required is that the Label is selectable in this example.

```
<?xml version="1.0"?>
<!-- fonts/EmbedBoth.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

  <fx:Style>
     @font-face {
        src:url("../assets/MyriadWebPro.ttf");
        fontFamily: myCFFFont;
        embedAsCFF: true;
     }

     @font-face {
        src:url("../assets/MyriadWebPro.ttf");
        fontFamily: myFontNoCFF;
        advancedAntiAliasing: true;
        embedAsCFF: false;
     }

     .myCFFStyle {
        fontSize: 32;
        fontFamily: myCFFFont;
     }

     .myStyleNoCFF {
        fontSize: 32;
        fontFamily: myFontNoCFF;
     }
  </fx:Style>

  <s:Panel title="Using Two Different Embedded Fonts">
    <s:VGroup>
        <s:Label text="Spark Label"
            styleName="myCFFStyle"/>
        <mx:Label text="MX Label"
            styleName="myStyleNoCFF" selectable="true"/>
    </s:VGroup>
  </s:Panel>

</s:Application>
```

Note that when embedding a non-CFF font, you have the option of specifying the `advancedAntiAliasing` property. With CFF fonts, this property is ignored. The advanced anti-aliasing functionality is provided natively with FTE.

Troubleshooting fonts in applications

There are some techniques that you can use to successfully embed fonts into your applications.

Resolving compiler errors

The following table describes common compiler errors and their solutions:

Error	Solution
`Unable to resolve '`*`swf_file_name`*`' for transcoding`	Indicates that the font was not found by the compiler. Ensure that the path to the font is correct in the `@font-face` declaration or the `[Embed]` tag and that the path is accessible by the compiler.
`Font '`*`font_name`*`' with` *`style_description`* `not found`	Indicates that the `fontName` property used in the `[Embed]` statement might not match the name of the font. For fonts in SWF files, ensure that the spelling and word spacing of the font name in the list of available fonts in Flash is the same as the `fontName` property in your `[Embed]` statement and the `fontFamily` property that you use in your style definitions. This error can also mean that the font's style was not properly embedded in Flash. Open the FLA file and ensure that there is a text area with the font and style described, that the text is dynamic, and that you selected a character range for that text.

Resolving run-time errors

To determine if your fonts are embedded properly, you can use the isFontFaceEmbedded() method of the SystemManager, as described in "Detecting embedded fonts" on page 1581.

If you are using fonts embedded for Spark controls with MX controls, you should refer to "Embedding fonts with MX components" on page 1592.

To properly embed your fonts, try the following techniques:

- If one type of control is not correctly displaying its text, ensure that you are embedding the appropriate typeface. For example, the MX Button control's text labels require the bold typeface. If you do not embed the bold typeface, the MX Button control does not display the label's text.
- In your application, ensure that you set all properties for each font typeface in the `@font-face` declaration or `[Embed]` statement. To embed a bold typeface, you must set the `fontWeight` property to `bold`, as the following example shows:

  ```
  @font-face {
      src: url(../assets/MyriadWebProEmbed.ttf);
      fontFamily: "Myriad Web Pro";
      fontWeight: bold;
      embedAsCFF: true;
  }
  ```

  You also must set the `fontWeight` style property in your style definition:

  ```
  .myStyle2 {
      fontFamily: "Myriad Web Pro";
      fontWeight: bold;
      fontSize: 12pt;
  }
  ```

  If you use the `[Embed]` statement, you must set the `fontWeight` property to `bold` as the following example shows:

  ```
  [Embed(source="MyriadWebProEmbed.ttf", fontName="Myriad Web Pro",fontWeight="bold")]
  ```

- For fonts that are embedded in SWF files that you import, open the FLA file in Flash and ensure that all of the typefaces were added properly. Select each text area and do the following:
  - Check that the font name is correct. Ensure that the spelling and word spacing of the font name in the list of available fonts in Flash is the same as the `fontFamily` property in the `@font-face` declaration or the `fontName` property in your `[Embed]` statement. This value must also match the `fontFamily` property that you use in your style definitions.

    If you did not select an anti-aliasing option for the font in Flash 8 (for example, you chose Bitmap Text (no anti-alias)), you might need to change the value of the font name to a format that matches *fontName_fontSize*pt_st (for example, "Wingdings_8pt_st"). In the CSS for that bitmap font, be sure to set `fontAntiAliasType` to `normal`.

    To determine the exact font name exported by Flash (which you must match as the value of the `fontFamily` property in your application), open the SWF file in Flash and select Debug > Variables.
  - Check that the style is properly applied. For example, select the bold text area and check that the typeface really is bold.
  - Click the Embed button and ensure that the range of embedded characters includes the characters that you use in your application.
  - Check that each text area is set to Dynamic Text and not Static Text or Input Text. The type of text is indicated by the first drop-down box in the text's Properties tab.
  - Unless the SWF file was compiled with CFF, you must set the value of the embedAsCFF property to false for the imported font.
- For fonts in SWF files, ensure that you are using the latest SWF file that contains your fonts and was generated in Flash. Regenerate the SWF file in Flash if necessary.

- Ensure that the value of the `embedAsCFF` property is correct for the way that you are using a font. For Spark controls, set `embedAsCFF` to `true`. For fonts that are used by MX controls, try setting `embedAsCFF` to `false`. The following example sets the `embedAsCFF` property to `false` in the @font-face declaration:

```
@font-face {
    src: url(../assets/MyriadWebProEmbed.ttf);
    fontFamily: "Myriad Web Pro";
    fontWeight: bold;
    embedAsCFF: false;
}
```

About the font managers

***Note:** This is an advanced topic. Most developers do not need to adjust the font managers for their applications.*

Flex includes several font managers to handle embedded fonts. The font managers take embedded font definitions and draw each character in Flash Player. This process is known as *transcoding*. The font managers are Batik, JRE, AFE (Adobe Font Engine), and CFF, represented by the BatikFontManager, JREFontManager, AFEFontManager, and CFFFontManager classes, respectively.

The CFF font manager supports both TrueType and OpenType fonts. It also supports URL and system fonts. Use this manager for all CFF fonts.

The AFE font manager supports both TrueType and OpenType fonts. It also adds support for all non-CFF font embedding in Flex 4. The AFE font manager is the only font manager that you can use to transcode TrueType or OpenType fonts for non-CFF fonts. The fonts can only be referenced by a path to the font file, not by an OS-specific font name. If you embed an OpenType font, the compiler will use the AFE font manager to transcode the font because the other font managers do not support OpenType fonts, unless that OpenType font is a system font, in which case, the compiler will throw an error. None of the font managers can transcode OpenType fonts that are embedded as system fonts.

The Batik font manager transcodes only TrueType fonts, but does not support TrueType Collections (*.ttc). It does not transcode system fonts. If you specify the font location when you embed the font, the compiler will use the Batik font manager. In general, the Batik font manager provides smoother rendering and more accurate line metrics (which affect multiline text and line-length calculations) than the JRE font manager.

The JRE font manager transcodes TrueType system fonts, but the quality of output is generally not as good as the Batik font manager. If you install the font on your system, the compiler will use the JRE font manager because the Batik font manager does not support system fonts.

The following table shows which fonts are supported by which font managers:

	CFF	**Batik**	**AFE**	**JRE**
Font type	TrueType, OpenType	TrueType	TrueType, OpenType	TrueType
Method of embedding	URL, system	URL	URL	System

You determine which font managers the compiler can use in the flex-config.xml file. The default setting is to use all of them, as the following example shows:

```
<fonts>
    <managers>
        <manager-class>flash.fonts.JREFontManager</manager-class>
        <manager-class>flash.fonts.BatikFontManager</manager-class>
        <manager-class>flash.fonts.AFEFontManager</manager-class>
         <manager-class>flash.fonts.CFFFontManager</manager-class>
    </managers>
</fonts>
```

The preference of `<manager>` elements is in reverse order. This means that by default the CFF font manager is the preferred font manager; the compiler checks to see if a font can be transcoded using it first. If not, then the compiler checks to see whether the font can be transcoded using the AFE font manager and then the Batik font manager. Finally, if the other font managers fail, the compiler checks to see whether the JRE font manager can transcode the font.

Spark Skinning

You create Spark skins by either editing an existing skin class or creating a new skin class for a Spark component. For information about skinning MX components, see “Skinning MX components” on page 1655.

About Spark skins

In the Flex 4 skinning model, the skin controls all visual elements of a component, including layout. The new architecture gives developers greater control over what their components look like a structured and tool-friendly way. Previously, MX components that used the Halo theme for their skins defined their look and feel primarily through style properties.

Spark skins can contain multiple elements, such as graphic elements, text, images, and transitions. Skins support states, so that when the state of a component changes, the skin changes as well. Skin states integrate well with transitions so that you can apply effects to one or more parts of the skins without adding much code.

You typically write Spark skin classes in MXML. You do this with MXML graphics tags (or FXG components) to draw the graphic elements, and specify child components (or subcomponents) using MXML or ActionScript.

The base class for Flex 4 skins is the spark.components.supportClasses.Skin class. The default Spark skins are based on the SparkSkin class, which subclasses the Skin class.

In general, you should try to put all visual elements of a component in the skin class. This helps maintain a necessary separation between the model (the logic and declarative structure of the application) and the view (the appearance of the application). Properties that are used by skins (for example, the placement of the thumb in a slider control) should be defined in the component so that they can be shared by more than one skin.

Most skins use the BasicLayout layout scheme within the skin class. This type of layout uses constraints, which means that you specify the distances that each element is from another with properties such as `left`, `right`, `top`, and `bottom`. You can also specify absolute positions such as the x and y coordinates of each element in the skin.

When creating skins, you generally do not subclass existing skin classes. Instead, it is often easier to copy the source of an existing skin class and create another class from that. Use this method especially if you are going to reuse the skin for multiple instances of a component or multiple components. If you want to change the appearance of a single instance of a component, you can use MXML graphics syntax or apply styles inline.

When creating a Spark skin, you can use MXML, ActionScript, FXG, embedded images, or any combination of the above. You do not generally use run-time loaded assets such as images in custom skins.

More Help topics

Skinning Custom Skinnable Components (video)

Applying skins

You usually apply Spark skins to components by using CSS or MXML. With CSS, you use the `skinClass` style property to apply a skin to a component, as the following example shows:

```
s|Button {
    skinClass: ClassReference("com.mycompany.skins.MyButtonSkin");
}
```

When applying skins with MXML, you specify the name of the skin as the value of the component's `skinClass` property, as the following example shows:

```
<s:Button skinClass="com.mycompany.skins.MyButtonSkin" />
```

You can also apply a skin to a component in ActionScript. You call the `setStyle()` method on the target component and specify the value of the `skinClass` style property, as the following example shows:

```
myButton.setStyle("skinClass", Class(MyButtonSkin));
```

Anatomy of a skin class

Custom Spark skins are MXML files that define the logic, graphic elements, subcomponents, states, and other objects that make up a skin for a Spark component.

The structure of Spark skin classes is similar to other custom MXML components. They include the following elements:

- Skin root tag, or a subclass of Skin (required)
- Host component metadata (optional, but recommended)
- States declarations (required if defined on the host component)
- Skin parts (required if defined on the host component)
- Script block (optional)
- Graphic elements and other controls (optional)

In addition to these elements, Spark skins can contain MXML language tags such as Declarations and Library.

Root tags

Skin classes use the Skin class, or a subclass of Skin such as SparkSkin, as their root tag. The root tag contains the namespace declarations for all namespaces used in the skin class. The following commonly appears at the top of each skin class file:

```
<s:Skin
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
```

You can set additional properties on the `<s:Skin>` tag, such as `minWidth` or `scaleX`. You can also set style properties such as `color` and `fontWeight`. In addition, you can specify values based on the state of the control on the root tag. For example, `color.down="0xFFFFFF"`. You cannot set the `includeIn` or `excludeFrom` properties on the root tag of the skin class.

If you create a custom theme for your application, or if you do not need support for global Spark styles in your custom skin class, you can use Skin rather than SparkSkin as your custom skin's root tag. The SparkSkin class adds support for the colorization styles (such as `chromeColor` and `symbolColor`) and supports excluding specific skin parts from colorization, or for specifying symbols to colorize.

Host components

Spark skin classes typically specify the host component on them. The host component is the component that uses the skin. By specifying the host component, Spark skins can gain a reference to the component instance that uses the skin by using the `hostComponent` property.

The following example from an MXML-based skin defines the Spark Button as the host component:

```
<fx:Metadata>
    [HostComponent("spark.components.Button")]
</fx:Metadata>
```

Adding the `[HostComponent]` metadata is optional, but it lets Flex perform compile-time checking for skin states and required skin parts. Without this metadata, no compile-time checking can be done.

You can specify a host component on an ActionScript-based skin, too. To do this, you declare a bindable public property called `hostComponent`. The `hostComponent` property must of the correct type. For example:

```
import spark.components.Button;
...
[Bindable]
public var hostComponent:Button;
```

The value of the `hostComponent` property is set by the component when the skin is loaded.

Skin states

Skin states are skin elements that are associated with component states. They are not the same as component states. For example, when a Button is down, the Button's skin displays elements that are associated with the `down` skin state. When the button is up, the button displays elements that are associated with the `up` skin state.

Skins must declare skin states that are defined on the host component. At runtime, the component sets the appropriate state on the skin. Skin states are referenced by using the dot-notation syntax, *`property.state`* (for example, `alpha.down` defines the value of the `alpha` property in the `down` state).

The following example shows the skin states for the Spark Button skin:

```
 <s:states>
    <s:State name="up" />
    <s:State name="over" />
    <s:State name="down" />
    <s:State name="disabled" />
</s:states>
```

Skin parts

Skin parts are components defined in the skin class and the host component. They often provide a way for a host component to push data into the skin. The component also uses skin parts to hook up behaviors.

Spark container skins include a content group that defines the group where the content children are pushed into and laid out in. This element has an ID of `contentGroup`. All skinnable containers have a `contentGroup`. The content group is a static skin part.

Layouts

Both the Skin and SparkSkin classes use BasicLayout as their default layout scheme. This is the equivalent of having the following defined in the skin class:

```
<s:layout>
    <s:BasicLayout/>
</s:layout>
```

The layout scheme is important when there is more than one graphical element or subcomponent used in the skin. BasicLayout relies on constraints and/or absolute positioning to determine where to place components.

Subcomponents

The Spark skin classes typically include graphic elements and other components that make up the appearance of the skin.

Script blocks

Optionally, the Spark skin class can include a Script block for skin-specific logic.

Most Spark skins have a special `<fx:Script>` block at the top of the skin class. This block typically defines style properties that the skin class respects, including the exclusions that the skin uses. The tag includes a special attribute, `fb:purpose="styling"`:

```
<fx:Script fb:purpose="styling">
```

This attribute is used by Flash Builder. When you create a copy of a skin class in Flash Builder, you can opt to make the skin styleable. If you choose to make it styleable, Flash Builder includes this section of the skin class. If you choose not to make the skin styleable, Flash Builder excludes this section.

Language tags

Like any MXML-based class, you can use the Library tag inside the root tag to declare repeatable element definitions. If you want to use non-visual objects in your skin class, you must wrap them in a Declarations tag.

Versions of included skin classes

While the new Spark skinning architecture makes creating your own skins easy, Flex 4 includes several sets of skins.

The following table describes the skinning packages that ship with Flex 4:

Package	Description
spark.skins.spark.*	Default skins for Spark components.
spark.skins.wireframe.*	A simplified theme for developing applications with a “prototype” look to them. To use wireframe skins, you can apply the wireframe theme or apply the skins on a per-component basis. For information about applying themes, see “Using themes” on page 1562.

Package	Description
mx.skins.halo.*	MX skins available for MX components that do not conform to the Spark skinning architecture. You can use these skins in your application instead of the Spark skins by overriding the styles, loading the Halo theme, or by setting the `compatibility-version` compiler option to 3.0.0 when compiling your application. For information about these skins, see "Skinning MX components" on page 1655.
mx.skins.spark.*	The default skins for MX components when using the default Spark theme. These skins are used by the MX components in Flex 4 applications. These skins give the MX components a similar appearance to the Spark components in Flex 4 applications.
mx.skins.wireframe.*	Wireframe skins for MX components.

Skins typically follow the naming convention *componentName*Skin.mxml. In the *ActionScript 3.0 Reference for the Adobe Flash Platform*, most skins have several versions. For example, there are four classes named ButtonSkin. The default skins for the Spark components are in the spark.skins.spark.* package.

Flex 4 also ships with several themes that use some of the skinning packages. For more information, see "About the included theme files" on page 1565.

Skinning contract

The *skinning contract* between a skin class and a component class defines the rules that each member must follow so that they can communicate with one another.

The skin class must declare skin states and define the appearance of skin parts. Skin classes also usually specify the host component, and sometimes bind to data defined on the host component.

The component class must identify skin states and skin parts with metadata. If the skin class binds to data on the host component, the host component must define that data.

The following table shows these rules of the skinning contract:

	Skin Class	Host Component

Host component	`<fx:Metadata>`
	`[HostComponent("spark.components.Button")]`
	`</fx:Metadata>`
		n/a

Skin states	`<s:states>`
	`<s:State name="up"/>`
	`</s:states>`
		`[SkinState("up")];`
		`public class Button {`
		`...`
		`}`

Skin parts	`<s:Button id="upButton"/>`	`[SkinPart(required="false")]`
		`public var upButton:Button;`

Data	`text="{hostComponent.title}"`	`[Bindable]`
		`public var title:String;`

The compiler validates the `[HostComponent]`, `[SkinPart]`, and `[SkinState]` metadata (as long as the `[HostComponent]` metadata is defined on the skin). This means that skin states and skin parts that are identified on the host component must be declared in the skin class.

For each [SkinPart] metadata in the host component, the compiler checks that a public variable or property exists in the skin. For each [SkinState] metadata in the host component, the compiler checks that a state exists in the skin. For skins with [HostComponent] metadata, the compiler tries to resolve the host component class, so it must be fully qualified.

After you have a valid contract between a component and its skin class, you can apply the skin to the component.

Accessing host components

Spark skins optionally specify a host component. This is not a reference to an instance of a component, but rather, to a component class. You define the host component by using a [HostComponent] metadata tag with the following syntax:

```
<fx:Metadata>
    [HostComponent(component_class)]
</fx:Metadata>
```

For example:

```
<fx:Metadata>
    [HostComponent("spark.components.Button")]
</fx:Metadata>
```

When a skin defines this metadata, Flex creates the typed property hostComponent on the skin class. You can then use this property to access members of the skin's host component instance from within the skin. For example, in a Button skin, you can access the Button's style properties or its data (such as the label).

You can access public properties of the skin's host component by using the strongly typed hostComponent property as a reference to the component.

```
<s:SolidColor color="{hostComponent.someColor as uint}" />
```

This only works with public properties that are declared directly on the host component. You cannot use this to access the host component's private or protected properties.

To access the values of style properties on a host component from within a skin, you are not required to specify the host component. You can use the getStyle() method as the following example shows:

```
<s:SolidColorStroke color="{getStyle('color')}" weight="1"/>
```

You can also access the root application's properties and methods by using the FlexGlobals.topLevelApplication property. For more information, see "Accessing application properties" on page 1623.

Defining skin states

Each skinnable component has a set of visual skin states. For example, when a Button is down, the Button's skin displays elements that are associated with the down skin state. When the button is up, the button displays elements that are associated with the up skin state.

To have a valid contract between a skinnable Spark component and its skin, you identify the skin states in the component. Then, define the state's appearance in the component's skin class.

Skin states are declared in the skin class and identify the different states that the component can assume visually. You can define how the visual appearance changes as the skin's state changes in the skin class.

Subclasses inherit the skin states of their parent. For example, the Button class defines the skin states up, down, over, and disabled. The ToggleButton class, which is a subclass of Button, declares the upAndSelected, overAndSelected, downAndSelected, and disabledAndSelected skin states, in addition to those states defined by the Button control.

Identifying skin states in a component

Part of the contract between a Spark skin and its host component is that the host component must identify the skin states that it supports. To identify a skin state in the component's class, you use the `[SkinState]` metadata tag. This tag has the following syntax:

```
[SkinState("state")]
```

You specify the metadata before the class definition. The following example defines four skin states for the Button control:

```
[SkinState("up")]
[SkinState("over")]
[SkinState("down")]
[SkinState("disabled")]
public class Button extends Component { .. }
```

Defining the skin states in the skin class

The Spark skinning contract requires that you declare supported skin states in the skin class. You can also optionally define the appearance of the skin state in the skin class. Even if you declare a skin state in the skin class, you are not required to define its appearance.

To define a skin state in a skin class:

1. Declare the skin state in a `<states>` tag.
2. Set the value of properties based on the state of the component. This step is optional, but if you don't define the skin state's appearance, then the skin does not change when the component enters that state.

To declare skin states in the skin class, you populate the top-level `<s:states>` tag with an array of State objects. Each State object corresponds to one skin state.

The following example defines four states supported by the Button skin class:

```
<s:Skin ...>
    <s:states>
        <s:State name="up"/>
        <s:State name="over"/>
        <s:State name="down"/>
        <s:State name="disabled"/>
    </s:states>
    ...
</s:Skin>
```

After you declare the skin states in the skin class, you can then define the appearance of the skin states. To do this, you specify the values of the properties based on the skin state by using the dot-notation syntax (*`property_name.state_name`*). To set the value of the `weight` property of a SolidColorStroke object in the `over` state, you specify the value on the `weight.over` property, as the following example shows:

```
<s:SolidColorStroke color="0x000000" weight="1" weight.over="2"/>
```

You can also specify the stateful values of properties by using the `includeIn` and `excludeFrom` properties.

Most commonly, you specify values of style properties based on the state. Flex applies the style based on the current state of the component. The skin is notified when the component's `currentState` property changes, so the skin can update the appearance at the right time.

A common use of this in the Spark skins is to set the `alpha` property of a component when the component is in its `disabled` state. This is often set on the top-level tag in the skin class, as the following example from the ButtonSkin class shows:

```
<s:Skin
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    minWidth="21" minHeight="21"
    alpha.disabled="0.5">
```

Another example is when a Button label's `alpha` property changes based on other states. The skin sets the value of the labelDisplay's `alpha` property. When the button is in its `up` state, the label has an `alpha` of 1. When the button is in its `over` state, the label has an `alpha` of .25, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning/StatesButtonExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:Button label="Alpha Changes" skinClass="mySkins.MyAlphaButtonSkin"/>
</s:Application>
```

The skin class for this example is as follows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning\mySkins\MyAlphaButtonSkin.mxml -->
<s:Skin
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    minWidth="21" minHeight="21">

    <fx:Metadata>
        [HostComponent("spark.components.Button")]
    </fx:Metadata>

    <!-- Specify one state for each SkinState metadata in the host component's class -->
    <s:states>
        <s:State name="up"/>
        <s:State name="over"/>
        <s:State name="down"/>
        <s:State name="disabled"/>
    </s:states>
    <s:Rect left="0" right="0" top="0" bottom="0" width="69" height="20" radiusX="2"
radiusY="2">
        <s:stroke>
            <s:SolidColorStroke color="0x000000" weight="1"/>
        </s:stroke>
    </s:Rect>

    <s:Label id="labelDisplay"
        alpha.up="1"
        alpha.down=".1"
        alpha.over=".25"
        horizontalCenter="0" verticalCenter="1"
        left="10" right="10" top="2" bottom="2">
    </s:Label>
</s:Skin>
```

You can set any property on a component based on the state. You are not limited to style properties. For example, you can change the label of a Button control in its skin based on its state, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning/ChangeLabelBasedOnStateExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
   <s:Button id="myButton" label="Basic Button" skinClass="mySkins.ChangeLabelBasedOnState"/>
</s:Application>
```

The custom skin class for this example is as follows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning\mySkins\ChangeLabelBasedOnState.mxml -->
<s:Skin
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    minWidth="21" minHeight="21">
    <fx:Metadata>
        [HostComponent("spark.components.Button")]
    </fx:Metadata>

    <!-- Specify one state for each SkinState metadata in the host component's class -->
    <s:states>
        <s:State name="up"/>
        <s:State name="over"/>
        <s:State name="down"/>
        <s:State name="disabled"/>
    </s:states>
    <s:Rect left="0" right="0" top="0" bottom="0" width="69" height="20" radiusX="2"
radiusY="2">
        <s:stroke>
            <s:SolidColorStroke color="0x000000" weight="1"/>
        </s:stroke>
       <!-- Add this fill to make the "hit area" cover the entire button. -->
       <s:fill>
            <s:SolidColor color="0xFFFFFF"/>
       </s:fill>
    </s:Rect>

    <s:Label id="labelDisplay"
         text.up="UP" text.over="OVER" text.down="DOWN"
         horizontalCenter="0" verticalCenter="1"
         left="10" right="10" top="2" bottom="2">
    </s:Label>
</s:Skin>
```

If you identify a skin state on the component, but do not declare it on the skin class, Flex throws a compiler error if the `[HostComponent]` metadata is set. You are not required to define the appearance of the skin state in the skin class, but you are required to declare it in the skin class in this case.

If you try to set the value of a style property in a skin class on a state that is not identified by the host component's class, Flex throws a compiler error. This error checking helps to enforce the contract between the component and the skin.

In addition to conditionalizing the values of properties, you can also include or exclude graphic elements from the skin based on the component's state. To do this, you use the `includeIn` and `excludeFrom` properties to define which states a graphic element applies to.

The following example displays a partially transparent gray box when the Button control is in the `down` state:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning/IncludeButtonExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:Button label="Click Me In the Button Class" skinClass="mySkins.MyIncludeButtonSkin"
color="0xCCC333"/>
</s:Application>
```

The custom skin class for this example is as follows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning\mySkins\MyIncludeButtonSkin.mxml -->
<s:Skin
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    minWidth="21" minHeight="21">
    <fx:Metadata>
        [HostComponent("spark.components.Button")]
    </fx:Metadata>

    <!-- Specify one state for each SkinState metadata in the host component's class -->
    <s:states>
        <s:State name="up"/>
        <s:State name="over"/>
        <s:State name="down"/>
        <s:State name="disabled"/>
    </s:states>
    <s:Rect left="0" right="0" top="0" bottom="0" width="69" height="20" radiusX="2"
radiusY="2">
        <s:stroke>
            <s:SolidColorStroke color="0x000000" weight="1"/>
        </s:stroke>
    </s:Rect>

    <s:Label id="labelDisplay"
        horizontalCenter="0" verticalCenter="1"
        left="10" right="10" top="2" bottom="2">
    </s:Label>
    <!-- Highlight (down state only) -->
    <!-- Note that you might need to adjust the radiusX and radiusY properties. -->
    <s:Rect left="0" right="0" top="0" bottom="0" width="69" height="20" includeIn="down">
        <s:fill>
            <s:SolidColor color="0x000000" alpha="0.25"/>
        </s:fill>
    </s:Rect>
</s:Skin>
```

When you exclude a graphic element with the `excludeFrom` property, Flex removes it from its parent's child list. The element can no longer be referenced.

If you do not specify either the `includeIn` or `excludeFrom` property for a graphic element in a skin class, the graphic element is used in all states of the control by default.

You can specify multiple states to be included or excluded by using a comma-separated list of states for the `includeIn` or `excludeFrom` properties. The following example excludes the Rect graphic element from the host component's `over` and `down` states:

```
<s:Rect left="0" right="0" top="0" bottom="0" width="69" height="20" excludeFrom="over, down">
```

The `excludeFrom` and `includeIn` properties can be set only in MXML. You cannot set the values of these properties in ActionScript.

All classes support the `includeIn` and `excludeFrom` properties when they are used in the skin class, as long as they are a visual child of a visual parent. This means that you cannot set these properties on the root tag of the skin file, nor can you set them on scalar properties. For example, the following shows a valid and an invalid use of the `includeIn` property:

```
<s:states>
    <s:State name="StateA" />
</s:states>

<!-- This is a valid use of the includeIn property: -->
<s:Button>
    <s:label.StateA>
        <fx:String>My Label</fx:String>
    </s:label.StateA>
</s:Button>

<!-- This is an invalid use of the includeIn property: -->
<s:Button>
    <s:label>
        <fx:String includeIn="StateA">My Label</fx:String>
    </s:label>
</s:Button>
```

If you exclude some graphic elements from a skin, the component sometimes resizes itself or its appearance fluctuates as it cycles through its states. For example, if you set the value of the `excludeFrom` property to `down` on a button skin's labelDisplay, the label disappears when the user clicks the button. As a result, the button resizes itself in the `down` state. This behavior is expected and is shown in the following example:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning/HideLabelOnDownExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:Button id="myButton"
        skinClass="mySkins.HideLabelOnDownSkin"
        label="This Is A Long Button Label"/>
</s:Application>
```

The custom skin class for this example is as follows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning\mySkins\HideLabelOnDownSkin.mxml -->
<s:Skin
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    minWidth="21" minHeight="21">
    <fx:Metadata>
        [HostComponent("spark.components.Button")]
    </fx:Metadata>

    <!-- Specify one state for each SkinState metadata in the host component's class -->
    <s:states>
        <s:State name="up"/>
        <s:State name="over"/>
        <s:State name="down"/>
        <s:State name="disabled"/>
    </s:states>
    <s:Rect
        left="0" right="0"
        top="0" bottom="0"
        width="69" height="20"
        radiusX="2" radiusY="2">
        <s:stroke>
            <s:SolidColorStroke color="0x000000" weight="1"/>
        </s:stroke>
    </s:Rect>

    <s:Label id="labelDisplay"
         excludeFrom="down"
         horizontalCenter="0" verticalCenter="1"
         left="10" right="10" top="2" bottom="2">
    </s:Label>
</s:Skin>
```

The button resizes because its size is dynamically determined by the contents of the label by default. Excluding the label results in the label being removed from its parent.

To prevent the Button from resizing itself, you can set the `alpha.down` property to 0 or the `visible.down` property to `false` rather than excluding the component altogether. The label then disappears but the button does not resize itself because the label is not removed from its parent, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning/HideLabelOnDownExample2.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:Button id="myButton"
        skinClass="mySkins.HideLabelOnDownSkin2"
        label="This Is A Long Button Label"/>
</s:Application>
```

The custom skin class for this example is as follows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning\mySkins\HideLabelOnDownSkin2.mxml -->
<s:Skin
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    minWidth="21" minHeight="21">
    <fx:Metadata>
        [HostComponent("spark.components.Button")]
    </fx:Metadata>

    <!-- Specify one state for each SkinState metadata in the host component's class -->
    <s:states>
        <s:State name="up"/>
        <s:State name="over"/>
        <s:State name="down"/>
        <s:State name="disabled"/>
    </s:states>
    <s:Rect
        left="0" right="0"
        top="0" bottom="0"
        width="69" height="20"
        radiusX="2" radiusY="2">
        <s:stroke>
            <s:SolidColorStroke color="0x000000" weight="1"/>
        </s:stroke>
    </s:Rect>

    <s:Label id="labelDisplay"
         visible.down="false"
         horizontalCenter="0" verticalCenter="1"
         left="10" right="10" top="2" bottom="2">
    </s:Label>
</s:Skin>
```

Skin parts

Some components have multiple skin parts. For example, a NumericStepper contains an up button, a down button, and text. These parts are declared by the component. The skin defines their appearance. Parts defined by the component can be optional or required in the skin.

Skin parts are an important part of the skinning contract. They let the component instance interact with the skin and can be used to push data down into a skin or to define behaviors.

Skin parts do not have to be top-level tags in the Spark skin class. They can be anywhere in the MXML file.

To declare a skin part on a component, you use the `[SkinPart]` metadata. For example, the Button class defines a skin part for the label in the ButtonBase class:

```
[SkinPart(required="false")]
public var labelDisplaIDisplayText;
```

The ButtonSkin class defines a Label component as the labelDisplay part:

```
 <s:Label id="labelDisplay"
    textAlign="center"
    verticalAlign="middle"
     maxDisplayedLines="1"
    horizontalCenter="0" verticalCenter="1"
    left="10" right="10" top="2" bottom="2">
</s:Label>
```

In this example, the `labelDisplay` skin part is technically not required (`required="false"`), but without it, Flex would not draw a label on the Button control. The default value for the `required` property is `false`. The contract between the Button class and its skin dictates that when you set the `label` property on a button, the value is pushed down into the skin and modifies the value of the labelDisplay skin part's text, if the `labelDisplay` skin part exists.

Parts are identified by their `id` attributes. The `id` attribute of the skin part in the skin class must match the property name of the skin part in the host component. This helps enforce the contract between the skin and the host component. For example, if you have the following declaration in your component:

```
[SkinPart(required="true")]
public var textInput:TextInput;
```

The skin class sets the `id` attribute of a TextInput instance to "textInput", as the following example shows:

```
<s:TextInput id="textInput" ... />
```

There are two primary types of skin parts: static and dynamic. *Static parts* are instantiated automatically by the skin. There can be only one instance of a static part. For example, the VScrollBar class has four static parts: track, thumb, incrementButton, and descrementButton. The Button class has one static part: label.

Dynamic parts are instantiated when needed. There can be more than one instance of a dynamic part. Dynamic parts are defined in the Declarations block of a skin so that one or more instances of the part can be instantiated and used by the skin. The Slider class's DataTip, for example, is a dynamic skin part. In the VSliderSkin and HSliderSkin, the dataTip skin part is defined in a Declarations block.

In your host component, you specify the type for a dynamic skin part as an IFactory. For example, in the Slider class, the dataTip is defined as:

```
[SkinPart(required="false", type="mx.core.IDataRenderer")]
public var dataTip:IFactory;
```

At runtime, when a component skin is loaded, the SkinnableComponent base class finds all the skin parts, assigns parts that were found, and throws a runtime error if any required parts are not defined by the skin. Deferred parts are found (because they are defined properties of the skin), but have a value of null when the component is first instantiated.

Applying skin classes to a component

After you have defined a skin, you can apply it to a component in one of the following ways:

- CSS
- MXML
- ActionScript

To associate a skin with a component in CSS, you set the value of the `skinClass` style property in the style sheet. You can use either type or class selectors to apply a skin class to a component.

The following example applies the mySkins.NewPanelSkin class with all Panel containers by using a type selector:

```
@namespace s "library://ns.adobe.com/flex/spark";
s|Panel {
    skinClass:ClassReference("mySkins.NewPanelSkin");
}
```

The following example associates the mySkins.CustomButtonSkin class with all components that use the myButtonStyle class selector:

```
.myButtonStyle {
    skinClass:ClassReference("mySkins.CustomButtonSkin");
}
...
<s:Button label="Spark Button" className="myButtonStyle"/>
```

To associate a skin with a component in MXML, you set the value of the `skinClass` property inline. The following example applies the mySkins.NewPanelSkin class to this instance of the Panel container:

```
<s:Panel skinClass="mySkins.NewPanelSkin"/>
```

The advantage to applying skins with CSS is that with CSS you can use type and class selectors to apply the skin to all components of a particular type (such as all Buttons) or all classes that are in a particular class (such as all components with the style name “myButtonStyle”).

CSS supports inheritance. If you apply a skin class to a Button control in the Button type selector, the skin applies to all Button controls and subclasses of Button controls, such as the ToggleButton control. This can have unexpected results in the case of subcomponents. If you apply a new skin to all Label controls, components that have Label subcomponents will also use that skin. As a result, you should generally use class selectors for applying skins to basic components.

Setting a skin class in MXML lets you only apply the skin to the instance of the component.

You can also apply a skin class to a component in ActionScript. Call the `setStyle()` method on the component, and set the value of the `skinClass` style property to the skin class. You must cast the skin class as a Class in the `setStyle()` method.

The following example applies the custom skin class to the Button when you click the Button:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning/SimpleLoadExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        import mySkins.*;

        private function changeSkinClickHandler():void {
            myButton.setStyle("skinClass", Class(MyButtonSkin));
        }
    </fx:Script>
    <s:Button id="myButton"
        label="Click Me"
        color="0xFFFFF"
        click="changeSkinClickHandler()"/>
</s:Application>
```

The custom skin class for this example is as follows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning\mySkins\MyButtonSkin.mxml -->
<s:Skin
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    minWidth="21" minHeight="21">
    <fx:Metadata>
        [HostComponent("spark.components.Button")]
    </fx:Metadata>

    <!-- Specify one state for each SkinState metadata in the host component's class -->
    <s:states>
        <s:State name="up"/>
        <s:State name="over"/>
        <s:State name="down"/>
        <s:State name="disabled"/>
    </s:states>
    <s:Rect left="0" right="0" top="0" bottom="0" width="69" height="20" radiusX="2" 
radiusY="2">
        <s:stroke>
            <s:SolidColorStroke color="0x000000" weight="1"/>
        </s:stroke>
    </s:Rect>

    <s:Label id="labelDisplay"
             horizontalCenter="0" verticalCenter="1"
             left="10" right="10" top="2" bottom="2">
    </s:Label>
</s:Skin>
```

Be sure to import the appropriate skin class package before you can use the class in your application.

As with CSS, you can use ActionScript to apply a skin class to all instances of a particular component type. Call the `setStyle()` method on the component's style declaration. The following example applies the custom Button skin to all buttons in the application:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning/ASTypeSelectorLoadExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        import mySkins.*;

        private function changeSkinClickHandler():void {
           styleManager.getStyleDeclaration("spark.components.Button").setStyle("skinClass",
Class(MyButtonSkin));
        }
    </fx:Script>
    <s:Button id="myButton1" label="Click Me" color="0xFFFFF"
        click="changeSkinClickHandler()"/>
    <s:Button id="myButton2" label="Click Me" color="0xFFFFF"
        click="changeSkinClickHandler()"/>
    <s:Button id="myButton3" label="Click Me" color="0xFFFFF"
        click="changeSkinClickHandler()"/>
</s:Application>
```

Documenting skin states and skin parts

The ASDoc utility supports documenting the `[SkinState]` and `[SkinPart]` metadata tags.

You can document the `[SkinState]` metadata tag by adding comments above the tag in the component's class file, as the following example shows:

```
/**
* Up state of the button.
*/
[SkinState("up")]
```

To document a `[SkinPart]` metadata tag, the ASDoc utility uses the description of the variable from the component's class file. You do not add a comment on the actual metadata tag, as the following example shows:

```
[SkinPart(required="false")]
/**
* A skin part that defines the  label of the button.
*/
public var labelDisplay:TextGraphicElement;
```

The ASDoc utility adds skin state documentation to the "Skin States" section of the class's documentation. It adds skin part documentation to the "Skin Parts" section of the class's documentation.

For more information about the ASDoc utility, see "ASDoc" on page 2241.

Creating skins from source files

When creating a custom Spark skin, the easiest way to get started is to use the source of an existing skin of a similar type as your base class. You can use the default Spark skins as a good starting point for creating skins, or the skins in the Wireframe theme. The Wireframe theme defines a set of simple skins that provide a "prototype" look to the application. They are lighter weight than the default skins but have less functionality.

The default Spark skins are more heavyweight than the Wireframe skins, but they let you maintain the default Spark look and feel. For example, if you are creating a custom Button skin, you can open the spark.skins.spark.ButtonSkin.mxml file. Save this file in a different location with a different name. You can then edit the contents of this file for your new custom skin.

The default skins have names that are similar to the component class name (for example, ToggleButton uses the ToggleButtonSkin class). If you are unsure of the skin class name is used by a component, look in the defaults.css file. This style sheet defines all the default skin classes for the components that have them.

In Flash Builder, you can create a new skin based on an existing skin in Design Mode. In the Properties view, click the Pencil icon for Skin and select Create New Copy of Skin. Flash Builder creates a file that implements a Skin class for the selected component. Flash Builder modifies the application file by specifying the new skin class as the `skinClass` property of the current component. Flash Builder also opens the generated Skin class file in Design mode of the MXML editor. For more information on using Flash Builder to design custom skins, see Generate and edit skins for Spark components.

When you copy a skin in Flash Builder, you can optionally include the style information to make the skin styleable. If you do not, then Flash Builder removes the style block that is tagged with `fx:purpose="styling"`. The skin will look similar, but will not respect styles such as `chromeColor`, `color`, and the exclusions.

Skins commonly contain graphic elements such as rectangles, lines, and ellipses, as well as visual effects such as blend modes, transforms, and filters. Using these graphic elements, sometimes referred to as MXML graphics, is simple and integrates well with most skins. For more information, see “MXML graphics” on page 1730.

Another way to create a spark skin is to generate its graphical elements from a tool that outputs FXG. FXG is a graphics interchange format that defines vector graphic elements. You can create a graphic in a tool such as Adobe Illustrator that can then export the instructions for drawing that graphic in the FXG format. You can either use the exported FXG as a component in your skin class, or you can convert the FXG syntax to use in your Spark skin class to define the appearance of your skins. Using FXG output as a custom component in your skin class is more efficient because the compiler optimizes FXG custom component source code. For more information about using FXG and converting it to MXML graphics, see “FXG” on page 1719.

Skinning Spark components

All Spark components and subcomponents that are subclasses of SkinnableComponent can be reskinned. Common tasks when reskinning Spark components include adding borders, drop shadows, and transitions to a skin class.

Setting minimum sizes of a skin

A common task when creating Spark skins is to set minimum sizes of the skin. This causes the Flex layout to not reduce the size of a component below a pre-defined width or height. You do this with the `minWidth` and `minHeight` properties on the skin class’s top-level element.

In general, you should not change the values of the minimum height and minimum width properties once they are set.

The following example creates a custom Button skin that has a minimum width of 100 pixels and a minimum height of 100 pixels.

```
<?xml version="1.0"?>
<!-- SparkSkinning/SquareButtonExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:Button id="myButton" skinClass="mySkins.SquareButtonSkin" label="Click Me"/>

</s:Application>
```

The following is the custom skin class used for this example:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning/mySkins/SquareButtonSkin.mxml -->
<s:SparkSkin
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    minWidth="100" minHeight="100"
    alpha.disabled="0.5">
    <fx:Metadata>
        [HostComponent("spark.components.Button")]
    </fx:Metadata>

    <fx:Script>
        <![CDATA[
            static private const exclusions:Array = ["labelDisplay"];
            override public function get colorizeExclusions():Array {return exclusions;}
        ]]>
    </fx:Script>

    <s:states>
        <s:State name="up" />
        <s:State name="over" />
        <s:State name="down" />
        <s:State name="disabled" />
    </s:states>

    <!-- layer 1: shadow -->
    <s:Rect left="-1" right="-1" top="-1" bottom="-1" radiusX="2" radiusY="2">
        <s:fill>
            <s:LinearGradient rotation="90">
                    <s:GradientEntry color="0x000000"
                                  color.down="0xFFFFFF"
                                  alpha="0.01"
                                  alpha.down="0" />
                    <s:GradientEntry color="0x000000"
                                  color.down="0xFFFFFF"
                                  alpha="0.07"
                                  alpha.down="0.5" />
            </s:LinearGradient>
        </s:fill>
    </s:Rect>

    <!-- layer 2: fill -->
    <s:Rect left="1" right="1" top="1" bottom="1" radiusX="2" radiusY="2">
        <s:fill>
```

```
            <s:LinearGradient rotation="90">
                <s:GradientEntry color="0xFFFFFF"
                               color.over="0xBBBDBD"
                               color.down="0xAAAAAA"
                               alpha="0.85" />
                <s:GradientEntry color="0xD8D8D8"
                               color.over="0x9FA0A1"
                               color.down="0x929496"
                               alpha="0.85" />
            </s:LinearGradient>
        </s:fill>
    </s:Rect>

    <!-- layer 2: border -->
    <s:Rect left="0" right="0" top="0" bottom="0" width="69" height="20" radiusX="2"
radiusY="2">
        <s:stroke>
            <s:LinearGradientStroke rotation="90" weight="1">
                <s:GradientEntry color="0x000000"
                               alpha="0.5625"
                               alpha.down="0.6375" />
                <s:GradientEntry color="0x000000"
                               alpha="0.75"
                               alpha.down="0.85" />
            </s:LinearGradientStroke>
        </s:stroke>
    </s:Rect>
    <s:Label id="labelDisplay"
             textAlign="center"
             verticalAlign="middle"
             lineBreak="toFit"
             horizontalCenter="0" verticalCenter="1"
             left="10" right="10" top="2" bottom="2">
    </s:Label>

</s:SparkSkin>
```

The default Button skin's minimum size is 21 pixels wide by 21 pixels high. These minimums are set on the root tag of the skin class, as the following example shows:

```
<s:SparkSkin
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    minWidth="21" minHeight="21"
    alpha.disabled="0.5">
    ...
</s:SparkSkin>
```

You might notice that in the default button skin's class, though, the Rect border sets its width to a value that is larger than the minimum width on the skin:

```
 <s:Rect id="border" left="0" right="0" top="0" bottom="0" width="69" height="20" radiusX="2">
```

The `width` property on the Rect border is used for buttons whose size is unset. The `minWidth` property on the SparkSkin is used when the button's width is variable, meaning that it hasn't been explicitly set. The previous example sets a default width and height of 69 and 20. However, it is pinned to (left=0, right=0, top=0, bottom=0) so that if the label is too large or the button is explicitly sized, then this rectangle will resize.

Accessing application properties

In addition to accessing the host component's properties, you can access properties of the application. This is useful if there are global settings that you want to access, or runtime information that is passed into the application that you want available in the skin class.

To access global variables in a custom skin, you use the `FlexGlobals.topLevelApplication` property. Using this property gives you access to all global variables, including variables that were passed into the application as `flashVars` variables.

The following example accesses a String that is a global variable on the application:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning/GlobalVariableAccessorExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        public var myLabelString:String = "Hello World";
    </fx:Script>
    <s:Button skinClass="mySkins.GlobalVariableAccessorSkin"/>
</s:Application>
```

The following is the custom skin class for this example:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning\mySkins\GlobalVariableAccessorSkin.mxml -->
<s:Skin
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    minWidth="21" minHeight="21">
    <fx:Metadata>
        [HostComponent("spark.components.Button")]
    </fx:Metadata>
    <fx:Script>
        import mx.core.FlexGlobals;

        [Bindable]
        private var localString:String = FlexGlobals.topLevelApplication.myLabelString;
    </fx:Script>

    <!-- Specify one state for each SkinState metadata in the host component's class -->
    <s:states>
        <s:State name="up"/>
        <s:State name="over"/>
        <s:State name="down"/>
        <s:State name="disabled"/>
    </s:states>
    <s:Rect
        left="0" right="0"
        top="0" bottom="0"
        width="69" height="20"
        radiusX="2" radiusY="2">
        <s:stroke>
            <s:SolidColorStroke color="0x000000" weight="1"/>
        </s:stroke>
    </s:Rect>

    <s:Label id="labelDisplay"
        text="{localString}"
        horizontalCenter="0" verticalCenter="1"
        left="10" right="10" top="2" bottom="2">
    </s:Label>
</s:Skin>
```

Using style properties in custom skins

Within the skin, you can get the value of certain style properties on the host component. The component declares what styles can be set so that they can be set inline in MXML. For example, you can set the `chromeColor` property on all skins that extend the SparkSkin class. On other skins, such as container skins, you can set the `backgroundColor`.

The following example sets the color of the border inside the skin to the same value as the Button's `color` style property:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning/BorderColorButtonExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:Button id="myButton"
        label="Basic Button"
        skinClass="mySkins.BorderColorButtonSkin"
        color="green"/>
</s:Application>
```

The following is the skin class for this example:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning\mySkins\BorderColorButtonSkin.mxml -->
<s:Skin
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    minWidth="21" minHeight="21"
    creationComplete="initSkin()">

    <fx:Script>
        private function initSkin():void {
            /* Note that because color can change, you could override the
                updateDisplayList() method and set it there so that the
                color is updated in the skin when it is updated on the
                host component. */
            outline.color = getStyle('color');
        }
    </fx:Script>

    <fx:Metadata>
        [HostComponent("spark.components.Button")]
    </fx:Metadata>

    <!-- Specify one state for each SkinState metadata in the host component's class -->
    <s:states>
        <s:State name="up"/>
        <s:State name="over"/>
        <s:State name="down"/>
        <s:State name="disabled"/>
    </s:states>
    <s:Rect left="0" right="0" top="0" bottom="0" width="69" height="20" radiusX="2" 
radiusY="2">
        <s:stroke>
            <s:SolidColorStroke id="outline" weight="1"/>
        </s:stroke>
    </s:Rect>

    <s:Label id="labelDisplay"
        horizontalCenter="0" verticalCenter="1"
        left="10" right="10" top="2" bottom="2">
    </s:Label>
</s:Skin>
```

You can use a binding expression to set properties in the skin based on values in the host component. The following example binds the value of the stroke’s `color` property to the host component’s `color` style property:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning/StyleWatcherExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:Button id="myButton"
        label="Basic Button"
        skinClass="mySkins.StyleWatcherSkin"
        click="myButton.setStyle('color','red')"
        color="green"/>
</s:Application>
```

The following is the skin class for this example:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning\mySkins\StyleWatcherSkin.mxml -->
<s:Skin
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    minWidth="21" minHeight="21">

    <fx:Metadata>
        [HostComponent("spark.components.Button")]
    </fx:Metadata>

    <!-- Specify one state for each SkinState metadata in the host component's class -->
    <s:states>
        <s:State name="up"/>
        <s:State name="over"/>
        <s:State name="down"/>
        <s:State name="disabled"/>
    </s:states>
    <s:Rect left="0" right="0" top="0" bottom="0" width="69" height="20" radiusX="2"
radiusY="2">
        <s:stroke>
            <!-- Match the border color to the button label's color. -->
            <s:SolidColorStroke color="{getStyle('color')}" weight="1"/>
        </s:stroke>
    </s:Rect>

    <s:Label id="labelDisplay"
        horizontalCenter="0" verticalCenter="1"
        left="10" right="10" top="2" bottom="2">
    </s:Label>
</s:Skin>
```

This example sets the color of the stroke when the application starts. When you click the Button, the `color` property later changes while the application is running because style properties are bindable.

For custom components, you must declare the style metadata on the component itself so that inline MXML styling will work.

To expose a property as a style, you can also define a getter and setter for the property. You then override the `styleChanged()` method to dispatch the binding change event. In the application, you call the `setStyle()` method on the instance's `skin` property, which sets the value of the style property on the skin.

The following example exposes a custom style property called `borderColor` on the custom skin:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning/mySkins/StyleableBorderSkin.mxml -->
<s:Skin
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    alpha.disabled="0.5">

    <fx:Script>
        [Bindable("borderColorChange")]

        public function get borderColor():uint {
            return getStyle("borderColor");
        }

        public function set borderColor(value:uint):void {
            setStyle("borderColor", value);
        }
        override public function styleChanged(styleProp:String):void {
            super.styleChanged(styleProp);
            if (styleProp == "borderColor" || styleProp == null)
                dispatchEvent(new Event("borderColorChange"));
        }
    </fx:Script>
    <fx:Metadata>
        [HostComponent("spark.components.SkinnableContainer")]
    </fx:Metadata>
    <s:states>
        <s:State name="normal" />
        <s:State name="disabled" />
    </s:states>
    <s:Group id="contentGroup" left="0" right="0" top="0" bottom="0">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
    </s:Group>
    <s:Rect left="0" right="0" top="0" bottom="0">
        <s:stroke>
            <s:SolidColorStroke color="{borderColor}" weight="1"/>
        </s:stroke>
    </s:Rect>
</s:Skin>
```

In the following application, you set the color of the border by using the ColorPicker control. This control uses the `setStyle()` method to change the color of the container's border.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning/StyleableBorderExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark" height="250" width="450">
    <s:layout>
        <s:HorizontalLayout/>
    </s:layout>
    <fx:Script>
        private function setSkinStyles(e:Event):void {
            myContainer.setStyle("borderColor",e.currentTarget.selectedColor);
        }
    </fx:Script>
    <s:SkinnableContainer id="myContainer"
        height="200" width="200"
        skinClass="mySkins.StyleableBorderSkin">
    </s:SkinnableContainer>

    <mx:ColorPicker id="myColorPicker" change="setSkinStyles(event)"/>
</s:Application>
```

Another way to expose style properties to the skin is to add code to the `updateDisplayList()` method to manually push style values into the skin's graphics. This is the more efficient method of pushing style properties to skins because it does not rely on binding. The following example overrides the `updateDisplayList()` method to push the background color's style property:

```
<fx:Script>
    override protected function updateDisplayList(unscaleWidth:Number,
unscaledHeight:Number):void {
        // Push style values into the graphics properties before calling
super.updateDisplayList
        backgroundFill.color = getStyle("backgroundColor");
        // Call super.updateDisplayList to do the rest of the work
        super.updateDisplayList(unscaledWidth, unscaledHeight);
    }
</fx:Script>
<s:Rect left="0" right="0" top="0" bottom="0">
    <s:SolidColor id="backgroundFill" />
</s:Rect>
```

Using events in custom skins

In general, you should use states to react to user interaction. If a skin part is removed from display list whenever the mouse hovers over a control, then that part cannot receive mouseDown events. Some skins, such as the Button control's skin, block user interaction to the skin so that the underlying control only can dispatch events. This means that you cannot trigger events defined on InteractiveObject on the skin. These include user interaction events such as `mouseDown`, `mouseOut`, and `click`.

You can trigger events defined on UIComponent on the skin, however. These events include `creationComplete` and other lifecycle events.

A Button control's default skin defines several Rect elements and a Label control. These simple classes do not support any events. To add lifecycle event listeners, you can wrap a simple element or series of elements in a Group tag. This lets you register lifecycle events that are defined on UIComponent.

The following example shows a Group inside the skin that triggers a `creationComplete` event:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning/mySkins/LifecycleEventExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    height="200" width="200">
    <s:layout>
        <s:HorizontalLayout/>
    </s:layout>
    <s:Group width="150" height="100">
        <s:Button label="Click It or Ticket" skinClass="mySkins.LifecycleEventSkin"/>
    </s:Group>
</s:Application>
```

The custom skin class for this example is as follows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning\mySkins\LifecycleEventSkin.mxml -->
<s:Skin
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    minWidth="21" minHeight="21">
    <fx:Metadata>
        [HostComponent("spark.components.Button")]
    </fx:Metadata>

    <s:states>
        <s:State name="up"/>
        <s:State name="over"/>
        <s:State name="down"/>
        <s:State name="disabled"/>
    </s:states>
    <s:Rect id="buttonBorder" width="100%" height="20" radiusX="2" radiusY="2">
        <s:stroke>
            <mx:SolidColorStroke color="0x000000" weight="1" weight.over="2"/>
        </s:stroke>
    </s:Rect>

    <s:Group creationComplete="trace('creationComplete')">
        <s:Label id="labelDisplay"
            horizontalCenter="0" verticalCenter="1"
            left="10" right="10" top="6" bottom="2">
        </s:Label>
    </s:Group>
</s:Skin>
```

Skinning Spark containers

Spark defines two types of containers:

- Skinnable containers
- Non-skinnable containers

Both types of containers are in the spark.components.* package. Most Spark containers are skinnable. For example, the SkinnableContainer, Panel, and TitleWindow containers are skinnable. Skinnable containers subclass the SkinnableContainer class.

Spark groups are examples of containers that are not skinnable. They provide a lightweight mechanism that you use to perform layout. However, Spark groups do not support skinning to ensure that they add minimal overhead to your application. To modify the visual appearance of a Spark group, you can use the corresponding Spark container, which is skinnable. By contrast, all MX containers are skinnable.

Skinnable container skins are just like other component skins. They define a group that defines where the content children are laid out. This element has an ID of `contentGroup`. All skinnable containers have a content group. All visual children of a container are pushed into the content group and laid out using that group's layout rules.

For a list of which containers are skinnable and/or scrollable, see "About Spark containers" on page 417.

Sizing Spark container skins

A common reason to skin a Spark container is to add a graphic element, such as a rectangle, to be the background of the container. You typically set its size by using the constraint properties or the percent size properties by using one of the following methods:

- Constraints (setting top=0, bottom=0, left=0, right=0)
- Percent sizes (setting height=100%, width=100%)

When the components are first drawn, constraint properties take precedence (so if you set them, then the dimensional properties are ignored). However, if you set the value of the constraint properties, but then later explicitly set the value of the percent size properties at runtime (for example, by setting the `percentHeight` property to 100), Flex honors the new settings.

Using constraint or percent size properties depends on the use case. In general, a skin resizes when the host component resizes. The choice of percent or constraint sizing is based on the resizing scenario. For example, if you want a label element to be always half as wide as the skin, then set the `width` property to 50%. If you want a label element to be always inset by 5 pixels, set the `left` and `right` properties to 5.

The resizable skin elements in the default Spark skins usually set the `left` and `right` properties. To specify their default size, they also set the `width` property. As a result, if the component size is not set in the application, the element's width sets the default size of the skin and the component.

The following example from the ButtonSkin.mxml class shows that the default size of the Button control is the default size of its skin. This is calculated from the rectangle in the skin, and is 69 pixels wide and 20 pixels high:

```
<s:Rect left="0" right="0" top="0" bottom="0" width="69" height="20" radiusX="2" radiusY="2">
    <s:stroke>
        <s:LinearGradientStroke rotation="90" weight="1">
            <s:GradientEntry color="0x000000" alpha="0.5625" alpha.down="0.6375" />
            <s:GradientEntry color="0x000000" alpha="0.75" alpha.down="0.85" />
        </s:LinearGradientStroke>
    </s:stroke>
</s:Rect>
```

Another technique for designing resizable skins is to specify a minimum size for the skin. For more information, see "Setting minimum sizes of a skin" on page 1620.

Adding borders to Spark containers

One common use of a custom Spark skin is to add a borders to a container. Borders can be simple boxes around the perimeter of a container, or they can define drop shadows, line styles, corner radii, and other properties of a border.

To add a simple rectangular border to a container's skin, you add a Rect object. You can set the height and width of the Rect to 100% so that the skin sizes itself to the size of the container automatically, or you can set the offsets to 0.

The following example adds a simple 1-point, black line as a border around the container:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning/SimpleContainerBorderExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:SkinnableContainer id="myContainer" height="200" width="200"
skinClass="mySkins.ContainerBorderSkin">
        <s:Button label="Click Me"/>
    </s:SkinnableContainer>
</s:Application>
```

The `contentGroup` container has left, right, top, and bottom offsets of 1. This lets the border display outside the content instead of sitting directly on top of the outside edges of container children. The custom skin class for this example is as follows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning/mySkins/ContainerBorderSkin.mxml -->
<s:Skin
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    alpha.disabled="0.5">
    <fx:Metadata>
        [HostComponent("spark.components.SkinnableContainer")]
    </fx:Metadata>

    <s:states>
        <s:State name="normal" />
        <s:State name="disabled" />
    </s:states>

    <s:Group id="contentGroup" left="1" right="1" top="1" bottom="1">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
    </s:Group>
    <s:Rect left="0" right="0" top="0" bottom="0">
        <s:stroke>
            <s:SolidColorStroke color="0x000000" weight="1"/>
        </s:stroke>
    </s:Rect>
</s:Skin>
```

The container's skin sets its constraint properties (`top`, `bottom`, `left`, and `right`) to 0, so the Rect object is set to the same size as the container.

To create a border with rounded corners in a skin, you set the values of the `radiusX` and `radiusY` properties of the Rect object. These properties define the number of pixels for the corners on the x and y axes of the Rect. The following example sets the `radiusX` and `radiusY` properties to 10 to round the corners of the container's skin:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning/RoundedContainerBorderExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:SkinnableContainer id="myContainer"
        height="200" width="200"
        skinClass="mySkins.ContainerRoundedBorderSkin">
        <s:Button label="Click Me"/>
    </s:SkinnableContainer>
</s:Application>
```

The custom skin class for this example is as follows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning/mySkins/ContainerRoundedBorderSkin.mxml -->
<s:Skin
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    alpha.disabled="0.5">
    <fx:Metadata>
        [HostComponent("spark.components.SkinnableContainer")]
    </fx:Metadata>

    <s:states>
        <s:State name="normal" />
        <s:State name="disabled" />
    </s:states>

    <s:Group id="contentGroup" left="10" right="10" top="10" bottom="10">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
    </s:Group>
    <s:Rect left="0" right="0" top="0" bottom="0" radiusX="10" radiusY="10">
        <s:stroke>
            <s:SolidColorStroke color="0x000000" weight="1"/>
        </s:stroke>
    </s:Rect>
</s:Skin>
```

You can add a border to a container by using the BorderContainer class. The BorderContainer class is a subclass of the SkinnableContainer class. Because you use CSS styles and class properties to control the appearance of the BorderContainer class, you typically do not create a custom skin for it.

The following example shows that the BorderContainer class takes the `cornerRadius`, `borderColor`, `borderVisible`, and `borderAlpha` style properties in addition to layout properties, which let you define a border similar to that shown in the previous example without skinning:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning/BorderContainerExample.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
               xmlns:s="library://ns.adobe.com/flex/spark"
               xmlns:mx="library://ns.adobe.com/flex/mx">

    <s:BorderContainer width="200" height="200"
        borderColor="0x000000"
        borderAlpha="1"
        cornerRadius="10"
        borderWeight="1">
        <s:layout>
            <s:HorizontalLayout
                paddingLeft="15" paddingRight="15"
                paddingTop="15" paddingBottom="15"/>
        </s:layout>
        <s:Button label="Click Me"/>
    </s:BorderContainer>

</s:Application>
```

Because the border-related properties are styles, you can use CSS to define a consistent border across all instances of the BorderContainer class; for example:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning/BorderContainerStyleExample.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
               xmlns:s="library://ns.adobe.com/flex/spark"
               xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Style>
        @namespace s "library://ns.adobe.com/flex/spark";

        s|BorderContainer {
            borderColor:#000000;
            borderAlpha:1;
            cornerRadius:10;
            borderWeight:1;
        }
    </fx:Style>
    <s:BorderContainer width="200" height="200">
        <s:layout>
            <s:HorizontalLayout
                paddingLeft="15" paddingRight="15"
                paddingTop="15" paddingBottom="15"/>
        </s:layout>
        <s:Button label="Click Me"/>
    </s:BorderContainer>

</s:Application>
```

To add a border to a single instance of a container or group, you are not required to create a custom skin for the container. You can instead add a Rect graphic in the application itself. This is a process known as *composition*, where you are adding graphical elements to the application that change the appearance of controls in the application. Sometimes skinning gives a better abstraction because it distinguishes between visual children and content children.

For example, you can define MXML graphic tags fragment that draws the graphic elements that make up the border. These graphic elements are typically a stroke or fill (or both).

The following example draws a border around a VGroup that contains Button controls without using a custom skin class:

```
<?xml version="1.0"?>
<!-- SparkSkinning/SimpleBorderExampleNoSkin.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <s:Group>
        <!-- border/background graphics -->
        <s:Rect width="100%" height="100%">
               <s:stroke>
                   <s:SolidColorStroke color="0x000000" weight="2"/>
               </s:stroke>
        </s:Rect>
        <!-- content of container -->
        <s:VGroup left="10" top="10" right="10" bottom="10">
            <s:Button label="Click Me"/>
            <s:Button label="Click Me"/>
        </s:VGroup>
    </s:Group>

</s:Application>
```

Adding drop shadows to Spark containers

To add a drop shadow to a Spark container, you use the DropShadowFilter class. You add the filter to one of the graphic elements defined on that container's skin class. The DropShadowFilter class supports the `alpha`, `angle`, `distance`, and other properties that let you customize the appearance of the drop shadow. In addition, you add a fill to the graphic element. The fill defines the color of the drop shadow. These settings are all in the custom skin class and not in the main application.

The following example defines a drop shadow on the container's skin:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning/DropShadowBorderExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:SkinnableContainer id="myContainer"
        height="200" width="200"
        skinClass="mySkins.DropShadowBorderSkin">
        <s:Button label="Click Me"/>
    </s:SkinnableContainer>
</s:Application>
```

The custom skin class for this example is as follows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning/mySkins/DropShadowBorderSkin.mxml -->
<s:Skin
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    alpha.disabled="0.5">
    <fx:Metadata>
        [HostComponent("spark.components.SkinnableContainer")]
    </fx:Metadata>

    <s:states>
        <s:State name="normal"/>
        <s:State name="disabled"/>
    </s:states>
    <!-- drop shadow -->
    <s:Rect left="0" top="0" right="0" bottom="0">
        <s:filters>
            <s:DropShadowFilter
                blurX="20" blurY="20"
                alpha="0.32"
                distance="11"
                angle="90"
                knockout="true"/>
        </s:filters>
        <s:fill>
            <s:SolidColor color="0x000000"/>
        </s:fill>
    </s:Rect>

    <!-- layer 1: border -->
    <s:Rect left="0" right="0" top="0" bottom="0">
        <s:stroke>
            <s:SolidColorStroke color="0x000000" alpha="0.50" weight="1"/>
        </s:stroke>
    </s:Rect>
    <s:Group id="contentGroup" left="0" right="0" top="0" bottom="0">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
    </s:Group>
</s:Skin>
```

In this example, the drop shadow is the first element on the skin. You can use the `depth` property to change the ordering of the elements. This property determines the order in which items inside of containers are rendered. Spark containers order their items based on their `depth` property, with the lowest depth in the back, and the higher in the front. Items with the same `depth` value appear in the order they are added to the container.

A more efficient alternative to the DropShadowFilter class is to use the `dropShadowEnabled` property to add a drop shadow. For more information, see “Using the dropShadowEnabled property” on page 1558

You can also add a drop shadow to any individual container in the application itself through composition. The downside to doing it this way is that the drop shadow is applied to a single instance of the container, and not all containers. It also removes the benefits of abstraction that skins provide.

Adding padding to Spark containers

Another common use of Spark skins is modify the padding of Spark containers.

To add padding, you can set the offset properties of the container's content group. These properties are `top`, `bottom`, `left`, and `right`.

The following example sets the offsets of the contentGroup to 10 so that the contents of the container are padded by 10 pixels in all directions:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning/PaddedContainerBorderExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:SkinnableContainer id="myContainer"
        height="200" width="200"
        skinClass="mySkins.ContainerPaddedBorderSkin"
    >
        <s:Button label="Click Me"/>
    </s:SkinnableContainer>
</s:Application>
```

The custom skin class for this example is as follows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning/mySkins/ContainerPaddedBorderSkin.mxml -->
<s:Skin
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    alpha.disabled="0.5">
    <fx:Metadata>
        [HostComponent("spark.components.SkinnableContainer")]
    </fx:Metadata>

    <s:states>
        <s:State name="normal" />
        <s:State name="disabled" />
    </s:states>

    <s:Group id="contentGroup" left="10" right="10" top="10" bottom="10">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
    </s:Group>
    <s:Rect left="0" right="0" top="0" bottom="0">
        <s:stroke>
            <s:SolidColorStroke color="0x000000" weight="1"/>
        </s:stroke>
    </s:Rect>
</s:Skin>
```

You can also add padding to the layout object. For example, the VerticalLayout object takes `paddingLeft`, `paddingRight`, `paddingBottom`, and `paddingTop` properties.

Specifying the layout in the skin changes the default layout for this container. However, you can set it on the container instance itself to override the default layout that you set in the skin.

More Help topics

"Using containers" on page 328

Adding scroll bars to Spark containers

Spark containers do not have scroll bars by default. To add scroll bars to a Spark container, use the Scroller class.

To add scroll bars to a container's skin class, you wrap the content group or other element in a Scroller tag. The child of a Scroller tag must implement the IViewport interface. This interface is implemented by Group and DataGroup, and some components such as the RichEditableText control.

To ensure that scroll bars appear, do not set explicit sizes on the group. If you set the size of the group explicitly, then that size becomes the size of the Group and no scroll bars will be shown.

The following example defines the size of the application, and sizes the container to a percent of the overall height and width. The scroller is constrained to the size of the viewport (in this case, the content group). Because the image is larger than the size of its parent, Flex displays scroll bars.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning/ScrollbarContainerExample.mxml -->
    <s:Application
        xmlns:fx="http://ns.adobe.com/mxml/2009"
        xmlns:mx="library://ns.adobe.com/flex/mx"
        xmlns:s="library://ns.adobe.com/flex/spark" height="200" width="200">

        <s:SkinnableContainer id="myContainer"
            height="50%" width="50%"
            skinClass="mySkins.ScrollBarContainerSkin">
            <s:Image source="@Embed(source='../assets/myImage.jpg')"/>
        </s:SkinnableContainer>

 </s:Application>
```

This example uses the following custom skin class:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning/mySkins/ScrollBarContainerSkin.mxml -->
<s:Skin
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    alpha.disabled="0.5">
    <fx:Metadata>
        [HostComponent("spark.components.SkinnableContainer")]
    </fx:Metadata>

    <s:states>
        <s:State name="normal"/>
        <s:State name="disabled"/>
    </s:states>
    <s:Scroller height="100%" width="100%">
        <s:Group id="contentGroup">
            <s:layout>
                <s:BasicLayout/>
            </s:layout>
        </s:Group>
    </s:Scroller>
</s:Skin>
```

The Scroller layout does not support the left/right/top/bottom constraints on the content group of the container. And in general, you should not explicitly set the `height` and `width` properties of the Scroller's content group. Instead, you should let the content group size naturally.

You can use the `minViewportInset` property on the Scroller class to inset the viewport relative to its Scroller along the edges where a scroll bar does not already keep the viewport away from the edge. For example, if you set the `minViewportInset` property to 10, then the right edge of the viewport would be 10 pixels from the right edge of its scroller, unless the vertical scroll bar was visible. When a scroll bar is visible, the viewport and the scroll bar would not have any space between them.

Adding background fills and images to Spark containers

To add background fills and background images to a Spark container's skin, you add a Rect or other graphic element and add the fill to that element.

To add a color fill, you add a graphic element that is a subclass of FilledElement and define a child fill tag. Subclasses of FilledElement include Rect, Ellipse, and Path. The fill must implement the IFill interface, which includes the BitmapFill, LinearGradient, RadialGradient, or SolidColor classes.

The following example defines three containers with three different fills:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning/BackgroundFillExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    width="700">

    <s:layout>
        <s:HorizontalLayout/>
    </s:layout>
    <s:SkinnableContainer id="myContainer"
        height="200" width="200"
        skinClass="mySkins.BackgroundFillSkin">
        <s:Button label="Basic Fill"/>
    </s:SkinnableContainer>
    <s:SkinnableContainer id="myContainer2"
        height="200" width="200"
        skinClass="mySkins.RadialBackgroundFillSkin">
        <s:Button label="Radial Gradient Fill"/>
    </s:SkinnableContainer>
    <s:SkinnableContainer id="myContainer3"
        height="200" width="200"
        skinClass="mySkins.LinearBackgroundFillSkin">
        <s:Button label="Linear Gradient Fill"/>
    </s:SkinnableContainer>
</s:Application>
```

The example uses the following custom skin class for the radial gradient fill:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning/mySkins/RadialBackgroundFillSkin.mxml -->
<s:Skin
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    alpha.disabled="0.5">
    <fx:Metadata>
        [HostComponent("spark.components.SkinnableContainer")]
    </fx:Metadata>

    <s:states>
        <s:State name="normal" />
        <s:State name="disabled" />
    </s:states>
    <!-- layer 1: border -->
    <s:Rect left="0" right="0" top="0" bottom="0">
        <s:stroke>
            <s:SolidColorStroke color="0" alpha="0.50" weight="1" />
        </s:stroke>
    </s:Rect>
    <!-- background fill -->
    <s:Rect id="background" left="1" top="1" right="1" bottom="1">
        <s:fill>
            <s:RadialGradient>
                <s:entries>
                    <s:GradientEntry color="0xFFAABB" ratio="0" alpha="1"/>
                    <s:GradientEntry color="0xFFCCDD" ratio=".33" alpha="1"/>
                    <s:GradientEntry color="0xFFEEFF" ratio=".66" alpha="1"/>
                </s:entries>
            </s:RadialGradient>
        </s:fill>
    </s:Rect>

    <s:Group id="contentGroup" left="10" right="10" top="10" bottom="10">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
    </s:Group>
</s:Skin>
```

The example uses the following custom skin class for the basic background fill:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning/mySkins/BackgroundFillSkin.mxml -->
<s:Skin
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark" alpha.disabled="0.5">
    <fx:Metadata>
        [HostComponent("spark.components.SkinnableContainer")]
    </fx:Metadata>

    <s:states>
        <s:State name="normal" />
        <s:State name="disabled" />
    </s:states>
    <!-- layer 1: border -->
    <s:Rect left="0" right="0" top="0" bottom="0">
        <s:stroke>
            <s:SolidColorStroke color="0" alpha="0.50" weight="1" />
        </s:stroke>
    </s:Rect>
    <!-- background fill -->
    <s:Rect id="background" left="1" top="1" right="1" bottom="1">
        <s:fill>
            <s:SolidColor id="bgFill" color="0xFF0000"/>
        </s:fill>
    </s:Rect>

    <s:Group id="contentGroup" left="10" right="10" top="10" bottom="10">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
    </s:Group>
</s:Skin>
```

The example uses the following custom skin class for the linear background fill:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning/mySkins/LinearBackgroundFillSkin.mxml -->
<s:Skin
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    alpha.disabled="0.5">
    <fx:Metadata>
        [HostComponent("spark.components.SkinnableContainer")]
    </fx:Metadata>

    <s:states>
        <s:State name="normal" />
        <s:State name="disabled" />
    </s:states>
    <!-- layer 1: border -->
    <s:Rect left="0" right="0" top="0" bottom="0">
        <s:stroke>
            <mx:SolidColorStroke color="0" alpha="0.50" weight="1"/>
        </s:stroke>
    </s:Rect>
    <!-- background fill -->
    <s:Rect id="background" left="1" top="1" right="1" bottom="1">
        <s:fill>
            <s:LinearGradient>
                <s:entries>
                    <s:GradientEntry color="0xFFAABB" ratio="0" alpha="1"/>
                    <s:GradientEntry color="0xFFCCDD" ratio=".33" alpha="1"/>
                    <s:GradientEntry color="0xFFFFFF" ratio=".66" alpha="1"/>
                </s:entries>
            </s:LinearGradient>
        </s:fill>
    </s:Rect>

    <s:Group id="contentGroup" left="10" right="10" top="10" bottom="10">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
    </s:Group>
</s:Skin>
```

You can also add a background fill to a content group, although the content group often defines an offset or padding properties. These constraints are applied to the background in addition to the content. As a result, you typically add the background fill to a graphic element that is set to the entire height and width of the container.

To add a background image, you can use the BitmapFill class or a BitmapImage fill. The following example adds a background with a BitmapFill object:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning/BackgroundFillExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:HorizontalLayout/>
    </s:layout>
    <s:SkinnableContainer id="myContainer"
        height="256" width="206"
        skinClass="mySkins.BitmapFillBackgroundSkin"
    >
        <s:Button label="Bitmap Fill"/>
    </s:SkinnableContainer>
</s:Application>
```

This example uses the following custom skin class:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning/mySkins/BitmapFillBackgroundSkin.mxml -->
<s:Skin
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    alpha.disabled="0.5">
    <fx:Metadata>
        [HostComponent("spark.components.SkinnableContainer")]
    </fx:Metadata>

    <s:states>
        <s:State name="normal" />
        <s:State name="disabled" />
    </s:states>
    <!-- layer 1: border -->
    <s:Rect left="0" right="0" top="0" bottom="0">
        <s:stroke>
            <s:SolidColorStroke color="0" alpha="0.50" weight="3" />
        </s:stroke>
    </s:Rect>
    <!-- background fill -->
    <s:Rect id="background" left="3" top="3" right="3" bottom="3" alpha=".25">
        <s:fill>
            <s:BitmapFill source="@Embed(source='../../assets/myImage.jpg')"/>
        </s:fill>
    </s:Rect>

    <s:Group id="contentGroup" left="10" right="10" top="10" bottom="10">
        <s:layout>
            <s:VerticalLayout/>
        </s:layout>
    </s:Group>
</s:Skin>
```

In this example, the container is perfectly sized to fit the bitmap background plus the width of the border. In many cases, though, you will have to set properties on the fill to avoid tiling or apply clipping. For more information, see the BitmapFill class in the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

The content group of the container's skin is typically the last element defined in the skin class. This is because the skin's layers are applied in the order in which they appear in the skin class. When a skin class has a background fill in a skin class, you add the content layer after it so that the content is not covered by the fill.

You can use the `depth` property, which gives you more control over the z-index. This lets you rearrange the appearance of the skin's elements so that it is not determined by the child order.

Swapping skins

You cannot unload or remove a skin class from its host component without specifying another skin to take its place. Otherwise, the component would have no definition of its visual parts (and would therefore break the skinning contract).

To swap a skin, you set the component's `skinClass` property to another skin class.

The following example applies a custom skin to the button when the application starts up. It then toggles the custom skin with the Button control's default skin class when you click the button:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning/SimpleUnloadExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        import spark.skins.spark.ButtonSkin;
        import mySkins.MyButtonSkin;
        import flash.utils.*;

        private function toggleSkin():void {
            if (getQualifiedClassName(myButton.getStyle("skinClass")) ==
getQualifiedClassName(MyButtonSkin)) {
                // Load the default skin class.
                myButton.setStyle("skinClass", Class(ButtonSkin));
            } else {
                // Load the custom skin class.
                myButton.setStyle("skinClass", Class(MyButtonSkin));
            }
        }
    </fx:Script>
    <s:Button id="myButton"
        skinClass="mySkins.MyButtonSkin"
        label="Toggle Skin"
        color="0x0099FF"
        click="toggleSkin()"/>
</s:Application>
```

Transitions with Spark skins

You can use transitions to add visual appeal to your Spark skins. Transitions are triggered off of state changes, which are explicitly supported in Spark skins. All the visuals for a transition should be defined in the skin class and not on the component.

You can use transitions in Spark skins in the same way you would use them in your application. You add a `<s:transitions>` tag as a child tag of the skin's root tag. You then define the transitions and which states they apply to with the `toState` and `fromState` on the `<s:Transition>` child tags. Because the skin is notified of state changes from the host component, you do not have to add any logic to support state changes to the skin.

Typically, you specify the values for transitions in states and not in the effect itself.

The following example uses the Resize transition to grow and shrink the Button control's label and border. The transitions are triggered when the user rolls the pointer over the Button control and when the user rolls the pointer off of the Button control.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning/ButtonTransitionExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    height="200" width="200">

    <s:layout>
        <s:HorizontalLayout/>
    </s:layout>
    <s:Button label="Click Me"
        skinClass="mySkins.ButtonTransitionSkin"/>

</s:Application>
```

The custom skin class for this example is as follows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning\mySkins\ButtonTransitionSkin.mxml -->
<s:Skin
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    minWidth="21" minHeight="21">
    <s:transitions>
        <s:Transition fromState="up" toState="over">
            <s:Resize target="{buttonBorder}"/>
        </s:Transition>
        <s:Transition fromState="over" toState="up">
            <s:Resize target="{buttonBorder}"/>
        </s:Transition>
    </s:transitions>
    <fx:Metadata>
        [HostComponent("spark.components.Button")]
    </fx:Metadata>

    <s:states>
        <s:State name="up"/>
        <s:State name="over"/>
        <s:State name="down"/>
        <s:State name="disabled"/>
    </s:states>
    <s:Rect id="buttonBorder" width="69" width.over="79" height="20" radiusX="2" radiusY="2">
        <s:stroke>
            <s:SolidColorStroke color="0x000000" weight="1"/>
        </s:stroke>
    </s:Rect>

    <!-- layer 8: text -->
    <s:Label id="labelDisplay"
        horizontalCenter="0" verticalCenter="1">
    </s:Label>
</s:Skin>
```

You typically declare the state values in the object or skin, and the effects use these values. The previous example defines the `width.over` property on the Rect rather than using the `widthBy` property of the effect to set the target width.

When using transitions inside Spark skins, you might have to assign IDs to elements that do not by default have IDs. This is because transitions require a target when you define them, and without an ID, you cannot target a specific element.

As with standard Flex controls, you can use transitions with multiple effects that are playing in parallel on a Spark skin. The following example resizes and changes the color of the button's label when the user moves their mouse over or out of the Button:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning/ButtonParallelTransitionExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    height="200" width="200">

    <s:layout>
        <s:HorizontalLayout/>
    </s:layout>
    <s:Button label="Click It or Ticket"
        skinClass="mySkins.ButtonParallelTransitionSkin"/>

</s:Application>
```

The custom skin class for this example is as follows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning/mySkins/ButtonParallelTransitionSkin.mxml -->
<s:SparkSkin
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    minWidth="21" minHeight="21"
    alpha.disabled="0.5">
    <s:transitions>
        <s:Transition>
            <s:Parallel target="{labelDisplay}">
                    <s:Animate>
                        <s:SimpleMotionPath property="fontSize"/>
                    </s:Animate>
                    <s:AnimateColor/>
            </s:Parallel>
        </s:Transition>
    </s:transitions>
    <fx:Metadata>
        [HostComponent("spark.components.Button")]
    </fx:Metadata>

    <fx:Script>
        static private const exclusions:Array = ["labelDisplay"];
        override public function get colorizeExclusions():Array {return exclusions;}
    </fx:Script>

    <s:states>
```

```
        <s:State name="up" />
        <s:State name="over" />
        <s:State name="down" />
        <s:State name="disabled" />
    </s:states>

    <!--  The following values are negative because they define a border or drop shadow.
           The negative values separate them from the Button's bounds. -->
    <s:Rect left="-1" right="-1" top="-1" bottom="-1" radiusX="2" radiusY="2">
        <s:fill>
            <s:LinearGradient rotation="90">
                    <s:GradientEntry color="0x000000"
                                   color.down="0xFFFFFF"
                                   alpha="0.01"
                                   alpha.down="0" />
                    <s:GradientEntry color="0x000000"
                                   color.down="0xFFFFFF"
                                   alpha="0.07"
                                   alpha.down="0.5" />
            </s:LinearGradient>
        </s:fill>
    </s:Rect>

    <s:Rect left="1" right="1" top="1" bottom="1" radiusX="2" radiusY="2">
        <s:fill>
            <s:LinearGradient rotation="90">
                <s:GradientEntry color="0xFFFFFF"
                               color.over="0xBBBDBD"
                               color.down="0xAAAAAA"
                               alpha="0.85" />
                <s:GradientEntry color="0xD8D8D8"
                               color.over="0x9FA0A1"
                               color.down="0x929496"
                               alpha="0.85" />
            </s:LinearGradient>
        </s:fill>
    </s:Rect>

    <s:Rect left="1" right="1" bottom="1" height="9" radiusX="2" radiusY="2">
        <s:fill>
            <s:LinearGradient rotation="90">
                <s:GradientEntry color="0x000000" alpha="0.0099" />
                <s:GradientEntry color="0x000000" alpha="0.0627" />
            </s:LinearGradient>
        </s:fill>
    </s:Rect>

    <s:Rect left="1" right="1" top="1" height="9" radiusX="2" radiusY="2">
        <s:fill>
            <s:SolidColor color="0xFFFFFF"
                        alpha="0.33"
                        alpha.over="0.22"
                        alpha.down="0.12" />
        </s:fill>
    </s:Rect>

    <s:Rect left="1" right="1" top="1" bottom="1"
```

```
            radiusX="2" radiusY="2" excludeFrom="down">
            <s:stroke>
                <s:LinearGradientStroke rotation="90" weight="1">
                    <s:GradientEntry color="0xFFFFFF" alpha.over="0.22" />
                    <s:GradientEntry color="0xD8D8D8" alpha.over="0.22" />
                </s:LinearGradientStroke>
            </s:stroke>
        </s:Rect>

        <s:Rect left="1" top="1" bottom="1" width="1" includeIn="down">
            <s:fill>
                <s:SolidColor color="0x000000" alpha="0.07" />
            </s:fill>
        </s:Rect>
        <s:Rect right="1" top="1" bottom="1" width="1" includeIn="down">
            <s:fill>
                <s:SolidColor color="0x000000" alpha="0.07" />
            </s:fill>
        </s:Rect>
        <s:Rect left="2" top="1" right="2" height="1" includeIn="down">
            <s:fill>
                <s:SolidColor color="0x000000" alpha="0.25" />
            </s:fill>
        </s:Rect>
        <s:Rect left="1" top="2" right="1" height="1" includeIn="down">
            <s:fill>
                <s:SolidColor color="0x000000" alpha="0.09" />
            </s:fill>
        </s:Rect>

        <s:Rect left="0" right="0" top="0" bottom="0"
            width="69" height="20"
            radiusX="2" radiusY="2">
            <s:stroke>
                <s:LinearGradientStroke rotation="90" weight="1">
                    <s:GradientEntry color="0x000000"
                               alpha="0.5625"
                               alpha.down="0.6375" />
                    <s:GradientEntry color="0x000000"
                               alpha="0.75"
                               alpha.down="0.85" />
                </s:LinearGradientStroke>
            </s:stroke>
        </s:Rect>
        <s:Label id="labelDisplay"
                 fontSize="{hostComponent.getStyle('fontSize')}"
                 fontSize.over="{hostComponent.getStyle('fontSize') + 4}"
                 color.over="0xFF0000"
                 textAlign="center"
                 verticalAlign="middle"
                 lineBreak="toFit"
                 maxDisplayedLines="1"
                 horizontalCenter="0" verticalCenter="1"
                 left="10" right="10" top="2" bottom="2">
        </s:Label>
    </s:SparkSkin>
```

The previous example uses the SparkSkin class rather than the Skin class as its root because it defines the `colorExclusions()` getter.

You can use transitions and states to effectively add and remove elements from the skin. For example, if you want an image to appear on a Button control during a mouse over, you can change the value of a property `height` from 0 to a new value in the `over` state.

The following example displays an image of a butterfly when you move the mouse over the Button control, and removes the image when you move the mouse out:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning/ButterflySkinExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    backgroundColor="0x999999">

    <s:Button id="myButton"
        fontWeight="bold"
        color="0xFFFFFF"
        label="Bug of the Day"
        skinClass="mySkins.ButterflySkin"/>

</s:Application>
```

The custom skin class for this example is as follows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning/mySkins/ButterflySkin.mxml -->
<s:SparkSkin
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    minWidth="21" minHeight="21" alpha.disabled="0.5">

    <!-- host component -->
    <fx:Metadata>
        <![CDATA[
        [HostComponent("spark.components.Button")]
        ]]>
    </fx:Metadata>

    <s:transitions>
        <mx:Transition fromState="up" toState="over">
            <mx:Parallel duration="350">
                <s:Resize target="{ myImage }"/>
                <s:Fade targets="{ [myImage,labelDisplay] }"/>
            </mx:Parallel>
        </mx:Transition>
        <mx:Transition fromState="over" toState="up">
            <mx:Parallel duration="200">
                <s:Resize target="{ myImage }"/>
                <s:Fade targets="{ [myImage,labelDisplay] }"/>
            </mx:Parallel>
        </mx:Transition>
    </s:transitions>
    <fx:Script>
        <![CDATA[
            static private const exclusions:Array = ["labelDisplay"];

            override public function get colorizeExclusions():Array {return exclusions;}
            override protected function initializationComplete():void  {
                useChromeColor = true;
                super.initializationComplete();
            }

            override protected function updateDisplayList(unscaledWidth:Number,
unscaledHeight:Number) : void  {
                var cr:Number = getStyle("cornerRadius");
                super.updateDisplayList(unscaledWidth, unscaledHeight);
            }

Subcomponent skinning

Some components are composites of other components. They use other components as part of their user interface. For example, a NumericStepper consists of a Button control with a down arrow, a Button control with an up arrow, and a TextInput control that displays the current value. The components that make up a composite component's user interface are known as subcomponents.

To skin Spark subcomponents you edit the skin parts in the skin class. Each subcomponent corresponds to a skin part that is defined on the host component. For example, to customize the button skin parts in a NumericStepperSkin class, you can set the value of their `skinClass` property to a custom class.

In many cases, the subcomponents that are defined in the main skin have their own skin classes. This is common if the subcomponents need to define their own appearance based on their state. For example, the buttons in a NumericStepper should react to their own `up` and `down` states rather than the `up` and `down` states of the composite component.

When skinning subcomponents, you typically use the SparkSkin class rather than the Skin class as the root. This is because Spark components usually rely on the colorize exclusions and other properties that require the SparkSkin class.

The following example defines custom subcomponent skins for the up and down buttons in a NumericStepper composite skin:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning/NumericStepperSkinPartExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    height="200" width="200">

    <s:layout>
        <s:HorizontalLayout/>
    </s:layout>
    <s:SkinnableContainer id="myContainer"
        height="200" width="200">
        <s:NumericStepper skinClass="mySkins.NumericStepperSkin"/>
    </s:SkinnableContainer>
</s:Application>
```

The following composite skin class is nearly identical to the default NumericStepperSkin except that it defines custom skins for the button subcomponents. In this case, the spark.skins.spark.SpinnerDecrementButtonSkin and spark.skins.spark.SpinnerIncrementButtonSkin classes are replaced with mySkins.SpinnerDownButton and mySkins.SpinnerUpButton respectively.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- SparkSkinning/mySkins/NumericStepperSkin.mxml -->
<s:SparkSkin
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    minHeight="24"
    alpha.disabled="0.5">
    <fx:Metadata>
        [HostComponent("spark.components.NumericStepper")]
    </fx:Metadata>

    <fx:Script>
        /*
           Define the skin elements that should not be colorized.
          For numeric stepper, the skin itself is colorized but the individual parts are not.
        */
        static private const exclusions:Array = ["textInput", "decrementButton",
"incrementButton"];
        override public function get colorizeExclusions():Array {return exclusions;}
    </fx:Script>

    <s:states>
        <s:State name="normal"/>
        <s:State name="disabled"/>
    </s:states>
    <s:Button id="incrementButton" right="0" top="0" height="50%"
            skinClass="mySkins.SpinnerUpButton"/>
    <s:Button id="decrementButton" right="0" bottom="0" height="50%"
            skinClass="mySkins.SpinnerDownButton"/>

    <s:TextInput id="textDisplay" left="0" top="0" right="18" bottom="0"
        skinClass="spark.skins.spark.NumericStepperTextInputSkin"/>

</s:SparkSkin>
```

The following skin classes replace the SpinnerIncrementButtonSkin and SpinnerDecrementButtonSkin classes in the custom NumericStepperSkin example. Instead of drawing arrows, these custom skins use + and - signs for incrementing and decrementing the value of the TextInput control.

```
<?xml version="1.0" encoding="utf-8"?>

Packaging skins

You can package custom Spark skins as a SWC file and distribute that SWC file to anyone interested in using your library of skins. The SWC file is also known as a theme SWC file. Theme SWC files for Spark skins typically consist of the following files:

- defaults.css
- One or more skin classes

The defaults.css file file can apply the Spark skin classes and any other style properties. The following sample CSS file from a theme SWC file applies a style property and custom skins to the Button and CheckBox controls in the Spark namespace:

```
@namespace s "library://ns.adobe.com/flex/spark";
s|Button {
    color: Green;
    skinClass: ClassReference("ButtonTransitionSkin");
}
s|CheckBox {
    color: Green;
    skinClass: ClassReference("CheckBoxTransitionSkin");
}
```

To include classes that are compiled, such as Spark skins, in a theme SWC file, you use the `include-classes` compiler option. To include files that are not compiled, such as a stylesheet, you use the include-file compiler option. All files included in a theme SWC file must be in the source path. You use the `output` compiler option to specify the location of the resulting SWC file.

The following command line compiles a new theme SWC file. This theme SWC file includes two Spark skins and a defaults.css file:

```
compc -source-path c:/temp/myskins
    -include-classes ButtonTransitionSkin CheckBoxTransitionSkin
    -include-file defaults.css c:/temp/myskins/defaults.css
    -output c:/temp/myskins/MySkins.swc
```

To use the theme SWC file in your application, you use the `theme` compiler option, as the following example shows:

```
mxmlc -theme=c:/temp/myskins/MySkins.swc c:myapps/ThemeExample.mxml
```

Skinning MX components

You add skins to Adobe® Flex® components by using ActionScript classes, MXML components, and image files. Image files can contain JPEG, GIF, and PNG images or SWF files.

This topic describes the process for skinning MX components. These are typically components that use the Halo theme. For information about skinning Spark components, see "Spark Skinning" on page 1602.

By default, MX components in a Flex 4 application use the Spark skin classes in the mx.skins.spark.* package. To use Halo skins, you can either apply the Halo theme to your application or set the `compatibility-version` compiler option to 3.0.0.

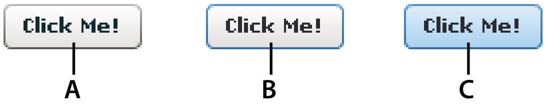
About MX component skinning

Skinning is the process of changing the appearance of a component by modifying or replacing its visual elements. These elements can be made up of bitmap images, SWF files, or class files that contain drawing methods that define vector images.

Skins can define the entire appearance, or only a part of the appearance, of a component in various states. For example, an MX Button control that uses the Halo theme has eight possible states, and eight associated skin properties, as the following example shows:

State	**Skin property**	**Default skin class**
down	`downSkin`	mx.skins.halo.ButtonSkin
over	`overSkin`	mx.skins.halo.ButtonSkin
up	`upSkin`	mx.skins.halo.ButtonSkin
disabled	`disabledSkin`	mx.skins.halo.ButtonSkin
selectedDisabled	`selectedDisabledSkin`	mx.skins.halo.ButtonSkin
selectedDown	`selectedDownSkin`	mx.skins.halo.ButtonSkin
selectedOver	`selectedOverSkin`	mx.skins.halo.ButtonSkin
selectedUp	`selectedUpSkin`	mx.skins.halo.ButtonSkin

The default skins for the up, over, and down states appear as follows:



***A.** up **B.** over **C.** down*

Other controls have similar states with associated skins. For example, RadioButton controls, which are subclasses of Button, also have up, down, and over skins. The ComboBox control has skins the define the appearance of the control when it is in the disabled, down, and over states.

You create a skin by using a bitmap image, a SWF file, or a class defined in ActionScript or in MXML. All components have a default skin class that can represent more than one state of the component. As you can see in the previous table, the eight states of the Button control use the same default skin class, mx.skins.halo.ButtonSkin, to draw the skin. Logic within the class determines the appearance of the Button control based on its current state.

You assign a skin to a component by using style properties. You can set a style property by using MXML tag properties, the StyleManager class, `<fx:Style>` blocks, or style sheets. Most application use style sheets to organize and apply skins. Style sheets can be loaded at compile time or at run time. For information on loading style sheets at run time, see "Loading style sheets at run time" on page 1547.

Types of MX component skins

You typically define a skin for the Halo theme as a bitmap graphic or as a vector graphic. Bitmap graphics, called *graphical skins* in Flex, are made up of individual pixels that together form an image. The downside of a bitmap graphic is that it is typically defined for a specific resolution and, if you scale or transform the image, you might notice a degradation in image quality.

A vector graphic, called a *programmatic skin* in Flex, consists of a set of line definitions that specify a line's starting and end point, thickness, color, and other information required by Adobe® Flash® Player to draw the line. When a vector graphic is scaled, rotated, or modified in some other way, it is relatively simple for Flash Player to calculate the new layout of the vector graphic by transforming the line definitions. Therefore, you can perform many types of modifications to vector graphics without noticing any degradation in quality.

One advantage of programmatic skins is you can create vector graphics that allow you a great deal of programmatic control over the skin. For example, you can control the radius of a Button control's corners by using programmatic skins, something you cannot do with graphical skins. You can develop programmatic skins directly in your Flex authoring environment or any text editor, without using a graphics tool such as Adobe Flash. Programmatic skins also tend to use less memory because they contain no external image files.

The following table describes the different types of skins:

Skin type	**Description**
Graphical skins	Images that define the appearance of the skin. These images can JPEG, GIF, or PNG files, or they can be symbols embedded in SWF files. Typically you use drawing software such as Adobe® PhotoShop® or Adobe® Illustrator® to create graphical skins. For more information, see "Creating graphical skins for MX components" on page 1671.
Programmatic skins	ActionScript or MXML classes that define a skin. To change the appearance of controls that use programmatic skins, you edit an ActionScript or MXML file. You can use a single class to define multiple skins. For more information, see "Creating programmatic skins for MX components" on page 1674.
Stateful skins	A type of programmatic skin that uses view states, where each view state corresponds to a state of the component. The definition of the view state controls the look of the skin. Since you can have multiple view states in a component, you can use a single component to define multiple skins. For more information, see "Creating stateful skins for MX components" on page 1687.

Creating graphical skins for MX components

When using graphical skins in the Halo theme, you must embed the image file for the skin in your application. To specify your skin, you can use the `setStyle()` method, set it inline, or use Cascading Style Sheets (CSS), as the following example shows:

```
<?xml version="1.0"?>
<!-- skins/SimpleButtonGraphicSkin.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Style>
        @namespace mx "library://ns.adobe.com/flex/mx";
        mx|Button {
            upSkin: Embed("../assets/orb_up_skin.gif");
        }
    </fx:Style>
    <mx:Button id="b1" label="Click Me"/>
</s:Application>
```

For information on setting skins by using the `setStyle()` method or by setting them inline, see "Applying MX component skins" on page 1663.

You can assign the same graphic or programmatic skin to two or more skins so that the skins display the same image, as the following example shows:

```
<?xml version="1.0"?>
<!-- skins/SimpleButtonGraphicSkinTwoSkins.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Style>
        @namespace mx "library://ns.adobe.com/flex/mx";
        mx|Button {
            upSkin: Embed("../assets/orb_up_skin.gif");
            overSkin: Embed("../assets/orb_up_skin.gif");
        }
    </fx:Style>
    <mx:Button id="b1" label="Click Me"/>
</s:Application>
```

For more information, see “Creating graphical skins for MX components” on page 1671.

Creating programmatic skins for MX components

You can define programmatic skins for the Halo theme in either MXML or ActionScript. When using programmatic skins, you can define a class for each state of the component, or define a single class for multiple skins. In the following example you create a custom ActionScript skin to define the skin for the up state of the Button control:

```
package {
  // skins\ButtonUpSkinAS.as
  import mx.skins.ProgrammaticSkin;
  public class ButtonUpSkinAS extends ProgrammaticSkin {
    // Constructor.
    public function ButtonUpSkinAS() {
      super();
    }
    override protected function updateDisplayList(unscaledWidth:Number,
      unscaledHeight:Number):void
    {
      graphics.lineStyle(1, 0x0066FF);
      graphics.beginFill(0x00FF00, 0.50);
      graphics.drawRoundRect(0, 0, unscaledWidth, unscaledHeight, 10, 10);
    }
  }
}
```

In ActionScript, you typically use the ProgrammaticSkin class as the base class for your skin. In the skin class, you must override the `updateDisplayList()` method to draw the skin. You then assign the skin component to the appropriate skin property of the Button control using a style sheet, as the following example shows:

```
<?xml version="1.0"?>
<!-- skins/ApplySimpleButtonSkinAS.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Style>
        @namespace mx "library://ns.adobe.com/flex/mx";
        mx|Button {
            upSkin: ClassReference("ButtonUpSkinAS");
        }
    </fx:Style>
    <mx:Button id="b1" label="Click Me"/>
</s:Application>
```

For information on applying skins, see “Applying MX component skins” on page 1663.

In the following example you create a custom MXML component to define the skin for the up state of the Button control. In MXML, you use ProgrammaticSkin as the base class of your skin. This is the same skin defined above in ActionScript:

```
<?xml version="1.0"?>
<!-- skins\ButtonUpMXMLSkin.mxml -->
<skins:ProgrammaticSkin
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:skins="mx.skins.*">
  <fx:Script>
    <![CDATA[
      override protected function updateDisplayList(unscaledWidth:Number,
        unscaledHeight:Number):void
      {
        graphics.lineStyle(1, 0x0066FF);
        graphics.beginFill(0x00FF00, 0.50);
        graphics.drawRoundRect(0, 0, unscaledWidth, unscaledHeight, 10, 10);
      }
    ]]>
  </fx:Script>
</skins:ProgrammaticSkin>
```

Notice that you include the `xmlns:skins="mx.skins.*"` namespace declaration in MXML. This is necessary because by default you cannot use the ProgrammaticSkin class as the base class of an MXML component.

In the following example, you create a component that defines skins for multiple Button states. In this example, you use a `case` statement to determine the current state of the Button control based on the `name` property of the skin, where the `name` property contains the current name of the skin. For example, if you define a programmatic skin for a Button control, the `name` property could be any of the skin states: `downSkin`, `upSkin`, `overSkin`, `disabledSkin`, `selectedDisabledSkin`, `selectedDownSkin`, `selectedOverSkin`, or `selectedUpSkin`.

```
package {
  // skins\ButtonUpAndOverSkinAS.as
  import mx.skins.ProgrammaticSkin;
  public class ButtonUpAndOverSkinAS extends ProgrammaticSkin {
    // Constructor.
    public function ButtonUpAndOverSkinAS() {
      super();
    }
    override protected function updateDisplayList(unscaledWidth:Number,
      unscaledHeight:Number):void
    {
      switch (name)
      {
       case "upSkin": {
        graphics.lineStyle(1, 0x0066FF);
        graphics.beginFill(0x00FF00, 0.50);
        graphics.drawRoundRect(0, 0, unscaledWidth, unscaledHeight, 10, 10);
       }
       case "overSkin": {
        graphics.lineStyle(1, 0x0066FF);
        graphics.beginFill(0x00CCFF, 0.50);
        graphics.drawRoundRect(0, 0, unscaledWidth, unscaledHeight, 10, 10);
       }
      }
    }
  }
}
```

You then assign the ActionScript class to the appropriate skin properties:

```
<?xml version="1.0"?>
<!-- skins/ApplyButtonUpOverSkinAS.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Style>
        @namespace mx "library://ns.adobe.com/flex/mx";
        mx|Button {
            upSkin: ClassReference("ButtonUpAndOverSkinAS");
            overSkin: ClassReference("ButtonUpAndOverSkinAS");
        }
  </fx:Style>
    <mx:Button id="b1" label="Click Me"/>
</s:Application>
```

For more information on creating programmatic skins, see "Creating programmatic skins for MX components" on page 1674.

Creating stateful skins for MX components

When using a stateful skin with the Halo theme, you define a skin that defines a view state for each state of a component.

You typically define a stateful skin as a subclass of UIComponent, in ActionScript or in MXML, because the view state mechanism is built into the UIComponent class. For more information, see "Creating stateful skins for MX components" on page 1687.

When using stateful skins, you must explicitly specify the default skin for all states not defined by the stateful skin component.

Sizing MX component skins

Before a component applies a skin, it first determines its size without the skin. The component then examines the skin to determine whether the skin defines a specific size. If not, the component scales the skin to fit. If the skin defines a size, the component sizes itself to the skin.

Most skins do not define any size constraints, which allows the component to scale the skin as necessary. For more information on writing skins that contain size information, see "Implementing the measuredWidth and measuredHeight getters" on page 1684.

Skinning MX subcomponents

In some cases, you want to reskin subcomponents. The following example reskins the vertical MX ScrollBar control that appears in List controls:

```
<?xml version="1.0"?>
<!-- skins/SubComponentSkins.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
  <fx:Script><![CDATA[
     [Bindable]
     private var theText:String = "Lorem ipsum dolor sit amet, consectetur " +
        "adipisicing elit, sed do eiusmod tempor incididunt ut labore et dolore " +
        "magna aliqua. Ut enim ad minim veniam, quis nostrud exercitation ullamco " +
        "laboris nisi ut aliquip ex ea commodo consequat. Duis aute irure dolor " +
        "in reprehenderit in voluptate velit esse cillum dolore eu fugiat " +
        "nulla pariatur. Excepteur sint occaecat cupidatat non proident, sunt " +
        "in culpa qui officia deserunt mollit anim id est laborum.";
  ]]></fx:Script>
  <fx:Style>
     .myScrollStyle {
        upArrowUpSkin: Embed("../assets/uparrow_up_skin.gif");
        downArrowUpSkin: Embed("../assets/downarrow_up_skin.gif");
     }
  </fx:Style>
  <mx:TextArea id="ta1"
     width="400"
     height="50"
     verticalScrollPolicy="on"
     verticalScrollBarStyleName="myScrollStyle"
     text="{theText}"
  />
</s:Application>
```

By setting the value of the `verticalScrollBarStyleName` property in the List type selector, all vertical ScrollBar controls in List components have a custom skin. The ScrollBar controls in other parts of the application do not have the custom skin.

As with all style sheets, you can define the skins in a separate CSS file and use the `source` property of the `<fx:Style>` tag to point to that file; for example:

```
<fx:Style source="../stylesheets/MySkins.css"/>
```

Creating a Halo theme

A *theme* is a collection of style definitions and skins that define the look and feel of an application built with Flex. Theme files can include both graphical and programmatic skins, as well as style sheets.

A theme takes the form of a SWC file that can be applied to an application. You compile a SWC file using the compc command-line compiler utility.

By compiling a SWC file and then using that SWC file as a theme in your application, you remove the burden of compiling all the skin files when you compile your main application. This can make compilation faster and make problems with the application code easier to debug. In addition, a SWC file is easier to transplant onto another application than are a set of classes and image files.

Halo, the default theme set that shipped with Flex 3, is almost entirely made up of programmatic skins, although there are some static graphic elements. Flex includes programmatic and graphical skins that use the Halo look and feel. You can edit the skins by using either the programmatic or graphical technique to reskin MX components for the Halo theme.

To use the Halo theme in a Flex 4 application, you can use the `theme` compiler option, or you can set the `compatibility-version` option to 3.0.0. If you use the Halo theme, then the Halo theme is applied to all MX components in your application. The Spark components continue to use the Spark theme unless you specifically override them.

For more information on creating and applying themes, see "About themes" on page 1561.

MX component skin resources

Flex includes the following graphical and programmatic source files for MX component skins:

Base skin classes in the mx.skins.* package These abstract skin classes define the basic functionality of Halo skin classes for MX components in Flex. For more information, see "Creating programmatic skins for MX components" on page 1674.

Programmatic skins in the mx.skins.halo.* package These concrete skin classes extend the base skin classes in the mx.skins.* package. They define the appearance of skins for MX components in the Halo theme. You can extend or edit these skins to create new programmatic skins based on the default Flex look and feel. For more information, see "Creating programmatic skins for MX components" on page 1674.

Spark skins in the mx.skins.spark.* package These skin classes define the default appearance of MX components in a Flex 4 application. For more information, see "Spark Skinning" on page 1602.

Graphical Aeon theme The Aeon theme for MX components includes the AeonGraphical.css file and the AeonGraphical.swf file that defines the skin symbols. These are in the framework/themes directory. In addition, Flex includes the FLA source file for the AeonGraphical.swf file. For more information, see "About themes" on page 1561.

You use these files to create skins for MX components based on the Flex look and feel, or create your own.

Creating MX component skins using Adobe tools

You can create graphical, programmatic, and stateful skins for the Halo theme by using Adobe® Flash® CS3, Adobe Illustrator CS3, Adobe Photoshop CS3, and Adobe® Fireworks® CS3. To create skins by using these tools, first download and install extensions that simplify the skinning process. These extensions include the skin templates for all components. For more information on using these tools to create skins, and to download the required extensions, see http://www.adobe.com/go/flex3_cs3_skinning_extensions.

Creating skins in Adobe Flash CS3

While the Flex skinning extensions provide tools that make it easy to create skins in Flash CS3, such as the template of all Flex skins, you are not required to use them to create skins in Flash CS3. Flex lets you use the `[Embed]` metadata tag to import a skin class into an application from a SWC file created in Flash CS3.

Creating a skin class in Flash CS3

1 In Flash CS3, select File > New to open the New Document dialog box.

2 Select Flash File (ActionScript 3.0) as the file type.

3 Create a movie clip symbol for the skin. The symbol name, for example Button_upSkin, becomes the class name of the skin.

Set the following properties on the movie clip symbol:

- Set the Type to Movie clip.
- Set the Base class to flash.display.MovieClip.
- Set the Export for ActionScript option.

- Set the Export in first frame option.
- Set the Class name to be the same as the symbol name.
- Optionally set Enable guides for 9-slice scaling.

4 Save the .fla file.

5 Use File > Publish Settings to open the Publish Settings dialog box.

6 Select Export SWC in the Flash tab in the Publish Settings dialog box.

7 Select File > Publish to publish your skin as a SWC file in the same directory as the .fla file.

Embed the skin class in an application

1 Add the SWC file to the library path of your application:

- In Flash Builder, use the Projects > Properties command to specify the location of the SWC file, or copy it to the libs directory of your Flash Builder project.
- For the mxmlc command-line compiler, use the `library-path` option to specify the location of the SWC file.

2 Use the `[Embed]` metadata tag to embed the skin in your application. You can use the `[Embed]` tag in an `<fx:Style>` block of an MXML file, or in a CSS file.

The `[Embed]` metadata tag has the following syntax for skin classes created in Flash CS3:

```
[Embed(skinClass="className")]
```

For example, if you create a skin named Button_upSkin for the up skin of the Flex Button control, embed the skin as the following example shows:

```
<fx:Style>
    @namespace s "library://ns.adobe.com/flex/spark";
    s|Button
    {
        upSkin: [Embed(skinClass="Button_upSkin")]
    }
</fx:Style>
```

3 Compile and run your application.

Applying MX component skins

You apply skins by using CSS, by specifying them inline in MXML, by calling the `setStyle()` method, or by using the StyleManager class.

Applying graphical skins inline

When you apply a skin inline, you specify it as the value of a skin style in MXML.

To apply a graphical skin inline, you embed the skin by using the appropriate skin property of the control, as the following example shows:

```
<?xml version="1.0"?>
<!-- skins/EmbedImagesInline.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <mx:Button id="b1"
        label="Click Me"
        overSkin="@Embed(source='../assets/orb_over_skin.gif')"
        upSkin="@Embed(source='../assets/orb_up_skin.gif')"
        downSkin="@Embed(source='../assets/orb_down_skin.gif')"/>

</s:Application>
```

The location of the skin asset is relative to the location of the MXML file that embeds it.

When embedding inline, you use `@Embed` (with an at [@] sign prefix) rather than `Embed`, which you use in CSS files.

Applying programmatic skins inline

For programmatic skins, you specify the class name for each state that you reskin and enclose the class name with curly braces { }. The skin's class definition must be in your source path when you compile the application. If the class file is in the same directory as the application, then you do not need to add it to your source path.

The following example applies the SampleButtonSkin.mxml programmatic skin to the Button control's `upSkin`, `overSkin`, `downSkin`, and `disabledSkin` states:

```
<?xml version="1.0"?>
<!-- skins/ApplyProgrammaticSkinsInline.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <mx:Button id="b1"
        label="Click Me"
        overSkin="{ButtonStatesSkin}"
        upSkin="{ButtonStatesSkin}"
        downSkin="{ButtonStatesSkin}"
        disabledSkin="{ButtonStatesSkin}"/>
</s:Application>
```

In this example, the SampleButtonSkin.mxml file is in the same directory as the application. If the skin class is in another directory, you must import the class into the application so that the compiler can resolve the class name, as the following example shows:

```
<?xml version="1.0"?>
<!-- skins/ApplyProgrammaticSkinsInlinePackage.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        import myComponents.*;
    </fx:Script>
    <mx:Button id="b1"
        label="Click Me"
        overSkin="{myComponents.ButtonStatesSkin}"
        upSkin="{myComponents.ButtonStatesSkin}"
        downSkin="{myComponents.ButtonStatesSkin}"
        disabledSkin="{myComponents.ButtonStatesSkin}"/>
</s:Application>
```

When you define stateful skin, you set the `skin` style property of the control to the class name of your skin component, as the following example shows:

```
<?xml version="1.0"?>
<!-- skins/ApplyButtonStatefulSkinInlineAll.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        import myComponents.*;
    </fx:Script>
    <mx:Button id="b"
        label="Hello"
        skin="{myComponents.MyButtonStatefulSkinAll}"/>

</s:Application>
```

Applying MX component skins by using CSS

When applying skins with CSS, you can use type or class selectors so that you can apply skins to one component or to all components of the same type. You can define the style sheet in the body of the `<fx:Style>` tag or reference an external style sheet, as the following example shows:

```
<?xml version="1.0"?>
<!-- skins/UseHaloSkinsStyleSheet.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Style source="../assets/UseHaloSkins.css"/>
    <mx:CheckBox id="cb1" label="Click Me"/>

    <mx:RadioButton id="rb1" label="Click Me"/>
</s:Application>
```

You can apply skins to a single instance of a component by defining a class selector. The following example applies the custom style to the second button only:

```
<?xml version="1.0"?>
<!-- skins/EmbedImagesClassSelector.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Style>
        .myButtonStyle {
            overSkin: Embed("../assets/orb_over_skin.gif");
            upSkin: Embed("../assets/orb_up_skin.gif");
            downSkin: Embed("../assets/orb_down_skin.gif");
        }
    </fx:Style>
    <mx:Button id="b1" label="Click Me"/>
    <mx:Button id="b2" label="Click Me" styleName="myButtonStyle"/>
</s:Application>
```

You can load style sheets at run time by compiling them into a SWF file. You then use the top-level StyleManager class's `loadStyleDeclarations()` method to load the CSS-based SWF file at run time, as the following example shows:

```
<?xml version="1.0"?>
<!-- styles/BasicApp.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Script>
        <![CDATA[
        public function applyRuntimeStyleSheet():void {
            styleManager.loadStyleDeclarations("assets/BasicStyles.swf")
        }
        ]]>
    </fx:Script>
    <s:VGroup>
        <s:Label text="Click the button to load a new CSS-based SWF file."/>
        <s:Button id="b1" label="Click Me" click="applyRuntimeStyleSheet()"/>
    </s:VGroup>

</s:Application>
```

For more information, see “Loading style sheets at run time” on page 1547.

Using CSS to apply graphical skins to MX components

You typically embed graphical skins as properties of a CSS file in the `<fx:Style>` tag or in an external style sheet, just as you would apply any style property, such as `color` or `fontSize`. The following example defines skins on the Button type selector. In this example, all Buttons controls get the new skin definitions.

```
<?xml version="1.0"?>
<!-- skins/EmbedImagesTypeSelector.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Style>
        @namespace mx "library://ns.adobe.com/flex/mx";

        mx|Button {
            overSkin: Embed("../assets/orb_over_skin.gif");
            upSkin: Embed("../assets/orb_up_skin.gif");
            downSkin: Embed("../assets/orb_down_skin.gif");
        }
    </fx:Style>
    <mx:Button id="b1" label="Click Me"/>
</s:Application>
```

When you embed the graphical skin, you embed it into your application's SWF file. For more information on embedding assets, see "Embedding assets" on page 1699.

Using CSS to apply programmatic skins to MX components

You apply programmatic skins in a CSS file by using the `ClassReference` directive. This directive takes a class name as the argument, where the class name corresponds to the ActionScript or MXML file containing your skin definition. The skin's class must be in your source path when you compile the application.

When using programmatic skins, you assign the component name to the associated skin property. In the following example, the skin is in the file myComponents/MyButtonSkin.as where myComponents is a subdirectory of the directory containing your application:

```
<?xml version="1.0"?>
<!-- skins/ApplyButtonSkin.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Style>
        @namespace mx "library://ns.adobe.com/flex/mx";
        mx|Button {
            upSkin: ClassReference("myComponents.MyButtonSkin");
        }
    </fx:Style>
    <mx:Button label="Hello World" id="b" />
</s:Application>
```

When you define stateful skin, you set the `skin` style property of the control to the class name of your skin component, as the following example shows:

```
<?xml version="1.0"?>
<!-- skins/ApplyButtonStatefulSkinAll.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Style>
        @namespace mx "library://ns.adobe.com/flex/mx";
        mx|Button {
            skin: ClassReference("myComponents.MyButtonStatefulSkinAll");
        }
    </fx:Style>
    <mx:Button label="Hello" id="b" />
</s:Application>
```

Applying MX component skins with the setStyle() method

Skins are defined as style properties, therefore, you can access them with the setStyle() and `getStyle()` methods. This lets you change skins during run time, or dynamically define them, as long as you embed the graphical asset at compile time.

For more information on using the `setStyle()` method, see "Using the setStyle() and getStyle() methods" on page 1540.

Using the setStyle() method to apply graphical skins to MX components

To embed an image so that you can use it with the `setStyle()` method, you use the `[Embed]` metadata tag and assign a reference to a variable. You can then use the `setStyle()` method to apply that image as a skin to a component.

The following example embeds three images and applies those images as skins to an instance of a Button control:

```
<?xml version="1.0"?>
<!-- skins/EmbedWithSetStyle.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    initialize="init();">
    <fx:Script>
        <![CDATA[
            [Embed("../assets/orb_over_skin.gif")]
            public var os:Class;

            [Embed("../assets/orb_down_skin.gif")]
            public var ds:Class;

            [Embed("../assets/orb_up_skin.gif")]
            public var us:Class;

            private function init():void {
                b1.setStyle("upSkin", us);
                b1.setStyle("overSkin", os);
                b1.setStyle("downSkin", ds);
            }
        ]]>
    </fx:Script>

    <mx:Button label="Click Me" id="b1"/>
</s:Application>
```

Using the setStyle() method to apply programmatic skins to MX components

For programmatic skins, you apply a skin to a control by using the setStyle() method. The skin component must be in your source path when you compile the application. The following example applies the ButtonStatesSkin.as component to an MX Button by using the `setStyle()` method:

```
<?xml version="1.0"?>
<!-- skins/ApplyProgrammaticSkinsSetStyle.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            public function changeSkins():void {
                if (cb1.selected) {
                    b1.setStyle("upSkin", ButtonStatesSkin);
                    b1.setStyle("downSkin", ButtonStatesSkin);
                    b1.setStyle("overSkin", ButtonStatesSkin);
                    b1.setStyle("disabledSkin", ButtonStatesSkin);
                } else {
                    b1.setStyle("upSkin", null);
                    b1.setStyle("downSkin", null);
                    b1.setStyle("overSkin", null);
                    b1.setStyle("disabledSkin", null);
                }
            }

        ]]>
    </fx:Script>
    <mx:Button id="b1" label="Click Me"/>
    <mx:CheckBox id="cb1" label="Apply custom skin class" click="changeSkins();"/>

</s:Application>
```

The reference to the ButtonStatesSkin class in the `setStyle()` method causes the compiler to link in the entire ButtonStatesSkin class at compile time. The resulting SWF file will be larger than if there were no reference to this class, even if the `changeSkins()` method is never called.

In the previous example, the SampleButtonSkin.mxml file is in the same directory as the application. If the skin class is in another directory, you must import the class into the application so that the compiler can resolve the class name, as the following example shows:

```
<?xml version="1.0"?>
<!-- skins/ApplyProgrammaticSkinsSetStylePackage.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            import myComponents.*;

            public function changeSkins():void {
                if (cb1.selected) {
                    b1.setStyle("upSkin", myComponents.ButtonStatesSkin);
                    b1.setStyle("downSkin", myComponents.ButtonStatesSkin);
                    b1.setStyle("overSkin", myComponents.ButtonStatesSkin);
                    b1.setStyle("disabledSkin", myComponents.ButtonStatesSkin);
                } else {
                    b1.setStyle("upSkin", null);
                    b1.setStyle("downSkin", null);
                    b1.setStyle("overSkin", null);
                    b1.setStyle("disabledSkin", null);
                }
            }
        ]]>
    </fx:Script>
    <mx:Button id="b1" label="Click Me"/>
    <mx:CheckBox id="cb1" label="Apply custom skin class" click="changeSkins();"/>

</s:Application>
```

When you define stateful skin, you use the `setStyle()` method to set the `skin` style property of the control to the class name of your skin component. For more information on applying stateful skins, see "Creating stateful skins for MX components" on page 1687.

Applying MX component skins with the StyleManager class

To apply skins to all instances of a control, you can use the StyleManager class, as the following example shows:

```
<?xml version="1.0"?>
<!-- skins/EmbedWithStyleManager.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark" initialize="init()">
    <fx:Script>
        <![CDATA[
            [Embed("../assets/orb_over_skin.gif")]
            public var os:Class;
            [Embed("../assets/orb_down_skin.gif")]
            public var ds:Class;
            [Embed("../assets/orb_up_skin.gif")]
            public var us:Class;
            private function init():void {
               styleManager.getStyleDeclaration("mx.controls.Button").setStyle("upSkin", us);
             styleManager.getStyleDeclaration("mx.controls.Button").setStyle("overSkin", os);
             styleManager.getStyleDeclaration("mx.controls.Button").setStyle("downSkin", ds);
            }
        ]]>
    </fx:Script>

    <mx:Button label="Click Me" id="b1"/>

</s:Application>
```

For more information on using the StyleManager class, see “Using the StyleManager class” on page 1537.

Creating graphical skins for MX components

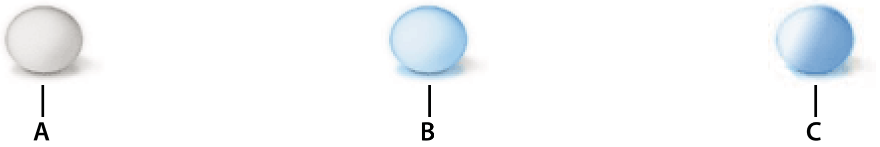
To use graphical skins with MX components, you embed image files in your application. These images can be JPEG, GIF, or PNG files, or they can be symbols embedded in SWF files.

When using SWF files for skins, you can use static assets, which are SWF files that contain symbol definitions but no ActionScript 3.0 code, or use dynamic assets. Dynamic assets correspond to components and contain ActionScript 3.0 code. These components are designed to work with Flex features such as view states and transitions. To use dynamic assets in an application, you export the symbols in the SWF file to a SWC file, and then link the SWC file to your application.

For more information on embedding assets into an application, see “Embedding assets” on page 1699.

Using JPEG, GIF, and PNG files as MX component skins

To use a JPEG, GIF, or PNG file as a skin, you must embed the file in your application. For example, to change the appearance of a Button control, you might create three image files called orb_up_skin.gif, orb_down_skin.gif, and orb_over_skin.gif:



A. orb_down_skin.gif B. orb_over_skin.gif C. orb_up_skin.gif

The following example uses graphical skins for the up, over, and down states of the Button control:

```
<?xml version="1.0"?>
<!-- skins/EmbedImagesTypeSelector.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Style>
        @namespace mx "library://ns.adobe.com/flex/mx";

        mx|Button {
            overSkin: Embed("../assets/orb_over_skin.gif");
            upSkin: Embed("../assets/orb_up_skin.gif");
            downSkin: Embed("../assets/orb_down_skin.gif");
        }
    </fx:Style>
    <mx:Button id="b1" label="Click Me"/>
</s:Application>
```

The reason that you must embed the file is that in order to determine a component's minimum and preferred sizes, skin assets must be present as soon as the component is created. If you reference external assets at run time, Flex does not have the sizing information and, therefore, cannot render the skins properly.

Because skins are embedded, if you change the graphics files that comprise one or more skins, you must recompile your application for the changes to take effect. For more information on embedding assets, see “Embedding assets” on page 1699.

One drawback to embedding images as skins is that they can become distorted if you resize the component that has a skin. You can use a technique called 9-slice scaling to create skins that do not become distorted when the component is resized. For information on the 9-slice scaling technique, see “Using 9-slice scaling with embedded images” on page 1711.

Using static SWF assets as MX component skins

Static SWF files created in Flash 8 or Flash 9 contain artwork or skins, but do not contain any ActionScript 3.0 code. You can use the entire SWF file as a single skin, or you can use one or more symbols inside the SWF file as a skin. To embed an entire SWF file, you point to the location of the SWF file with the `source` property in the `Embed` statement, as follows:

```
<?xml version="1.0"?>
<!-- skins/EmbedSWFSource.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
  <fx:Style>
     @namespace mx "library://ns.adobe.com/flex/mx";

     mx|Button {
        upSkin: Embed(source="../assets/SubmitButtonUpSkin.swf");
     }
  </fx:Style>

  <mx:Button id="b1"/>
</s:Application>
```

To import a symbol from a SWF file, you use the `symbol` property to specify the symbol name that you want to use in addition to pointing to the location of the SWF file with the `source` property. You must separate each property of the `Embed` statement with a comma. The following example replaces the MX Button control's up, over, and down skins with individual symbols from a SWF file:

```
<?xml version="1.0"?>
<!-- skins/EmbedSymbolsCSS.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
  <fx:Style>
    @namespace mx "library://ns.adobe.com/flex/mx";
    mx|Button {
        upSkin: Embed(source='../assets/SubmitButtonSkins.swf',
            symbol='MyUpSkin');
        overSkin: Embed(source='../assets/SubmitButtonSkins.swf',
            symbol='MyOverSkin');
        downSkin: Embed(source='../assets/SubmitButtonSkins.swf',
            symbol='MyDownSkin');
    }
 </fx:Style>

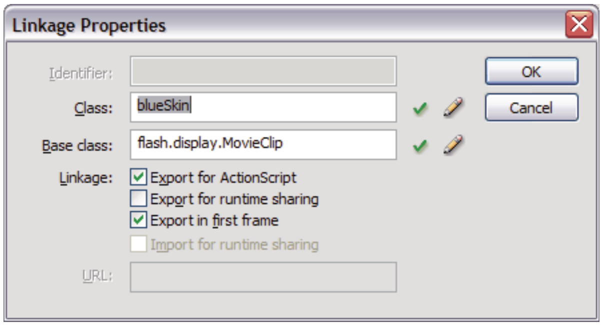
  <mx:Button id="b1"/>
</s:Application>
```

You use the same syntax when embedding skin symbols inline, as follows:

```
<?xml version="1.0"?>
<!-- skins/EmbedSymbolsInline.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
  <mx:Button id="b1"
     overSkin="@Embed(source='../assets/SubmitButtonSkins.swf',
        symbol='MyOverSkin')"
     upSkin="@Embed(source='../assets/SubmitButtonSkins.swf',
        symbol='MyUpSkin')"
     downSkin="@Embed(source='../assets/SubmitButtonSkins.swf',
        symbol='MyDownSkin')"/>
</s:Application>
```

In the source FLA file, all symbols that you use must meet the following conditions:

- The symbol must be on the Stage. After you create an image file and convert it to a symbol, you must drag it from the library to the Stage. Flash does not export symbols that are not on the Stage. Alternatively, you can select the Export in First Frame option in the Linkage Properties dialog box.
- The symbol must have been exported for ActionScript with a linkage name. In Flash, you select the Export for ActionScript option in the symbol's Linkage Properties dialog box, as the following example shows:



Linkage Properties

Identifier:

Class: blueSkin

Base class: flash.display.MovieClip

Linkage: ☑ Export for ActionScript
☐ Export for runtime sharing
☑ Export in first frame
☐ Import for runtime sharing

URL:

The linkage name is the name used by Flex. Symbol names are ignored.

- The FLA files cannot contain any ActionScript.
- The symbol must have an upper-left registration point that you select in the Convert to Symbol dialog box. The following example shows an upper-left registration point:

Registration:

You can use 9-slice scaling with image files (a grid with nine regions) so that the skin scales well when the component's size changes. You define the properties for 9-slice scaling of images when you apply the skin in CSS, as the following example shows:

```
@namespace mx "library://ns.adobe.com/flex/mx";
mx|Button {
    overSkin: Embed(
        "../assets/orb_over_skin.gif",
        scaleGridTop=6,
        scaleGridLeft=12,
        scaleGridBottom=44,
        scaleGridRight=49
    );
}
```

For information on embedding assets that use the 9-slice scaling technique, see "Using 9-slice scaling with embedded images" on page 1711.

Using dynamic SWF assets as MX component skins

Dynamic SWF assets are components that you create in Flash CS3 and then import into your application. Since these assets are components, you can use them just as you would a component shipped with Flex or as you would a custom component that you created as an MXML file or as an ActionScript class.

To create a Flash component, you define the symbol in your FLA file and specify the base class of the symbol as mx.flash.UIMovieClip. To integrate components from a dynamic SWF asset created in Flash CS3, you publish your FLA file as a SWC file.

For more information on creating dynamic SWF assets and using them as skins, see http://www.adobe.com/go/flex3_cs3_skinning_extensions and http://www.adobe.com/go/flex3_cs3_swfkit.

Creating programmatic skins for MX components

You create programmatic skins as ActionScript classes or as MXML components for MX components. You use the basic drawing methods of the Flash Graphics (flash.display.Graphics) package, and apply those skins to your Flex controls.

You can modify programmatic skins that come with Flex or create your own. The programmatic skins used by components are in the mx.skins.halo.* package. All of the skins extend one of the following classes: UIComponent, ProgrammaticSkin, Border, or RectangularBorder.

For information on creating your own skins, see "Programmatic skins recipe for MX components" on page 1675.

One type of programmatic skin, called a stateful skin, uses view states. For information on creating stateful skins, see "Creating stateful skins for MX components" on page 1687.

Flex handles much of the overhead of class definition when you use an MXML component, so in some cases you might find it easier to define your skins as MXML components. The only restriction on MXML components is that you cannot define a constructor. Instead, you use an event handler for the `preinitialize` event to perform the work that you do in an ActionScript constructor.

For general information on creating ActionScript classes and MXML components, see *"Custom Flex components" on page 2356*.

Programmatic skins recipe for MX components

At a minimum, a programmatic skin consists of a constructor (for an ActionScript class), an updateDisplayList() method, and a set of getters and setters for the skin's properties. Programmatic skins generally extend one of the classes in the mx.skins package or the UIComponent class.

To see examples of skins that follow the programmatic skin recipe, look at the concrete classes in the mx.skins.halo package. These are the skins that the components use. Those skins follow the same recipe presented here.

The following example is a typical outline of a programmatic skin:

```
package { // Use unnamed package if this skin is not in its own package.
  // skins/MySkinOutline.as

  // Import necessary classes here.
  import flash.display.Graphics;
  import mx.skins.Border;
  import mx.skins.ProgrammaticSkin;
  import mx.styles.StyleManager;
  // Extend ProgrammaticSkin.
  public class MySkinOutline extends ProgrammaticSkin {
     // Constructor.
     public function MySkinOutline() {
        // Set default values here.
     }
     // Override updateDisplayList().
     override protected function updateDisplayList(w:Number,
        h:Number):void {
        // Add styleable properties here.
        // Add logic to detect component s state and set properties here.
        // Add drawing methods here.
     }
  }
} // Close unnamed package.
```

In your application, you can apply a programmatic skin using the `ClassReference` statement in CSS:

```
<?xml version="1.0"?>
<!-- skins/ApplyMySkinOutline.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
  <fx:Style>
     @namespace mx "library://ns.adobe.com/flex/mx";

     mx|Button {
        overSkin: ClassReference("MySkinOutline");
        upSkin: ClassReference("MySkinOutline");
        downSkin: ClassReference("MySkinOutline");
     }
  </fx:Style>
  <mx:Button id="b1" label="Click Me"/>
</s:Application>
```

Selecting an interface or base class for your skin

Skin classes must implement one or more interfaces. When you create a programmatic skin, you can either create a class that implements the required interfaces, or you can create a subclass of a class that already implements the required interfaces.

Your decision on which interface to implement, or which class to use as the base class of your skin, might depend on the type of skin that you want to create. For example, if you want to create a skin that defines a border, you might create a subclass of Border. If you want to create a stateful skin, you can create subclass of UIComponent or create a class that implement the IStateClient interface.

You can extend the abstract base classes in the mx.skins package or the concrete classes in the mx.skins.halo package. Extending the former gives you greater control over the look and feel of your skins. Extending the latter is a good approach if you use the default behaviors of the components but also want to add extra styling to them.

Some rules to consider:

- A stateful skin must implement either the IStateClient interface or the IProgrammaticSkin interface. The UIComponent class implements the IStateClient interface. The ProgrammaticSkin class implements the IProgrammaticSkin interface.
- A skin passed to any skin property other than a stateful skin property, such as `Button.upSkin` or `NumericStepper.upArrowOverSkin`, must implement the IFlexDisplayObject interface. The UIComponent class and the ProgrammaticSkin class implement the IFlexDisplayObject interface.

Most Halo skins for MX components extend the mx.skins.ProgrammaticSkin class, but you can select any one of the following as a superclass for your skin:

- The ProgrammaticSkin class implements the IFlexDisplayObject, ILayoutManagerClient, IInvalidating, and ISimpleStyleClient interfaces, so it is the easiest and most common superclass to use.
- The Border class extends the ProgrammaticSkin class and adds support for the `borderMetrics` property. Use this class or the RectangularBorder class if your skin defines the component's border.
- The RectangularBorder class extends the Border class and adds support for the `backgroundImage` style.
- The UIComponent class implements the IStateClient interface, making it easy to use for stateful skins. It is also the component that you use when implementing skins in MXML.

Use the following list of steps to create programmatic skins for your Flex controls. Each step is explained in more detail in the following sections.

Create programmatic skins for MX components

1 Select one of the following base classes as a superclass for your programmatic skin:

- Border or a subclass of Border
- ProgrammaticSkin or a subclass of ProgrammaticSkin
- RectangularBorder or a subclass of RectangularBorder
- UIComponent or a subclass of UIComponent

You can also extend one of the concrete classes in the mx.skins.Halo package.

2 Implement the `updateDisplayList()` method. Put all the drawing and styling calls in this method.

For more information, see “Implementing the updateDisplayList() method” on page 1677.

3 For an ActionScript class, implement the constructor.

4 (Optional) Implement getters for the `measuredWidth` and `measuredHeight` properties.

For more information, see “Implementing the measuredWidth and measuredHeight getters” on page 1684.

5 If the skin is a subclass of Border or RectangularBorder, implement a getter for the `borderMetrics` property.

For more information, see “Implementing a getter for the borderMetrics property” on page 1685.

6 (Optional) Make properties styleable.

If you create a skin that has properties that you want users to be able to set with CSS or with calls to the `setStyle()` method, you must add code to your skin class. For more information, see “Making properties styleable” on page 1695.

Compiling programmatic skins for MX components

When you compile an application that uses programmatic skins, you treat programmatic skins as you would treat any ActionScript class or MXML component, which means that you must add the skins to the `source-path` argument of the compiler. If the skins are in the same directory as the MXML file that you are compiling, you set the `source-path` to a period. The following example shows this with the mxmlc command-line compiler:

```
$ ./mxmlc -source-path=. c:/flex/MyApp.mxml
```

If the programmatic skins are not in a package, you must add them to the unnamed package to make them externally visible. Otherwise, mxmlc throws a compiler error. To do this, you surround the class with a package statement, as the following example shows:

```
package { // Open unnamed package.
    import flash.display.*;
    import mx.skins.ProgrammaticSkin;

    public class MySkin extends ProgrammaticSkin {
        ...
    }
} // Close unnamed package.
```

Implementing the updateDisplayList() method

The updateDisplayList() method defines the look of the skin. It is called after the skin’s construction to initially draw the skin, and then is subsequently called whenever the component is resized, restyled, moved, or is interacted with in some way.

You use the Flash Player drawing methods to draw the programmatic skin in the `updateDisplayList()` method. For more information on the drawing methods, see “Drawing programmatically” on page 1680.

When you implement the `updateDisplayList()` method, you must do the following:

- Use the `override` keyword to override the superclass's implementation.
- Set the return type to `void`.
- Declare the method as `protected`.

The `updateDisplayList()` method takes the height and width of the component as arguments. You use the values of these arguments as the boundaries for the region in which you can draw. The method returns `void`.

You use methods of theGraphics class (such as the `lineTo()` and `drawRect()` methods) to render the skin. To ensure that the area is clear before adding the component's shapes, you should call the `clear()` method before drawing. This method erases the results of previous calls to the `updateDisplayList()` method and removes all the images that were created by using previous draw methods. It also resets any line style that was specified with the `lineStyle()` method.

To use the methods of the Graphics package, you must import the flash.display.Graphics class, and any other classes in the flash.display package that you use, such as GradientType or Font. The following example imports all classes in the flash.display package:

```
import flash.display.*;
```

The following example draws a rectangle as a border around the component with the `drawRect()` method:

```
g.drawRect(0, 0, width, height);
```

The following example skin class draws an *X* with a border around it:

```
package { // Use unnamed package if this skin is not in its own package.
  // skins/CheckboxSkin.as

  // Import necessary classes here.
  import flash.display.Graphics;
  import mx.skins.Border;
  import mx.skins.ProgrammaticSkin;
  import mx.styles.StyleManager;
  public class CheckboxSkin extends ProgrammaticSkin {
     // Constructor.
     public function CheckboxSkin() {
        // Set default values here.
     }
  override protected function updateDisplayList(w:Number, h:Number):void {
     var g:Graphics = graphics;
     g.clear();
     g.beginFill(0xFFFFFF,1.0);
     g.lineStyle(2, 0xFF0000);
     g.drawRect(0, 0, w, h);
     g.endFill();
     g.moveTo(0, 0);
     g.lineTo(w, h);
     g.moveTo(0, h);
     g.lineTo(w, 0);
  }
  }
} // Close unnamed package.
```

For a description of common methods of the Graphics package, see "Drawing programmatically" on page 1680. For details about these methods, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

One common task performed in the `updateDisplayList()` method is to change properties of the skin, depending on the current state of the control. For example, if you define a programmatic skin for a Button control, you can change the border thickness or color of the background when the user moves the mouse over or clicks the Button control.

You check the state by using the `name` property of the skin. The `name` is the current name of the skin. For example, if you define a programmatic skin for a Button control, the `name` property could be any of the skin states: `downSkin`, `upSkin`, `overSkin`, `disabledSkin`, `selectedDisabledSkin`, `selectedDownSkin`, `selectedOverSkin`, or `selectedUpSkin`.

The following example checks which state the Button control is in and adjusts the line thickness and background fill color appropriately. The result is that when the user clicks the Button control, Flex redraws the skin to change the line thickness to 2 points. When the user releases the mouse button, the skin redraws again and the line thickness returns to its default value of 4. The background fill color also changes depending on the Button control's state.

```
package { // Use unnamed package if this skin is not in its own package.
  // skins/ButtonStatesSkin.as
  // Import necessary classes here.
  import flash.display.Graphics;
  import mx.skins.Border;
  import mx.skins.ProgrammaticSkin;
  import mx.styles.StyleManager;
  public class ButtonStatesSkin extends ProgrammaticSkin {
     public var backgroundFillColor:Number;
     public var lineThickness:Number;
     // Constructor.
     public function ButtonStatesSkin() {
        // Set default values.
        backgroundFillColor = 0xFFFFFF;
        lineThickness = 4;
     }
     override protected function updateDisplayList(w:Number, h:Number):void {
        // Depending on the skin's current name, set values for this skin.
        switch (name) {
           case "upSkin":
            lineThickness = 4;
            backgroundFillColor = 0xFFFFFF;
            break;
           case "overSkin":
            lineThickness = 4;
            backgroundFillColor = 0xCCCCCC;
            break;
           case "downSkin":
            lineThickness = 2;
            backgroundFillColor = 0xFFFFFF;
```

```
                break;
              case "disabledSkin":
                lineThickness = 2;
                backgroundFillColor = 0xCCCCCC;
                break;
            }
            // Draw the box using the new values.
            var g:Graphics = graphics;
            g.clear();
            g.beginFill(backgroundFillColor,1.0);
            g.lineStyle(lineThickness, 0xFF0000);
            g.drawRect(0, 0, w, h);
            g.endFill();
            g.moveTo(0, 0);
            g.lineTo(w, h);
            g.moveTo(0, h);
            g.lineTo(w, 0);
        }
    }
} // Close unnamed package.
```

If you use a single programmatic skin class to define multiple states of a control, you must apply the skin to all appropriate states of that control in your application; for example:

```
<?xml version="1.0"?>
<!-- skins/ApplyButtonStatesSkin.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">

    <fx:Style>
        @namespace mx "library://ns.adobe.com/flex/mx";
        mx|Button {
            overSkin: ClassReference("ButtonStatesSkin");
            upSkin: ClassReference("ButtonStatesSkin");
            downSkin: ClassReference("ButtonStatesSkin");
        }
    </fx:Style>
    <mx:Button id="b1" label="Click Me"/>
</s:Application>
```

If the skin is a subclass of RectangularBorder, you must also call `super.updateDisplayList()` from within the body of the `updateDisplayList()` method.

Drawing programmatically

You use the drawing methods of the Graphics class to draw the parts of a programmatic skin. These methods let you describe fills or gradient fills, define line sizes and shapes, and draw lines. By combining these very simple drawing methods, you can create complex shapes that make up your component skins.

The following table briefly describes the most commonly used drawing methods in the Graphics package:

Method	Summary
`beginFill()`	Begins drawing a fill; for example: `beginFill(0xCCCCFF,1);` If an open path exists (that is, if the current drawing position does not equal the previous position that you specified in a `moveTo()` method) and it has a fill associated with it, that path is closed with a line, and then filled.
`beginGradientFill()`	Begins drawing a gradient fill. If an open path exists (that is, if the current drawing position does not equal the previous position that you specified in a `moveTo()` method), and it has a fill associated with it, that path is closed with a line, and then filled.
`clear()`	Removes all the drawing output associated with the current object. The `clear()` method takes no arguments.

`curveTo()`	Draws a curve using the current line style; for example:
	`moveTo(500, 500);`
	`curveTo(600, 500, 600, 400);`
	`curveTo(600, 300, 500, 300);`
	`curveTo(400, 300, 400, 400);`
	`curveTo(400, 500, 500, 500);`

`drawCircle()`	Draws a circle after you set the line style and fill. You pass the method the x and y positions of the circle, as well as the radius, as the following example shows: `drawCircle(10,10,50);`
`drawRect()`	Draws a rectangle once you set the line style and fill. You pass the method the x and y positions of the rectangle, as well as the length and width of the rectangle, as the following example shows: `drawRect(10,10,100,20);`
`drawRoundRect()`	Draws a rectangle with rounded corners, after you set the line and fill. You pass the method the x and y position of the rectangle, length and height of the rectangle, and the width and height of the ellipse that is used to draw the rounded corners, as the following example shows: `drawRoundRect(10,10,100,20,9,5)`
`endFill()`	Ends the fill specified by the `beginFill()` or `beginGradientFill()` methods. The `endFill()` method takes no arguments. If the current drawing position does not equal the previous position that you specified in a `moveTo()` method and a fill is defined, the path is closed with a line, and then filled.
`lineStyle()`	Defines the stroke of lines created with subsequent calls to the `lineTo()` and `curveTo()` methods. The following example sets the line style to a 2-point gray line with 100% opacity: `lineStyle(2,0xCCCCCC,1)` You can call the `lineStyle()` method in the middle of drawing a path to specify different styles for different line segments within a path. Calls to the `clear()` method reset line styles back to `undefined`.

`lineTo()`	Draws a line using the current line style. The following example draws a triangle:
	`moveTo (200, 200);`
	`lineTo (300, 300);`
	`lineTo (100, 300);`
	`lineTo (200, 200);`
	If you call the `lineTo()` method before any calls to the `moveTo()` method, the current drawing position returns to the default value of (0, 0).

`moveTo()`	Moves the current drawing position to the specified coordinates; for example: `moveTo(100,10);`

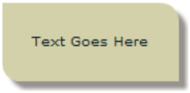
The following example draws a triangle:

```
package { // Use unnamed package if this skin is not in its own package.
  // skins/CheckBoxAsArrowSkin.as

  // Import necessary classes here.
  import flash.display.Graphics;
  import mx.skins.Border;
  import mx.skins.ProgrammaticSkin;
  import mx.styles.StyleManager;
  public class CheckBoxAsArrowSkin extends ProgrammaticSkin {

     // Constructor.
     public function CheckBoxAsArrowSkin() {
        // Set default values.
     }
     override protected function updateDisplayList(w:Number, h:Number):void {
        var unscaledHeight:Number = 2;
        var unscaledWidth:Number = 2;
        var arrowColor:Number;
        var g:Graphics = graphics;
        g.clear();
        switch (name) {
           case "upIcon":
           case "selectedUpIcon": {
            arrowColor = 0x666666;
            break;
           }
           case "overIcon":
           case "downIcon":
           case "selectedOverIcon":
           case "selectedDownIcon": {
            arrowColor = 0xCCCCCC;
            break;
           }
        }
        // Draw an arrow.
        graphics.lineStyle(1, 1, 1);
        graphics.beginFill(arrowColor);
        graphics.moveTo(unscaledWidth, unscaledHeight-20);
        graphics.lineTo(unscaledWidth-30, unscaledHeight+20);
        graphics.lineTo(unscaledWidth+30, unscaledHeight+20);
        graphics.lineTo(unscaledWidth, unscaledHeight-20);
        graphics.endFill();
     }
  }
} // Close unnamed package.
```

The ProgrammaticSkin class also defines drawing methods, the most common of which is the drawRoundRect() method. This method programmatically draws a rectangle and lets you set the corner radius, gradients, and other properties. You can use this method to customize borders of containers so that they might appear as the following example shows:



The following code uses the `drawRoundRect()` method to draw this custom VBox border:

```
package { // Use unnamed package if this skin is not in its own package.
  // skins/CustomContainerBorderSkin.as

  // Import necessary classes here.
  import flash.display.Graphics;
  import mx.graphics.RectangularDropShadow;
  import mx.skins.RectangularBorder;
  public class CustomContainerBorderSkin extends RectangularBorder {
    private var dropShadow:RectangularDropShadow;
    // Constructor.
    public function CustomContainerBorderSkin() {
    }
    override protected function updateDisplayList(unscaledWidth:Number,
       unscaledHeight:Number):void
    {
       super.updateDisplayList(unscaledWidth, unscaledHeight);
       var cornerRadius:Number = getStyle("cornerRadius");
       var backgroundColor:int = getStyle("backgroundColor");
       var backgroundAlpha:Number = getStyle("backgroundAlpha");
       graphics.clear();
       // Background
       drawRoundRect(0, 0, unscaledWidth, unscaledHeight,
           {tl: 0, tr:cornerRadius, bl: cornerRadius, br: 0},
           backgroundColor, backgroundAlpha);
       // Shadow
       if (!dropShadow)
          dropShadow = new RectangularDropShadow();
       dropShadow.distance = 8;
       dropShadow.angle = 45;
       dropShadow.color = 0;
       dropShadow.alpha = 0.4;
       dropShadow.tlRadius = 0;
       dropShadow.trRadius = cornerRadius;
       dropShadow.blRadius = cornerRadius;
       dropShadow.brRadius = 0;
       dropShadow.drawShadow(graphics, 0, 0, unscaledWidth, unscaledHeight);
    }
  }
}
```

In your application, you apply this skin as the following example shows:

```
<?xml version="1.0"?>
<!-- skins/ApplyContainerBorderSkin.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
  <mx:VBox id="vb1"
     borderSkin="CustomContainerBorderSkin"
     backgroundColor="0xCCCC99"
     backgroundAlpha="0.8"
     cornerRadius="14"
     paddingLeft="20"
     paddingTop="20"
     paddingRight="20"
     paddingBottom="20">
     <mx:Label text="This is a VBox with a custom skin."/>
  </mx:VBox>
</s:Application>
```

The `unscaledWidth` and `unscaledHeight` properties in the previous examples refer to the measurements of the skin as the skin itself understands them. These measurements ignore the fact that external components might have changed the dimensions of the skin. When working inside the component, it is best to use the unscaled measurements.

Implementing the measuredWidth and measuredHeight getters

The `measuredWidth` and `measuredHeight` properties define the default width and height of a component. You can implement getter methods for the `measuredWidth` and `measuredHeight` properties of your skin, but it is not required by most skins. Some skins such as the skins that define the ScrollBar arrows do require that you implement these getters. If you do implement these getters, you must specify the `override` keyword when implementing the superclass's getter methods, and you must make the getters public.

The `measuredWidth` and `measuredHeight` getters typically return a constant number. The application usually honors the measured sizes, but not always. If these getters are omitted, the values of `measuredWidth` and `measuredHeight` are set to the default value of 0.

The following example sets the `measuredWidth` and `measuredHeight` properties to 10, and then overrides the getters:

```
package { // Use unnamed package if this skin is not in its own package.
  // skins/ButtonStatesWithMeasuredSizesSkin.as
  // Import necessary classes here.
  import flash.display.Graphics;
  import mx.skins.Border;
  import mx.skins.ProgrammaticSkin;
  import mx.styles.StyleManager;
  public class ButtonStatesWithMeasuredSizesSkin extends ProgrammaticSkin {
     public var backgroundFillColor:Number;
     public var lineThickness:Number;
     private var _measuredWidth:Number;
     private var _measuredHeight:Number;
     // Constructor.
     public function ButtonStatesWithMeasuredSizesSkin() {
        // Set default values.
        backgroundFillColor = 0xFFFFFF;
        lineThickness = 4;
        _measuredHeight = 100;
        _measuredWidth = 150;
     }
     override public function get measuredWidth():Number {
        return _measuredWidth;
     }
     override public function get measuredHeight():Number {
        return _measuredHeight;
     }
     override protected function updateDisplayList(w:Number, h:Number):void {
        // Depending on the skin's current name, set values for this skin.
        switch (name) {
           case "upSkin":
            lineThickness = 4;
            backgroundFillColor = 0xFFFFFF;
            break;
           case "overSkin":
            lineThickness = 4;
            backgroundFillColor = 0xCCCCCC;
            break;
           case "downSkin":
            lineThickness = 2;
            backgroundFillColor = 0xFFFFFF;
            break;
           case "disabledSkin":
            lineThickness = 2;
            backgroundFillColor = 0xCCCCCC;
            break;
        }
        // Draw the box using the new values.
        var g:Graphics = graphics;
        g.clear();
        g.beginFill(backgroundFillColor,1.0);
        g.lineStyle(lineThickness, 0xFF0000);
        g.drawRect(0, 0, w, h);
        g.endFill();
        g.moveTo(0, 0);
        g.lineTo(w, h);
        g.moveTo(0, h);
        g.lineTo(w, 0);
     }
  }
} // Close unnamed package.
```

Implementing a getter for the borderMetrics property

The `borderMetrics` property defines the thickness of the border on all four sides of a programmatic skin. If the programmatic skin is a subclass of Border or RectangularBorder, you must implement a getter for the `borderMetrics` property. Otherwise, this step is optional. This property is of type EdgeMetrics, so your getter must set EdgeMetrics as the return type.

The following example gets the `borderThickness` style and uses that value to define the width of the four sides of the border, as defined in the EdgeMetrics constructor:

```
package { // Use unnamed package if this skin is not in its own package.
  // skins/ButtonStatesWithBorderMetricsSkin.as
  // Import necessary classes here.
  import flash.display.Graphics;
  import mx.skins.Border;
  import mx.skins.ProgrammaticSkin;
  import mx.styles.StyleManager;
  import mx.core.EdgeMetrics;
  public class ButtonStatesWithBorderMetricsSkin extends ProgrammaticSkin {
     public var backgroundFillColor:Number;
     public var lineThickness:Number;
     private var _borderMetrics:EdgeMetrics;
     // Constructor.
     public function ButtonStatesWithBorderMetricsSkin() {
        // Set default values.
        backgroundFillColor = 0xFFFFFF;
        lineThickness = 4;
     }
     public function get borderMetrics():EdgeMetrics {
        if (_borderMetrics) {
           return _borderMetrics;
        }
        var borderThickness:Number = getStyle("borderThickness");
        _borderMetrics = new EdgeMetrics(borderThickness,
            borderThickness, borderThickness, borderThickness);
        return _borderMetrics;
     }
     override protected function updateDisplayList(w:Number, h:Number):void
     {
        // Depending on the skin's current name, set values for this skin.
        switch (name) {
           case "upSkin":
            lineThickness = 4;
            backgroundFillColor = 0xFFFFFF;
            break;
           case "overSkin":
            lineThickness = 4;
            backgroundFillColor = 0xCCCCCC;
            break;
           case "downSkin":
            lineThickness = 2;
            backgroundFillColor = 0xFFFFFF;
            break;
           case "disabledSkin":
            lineThickness = 2;
            backgroundFillColor = 0xCCCCCC;
            break;
        }
        // Draw the box using the new values.
        var g:Graphics = graphics;
        g.clear();
        g.beginFill(backgroundFillColor,1.0);
        g.lineStyle(lineThickness, 0xFF0000);
        g.drawRect(0, 0, w, h);
        g.endFill();
        g.moveTo(0, 0);
        g.lineTo(w, h);
        g.moveTo(0, h);
        g.lineTo(w, 0);
     }
  }
} // Close unnamed package.
```

Creating stateful skins for MX components

Many MX components that use the Halo theme, such as Button, Slider, and NumericStepper, support stateful skins. A stateful skin uses view states to specify the skins for the different states of the component. For more information on view states, see “View states” on page 1847.

You can determine whether a skin property supports stateful skins from its description in the *ActionScript 3.0 Reference for the Adobe Flash Platform*. For example, all stateful skin properties contain a sentence in the form shown below for the `TitleWindow.closeButtonSkin` property:

“You can use the `closeButtonSkin` style to assign the skin for the following skin states: disabled, down, over, up.”

To function as a stateful skin, the skin must implement the IStateClient interface. Because that interface is implemented by the UIComponent class, you can use any subclass of UIComponent to define a stateful skin. You then assign the stateful skin class to a stateful skin property of the component.

For example, an MX Button control has eight possible states, and eight associated skins. To create a single skin class that defines the skins for all eight states, you create a skin based on the UIComponent control. You then define eight view states within your skin where the name of each view state corresponds to a state of the Button control, as the following example shows:

```
<?xml version="1.0"?>
<mx:UIComponent xmlns:mx="http://www.adobe.com/2006/mxml">
    <mx:states>
        <mx:State name="down">
        </mx:State>

        <mx:State name="over">
        </mx:State>

        ...

        <mx:State name="selectedUp">
        </mx:State>
    </mx:states>

    <fx:Script>
        <![CDATA[
            <!-- Define the skin by using the Flash drawing API. -->
        ]]>
    </fx:Script>
</mx:UIComponent>
```

***Note:** You can create a stateful skin in either ActionScript or MXML. The examples in this section use MXML because it requires fewer lines of code to define view states.*

After defining your stateful skin, you assign it to the `skin` style property of the control. You can assign the stateful control by using CSS, the `setStyle()` method, by using inline styles, or by using the StyleManager class. The following example sets it by using CSS:

```
<?xml version="1.0"?>
<!-- skins/ApplyButtonStatefulSkinAll.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Style>
        @namespace mx "library://ns.adobe.com/flex/mx";
        mx|Button {
            skin: ClassReference("myComponents.MyButtonStatefulSkinAll");
        }
    </fx:Style>
    <mx:Button label="Hello" id="b" />
</s:Application>
```

You do not have to define all eight skins; you only define the skins that you want to create. For all others, you use the default skins supplied with the theme.

For more information, see “Applying MX component skins” on page 1663.

Example: Creating a stateful Halo skin

A stateful skin is a programmatic skin, so you have to define it using the rules defined in the section “Programmatic skins recipe for MX components” on page 1675. That means you have to define an override of the `updateDisplayList()` method, and for an ActionScript class, you also define a constructor.

To create a view state, you define a base view state, and then define a set of changes, or overrides, that modify the base view state to define each new view state. Each new view state can modify the base state by adding or removing child components, by setting style and property values, or by defining state-specific event handlers.

One of the most common ways to define stateful skins is to define the skin with several properties or styles that can be modified by each view state. For example, the following stateful skin defines a property to control the line weight, fill color, and drop shadow for a skin used by the Button control:

```
<?xml version="1.0"?>
<!-- skins/myComponents/MyButtonStatefulSkin.mxml -->
<mx:UIComponent xmlns:mx="http://www.adobe.com/2006/mxml">
  <mx:Script>
    <![CDATA[
      import flash.filters.DropShadowFilter;

      // Define a drop shadow for the over and down states.
      [Bindable]
      private var myFilter:DropShadowFilter = new DropShadowFilter(0);

      // Define a private var for line weight.
      private var _lineWeight:Number = 1;

      // Define public setter and getter for line weight.
      public function get lineWeight():Number
      {
        return _lineWeight;
      }

      public function set lineWeight(value:Number):void
      {
        _lineWeight = value;
        invalidateDisplayList();
      }

      // Define a private var for the fill color.
      private var _rectFill:uint = 0x00FF00;

      // Define public setter and getter for fill color.
      public function get rectFill():uint
      {
        return _rectFill;
      }

      public function set rectFill(value:uint):void
      {
        _rectFill = value;
        invalidateDisplayList();
      }
      override protected function updateDisplayList(unscaledWidth:Number,
          unscaledHeight:Number):void
      {
        graphics.lineStyle(lineWeight, 0x0066FF);
        graphics.beginFill(rectFill, 0.50);
        graphics.drawRoundRect(0, 0, unscaledWidth, unscaledHeight, 10, 10);
        filters = [myFilter];
      }
    ]]>
  </mx:Script>
```

```
    <mx:states>
        <mx:State name="up">
        </mx:State>
        <mx:State name="over">
            <mx:SetProperty target="{this}"
                name="rectFill" value="0x00CC33"/>
            <mx:SetProperty target="{myFilter}"
                name="distance" value="4"/>
        </mx:State>
        <mx:State name="down">
            <mx:SetProperty target="{this}"
                name="rectFill" value="0x00CC33"/>
            <mx:SetProperty target="{myFilter}"
                name="inner" value="true"/>
            <mx:SetProperty target="{myFilter}"
                name="distance" value="2"/>
        </mx:State>
    </mx:states>
</mx:UIComponent>
```

This examples defines skins the for following states:

up Does not define any changes; therefore, the base view state defines the skin for the up state.

over Changes the fill color to 0x00CC33, sets the line width to 2 pixels, and creates a 2-pixel wide drop shadow.

down Changes the fill color to 0x00CC33, sets the drop shadow type to inner, and creates a 2-pixel wide drop shadow.

The following application uses this skin:

```
<?xml version="1.0"?>
<!-- skins/ApplyButtonStatefulSkin.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <fx:Style>
        @namespace mx "library://ns.adobe.com/flex/mx";
        mx|Button {
          skin: ClassReference("myComponents.MyButtonStatefulSkin");
          disabledSkin: ClassReference("mx.skins.halo.ButtonSkin");
          selectedUpSkin: ClassReference("mx.skins.halo.ButtonSkin");
          selectedOverSkin: ClassReference("mx.skins.halo.ButtonSkin");
          selectedDownSkin: ClassReference("mx.skins.halo.ButtonSkin");
          selectedDisabledSkin: ClassReference("mx.skins.halo.ButtonSkin");
        }
    </fx:Style>
    <mx:Button label="Hello" id="b" />
</s:Application>
```

Creating a stateful Halo skin using images

You can use images in a stateful skin where a change of state causes the skin to display a different image. One issue when using images is that the base view state must contain the image so that when the skin is first created it has values for the `measuredWidth` and `measuredHeight` properties, otherwise Flex sets the height and width of the skin to 0.

In the following example, you embed images for the up, over, down, and disabled states of the Button control:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- skins/myComponents/MyButtonStatefulSkinImages.mxml -->
<mx:Canvas xmlns:mx="http://www.adobe.com/2006/mxml">
    <mx:Script>
        <![CDATA[
            // Embed the skin images.
            [Bindable]
            [Embed(source="../../assets/orb_up_skin.gif")]
            private var buttonUp:Class;
            [Bindable]
            [Embed(source="../../assets/orb_over_skin.gif")]
            private var buttonOver:Class;
            [Bindable]
            [Embed(source="../../assets/orb_down_skin.gif")]
            private var buttonDown:Class;
            [Bindable]
            [Embed(source="../../assets/orb_disabled_skin.gif")]
            private var buttonDisabled:Class;
        ]]>
    </mx:Script>
    <mx:states>
        <mx:State name="up"/>
        <mx:State name="notBase">
            <mx:RemoveChild target="{baseButton}"/>
        </mx:State>
        <mx:State name="over" basedOn="notBase">
            <mx:AddChild creationPolicy="all">
                <mx:Image source="{buttonOver}"
                    maintainAspectRatio="false"
                    width="100%" height="100%"/>
            </mx:AddChild>
        </mx:State>
        <mx:State name="down" basedOn="notBase">
            <mx:AddChild creationPolicy="all">
                <mx:Image source="{buttonDown}"
                    maintainAspectRatio="false"
                    width="100%" height="100%"/>
            </mx:AddChild>
        </mx:State>
        <mx:State name="disabled" basedOn="notBase">
            <mx:AddChild creationPolicy="all">
                <mx:Image source="{buttonDisabled}"
                    maintainAspectRatio="false"
                    width="100%" height="100%"/>
            </mx:AddChild>
        </mx:State>
    </mx:states>

    <mx:Image id="baseButton"
        width="100%" height="100%"
        source="{buttonUp}"
        maintainAspectRatio="false"/>
</mx:Canvas>
```

In this example the skin performs the following actions:

- Defines no changes from the base view state to create the up view state.

- Defines the notBase view state to remove the image defined by the base view state. All other view states, except for the up view state, are based on the notBase view state.
- Sets the `creationPolicy` property to `all` for each AddChild tag. This property specifies to create the child instance at application startup, rather than on the first change to the view state. This prevents flickering when viewing a view state for the first time. For more information, see “View states” on page 1847.
- Sets the `width` and `height` properties to 100% for the Image tags because the Canvas container is what is being resized by the skin parent, not the individual Image controls. This setting configures the Image control to size itself to its parent.
- Sets the `maintainAspectRatio` property to `false` on each Image tag so that the image stretches to fill the full size of the Canvas container.

Using transitions with a stateful Halo skin

View states let you change appearance of a component, typically in response to a user action. Transitions define how a change of view state looks as it occurs on the screen. You define a transition by using the effect classes, in combination with several effects designed explicitly for handling transitions. For more information on transitions, see “Transitions” on page 1870.

In the following example, you add a transition to the stateful skin definition from the previous section. In this example, the transition defines a 100 ms animation to occur when changing the fill color of the skin:

```
<?xml version="1.0"?>
<!-- skins/myComponents/MyButtonStatefulSkinTrans.mxml -->
<mx:UIComponent xmlns:mx="http://www.adobe.com/2006/mxml">
  <mx:Script>
    <![CDATA[
      import flash.filters.DropShadowFilter;

      // Define a drop shadow for the over and down states.
      [Bindable]
      private var myFilter:DropShadowFilter = new DropShadowFilter(0);

      // Define a private var for line weight.
      private var _lineWeight:Number = 1;

      // Define public setter and getter for line weight.
      public function get lineWeight():Number
      {
        return _lineWeight;
      }

      public function set lineWeight(value:Number):void
      {
        _lineWeight = value;
        invalidateDisplayList();
      }

      // Define a private var for the fill color.
      private var _rectFill:uint = 0x00FF00;

      // Define public setter and getter for fill color.
      public function get rectFill():uint
      {
        return _rectFill;
      }

      public function set rectFill(value:uint):void
      {
        _rectFill = value;
        invalidateDisplayList();
      }
      override protected function updateDisplayList(unscaledWidth:Number,
          unscaledHeight:Number):void
      {
        graphics.lineStyle(lineWeight, 0x0066FF);
        graphics.beginFill(rectFill, 0.50);
        graphics.drawRoundRect(0, 0, unscaledWidth, unscaledHeight, 10, 10);
        filters = [myFilter];
      }
    ]]>
  </mx:Script>

    <mx:states>
        <mx:State name="up">
        </mx:State>
        <mx:State name="over">
            <mx:SetProperty target="{this}"
                name="rectFill" value="0x00CC33"/>
            <mx:SetProperty target="{myFilter}"
                name="distance" value="4"/>
        </mx:State>
        <mx:State name="down">
            <mx:SetProperty target="{this}"
                name="rectFill" value="0x00CC33"/>
            <mx:SetProperty target="{myFilter}"
                name="inner" value="true"/>
            <mx:SetProperty target="{myFilter}"
                name="distance" value="2"/>
        </mx:State>
    </mx:states>
    <mx:transitions>
        <mx:Transition>
            <mx:AnimateProperty target="{this}"
                property="rectFill" duration="100"/>
        </mx:Transition>
    </mx:transitions>
</mx:UIComponent>
```

Creating advanced programmatic skins for MX components

Accessing the parent component

It is possible to get a reference to the parent of the programmatic skin from within the programmatic skin class. You can use this reference to access properties of the parent component or call methods on it.

You can access the parent from the updateDisplayList() method by using the skin's `parent` property. You cannot access the parent in the skin's constructor because the skin has not yet been added to the parent control. The value of the skin's `parent` property is set when the parent MX container calls the `addChild()` method to add the skin as a child.

When instantiating components with programmatic skins, the order of events is as follows:

1 Create an instance of the parent component.

2 Create an instance of the skin class.

3 Call the `addChild()` method on the parent MX container to add the skin class.

To get a reference to the skin's parent, you must cast the skin's `parent` property to a UIComponent. The skin inherits this read-only property from the IFlexDisplayObject interface. You should also confirm that the parent is a UIComponent by using the `is` operator, because Flex throws a run-time error if the cast cannot be made.

The following example gets the class name of the parent control and draws the border and fill, depending on the type of component the parent is:

```
package {
import flash.display.GradientType;
import flash.display.Graphics;
import mx.skins.Border;
import mx.styles.StyleManager;
import mx.utils.ColorUtil;
import mx.skins.halo.HaloColors;
import mx.core.UIComponent;
public class IconSkin extends Border {
  public function IconSkin() {
     //super();
  }

  override public function get measuredWidth():Number {
     return 14;
  }
  override public function get measuredHeight():Number {
     return 14;
  }

  override protected function updateDisplayList(w:Number, h:Number):void {
     super.updateDisplayList(w, h);
     // User-defined styles
     var borderColor:uint = getStyle("borderColor");
     var fillAlphas:Array = getStyle("fillAlphas");
     var fillColors:Array = getStyle("fillColors");
     styleManager.getColorNames(fillColors);
     var highlightAlphas:Array = getStyle("highlightAlphas");
     var themeColor:uint = getStyle("themeColor");

     var r:Number = width / 2;

     var upFillColors:Array;
     var upFillAlphas:Array;
     var disFillColors:Array;
     var disFillAlphas:Array;
     var g:Graphics = graphics;
     g.clear();

     var myParent:String;

     switch (name) {
        case "upIcon": {
           upFillColors = [ fillColors[0], fillColors[1] ];
           upFillAlphas = [ fillAlphas[0], fillAlphas[1] ];
           if (parent is UIComponent) {
            myParent = String(UIComponent(parent).className);
           }
           if (myParent=="RadioButton") {
            // RadioButton border
            g.beginGradientFill(GradientType.LINEAR,
                [ borderColor, 0x000000 ],
                [100,100], [0,0xFF],
                verticalGradientMatrix(0,0,w,h));
            g.drawCircle(r,r,r);
            g.drawCircle(r,r,(r-1));
            g.endFill();
            // RadioButton fill
            g.beginGradientFill(GradientType.LINEAR,
                upFillColors,
                upFillAlphas,
                [0,0xFF],
                verticalGradientMatrix(1,1,w-2,h-2));
            g.drawCircle(r,r,(r-1));
            g.endFill();
           } else if (myParent=="CheckBox") {
            // CheckBox border
            drawRoundRect(0,0,w,h,0,
                [borderColor, 0x000000], 1,
                verticalGradientMatrix(0,0,w,h),
                GradientType.LINEAR,
                null, {x: 1,y:1,w:w-2,h:h-2,r:0});
            // CheckBox fill
            drawRoundRect(1, 1, w-2, h-2, 0,
                upFillColors, upFillAlphas,
                verticalGradientMatrix(1,1,w-2,h-2));
           }
           // top highlight
           drawRoundRect(1, 1, w-2,
                (h-2)/2, {tl:r,tr:r,bl:0,br:0},
                [0xFFFFFF, 0xFFFFFF],
                highlightAlphas,
                verticalGradientMatrix(0,0,w-2,(h-2)/2));
        }

        // Insert other cases such as downIcon and overIcon here.

     }
  }
}
}
```

Making properties styleable

In many cases, you define a programmatic skin that defines style properties, such as the background color of the skin, the border thickness, or the roundness of the corners. You can make these properties styleable so that your users can change their values in a CSS file or with the `setStyle()` method from inside their applications. You cannot set styles that are defined in programmatic skins by using inline syntax.

To make a custom property styleable, add a call to the `getStyle()` method in the `updateDisplayList()` method and specify that property as the method's argument. When Flex renders the skin, it calls `getStyle()` on that property to find a setting in CSS or on the display list. You can then use the value of the style property when drawing the skin.

You should wrap this call to the `getStyle()` method in a check to see if the style exists. If the property was not set, the result of the `getStyle()` method can be unpredictable.

The following example verifies if the property is defined before assigning it a value:

```
if (getStyle("lineThickness")) {
    _lineThickness = getStyle("lineThickness");
}
```

You must define a default value for the skin's styleable properties. You usually do this in the skin's constructor function. If you do not define a default value, the style property is set to `NaN` or `undefined` if the application does not define that style. This can cause a run-time error.

The following example of the MyButtonSkin programmatic skin class defines default values for the `_lineThickness` and `_backgroundFillColor` styleable properties in the skin's constructor. It then adds calls to the `getStyle()` method in the `updateDisplayList()` method to make these properties styleable:

```
package { // Use unnamed package if this skin is not in its own package.
  // skins/ButtonStylesSkin.as
  // Import necessary classes here.
  import flash.display.Graphics;
  import mx.skins.Border;
  import mx.skins.ProgrammaticSkin;
  import mx.styles.StyleManager;
  public class ButtonStylesSkin extends ProgrammaticSkin {
     public var _backgroundFillColor:Number;
     public var _lineThickness:Number;
     // Constructor.
     public function ButtonStylesSkin() {
        // Set default values.
        _backgroundFillColor = 0xFFFFFF;
        _lineThickness=2;
     }
     override protected function updateDisplayList(w:Number, h:Number):void {
        if (getStyle("lineThickness")) {
           // Get value of lineThickness style property.
           _lineThickness = getStyle("lineThickness");
        }
        if (getStyle("backgroundFillColor")) {
           // Get value of backgroundFillColor style property.
           _backgroundFillColor = getStyle("backgroundFillColor");
        }
        // Draw the box using the new values.
        var g:Graphics = graphics;
        g.clear();
        g.beginFill(_backgroundFillColor,1.0);
        g.lineStyle(_lineThickness, 0xFF0000);
        g.drawRect(0, 0, w, h);
        g.endFill();
        g.moveTo(0, 0);
        g.lineTo(w, h);
        g.moveTo(0, h);
        g.lineTo(w, 0);
     }
  }
} // Close unnamed package.
```

In your application, you can set the values of styleable properties by using CSS or the `setStyle()` method.

The following example sets the value of styleable properties on all Button controls with CSS:

```
<?xml version="1.0"?>
<!-- skins/ApplyButtonStylesSkin.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    width="600" height="600">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

  <fx:Style>
     @namespace mx "library://ns.adobe.com/flex/mx";
     mx|Button {
        upSkin:ClassReference('ButtonStylesSkin');
        downSkin:ClassReference('ButtonStylesSkin');
        overSkin:ClassReference('ButtonStylesSkin');
        disabledSkin:ClassReference('ButtonStylesSkin');
        lineThickness:4;
        backgroundFillColor:#CCCCCC;
     }
  </fx:Style>
  <fx:Script><![CDATA[
     public function changeLineThickness(e:Event):void {
        var t:int = Number(b1.getStyle("lineThickness"));
        if (t == 4) {
           b1.setStyle("lineThickness",1);
        } else {
           b1.setStyle("lineThickness",4);
        }
     }
  ]]></fx:Script>
  <mx:Button id="b1" label="Change Line Thickness" click="changeLineThickness(event)"/>

</s:Application>
```

When using the `setStyle()` method to set the value of a style property in your application, you can set the value of a styleable property on a single component instance (as in the previous example) or on all instances of a component.

The following example uses the `setStyle()` method to set the value of a styleable property on all instances of the control (in this case, all MX Button controls):

```
<?xml version="1.0"?>
<!-- skins/ApplyGlobalButtonStylesSkin.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    width="600" height="600">
  <fx:Style>
     @namespace mx "library://ns.adobe.com/flex/mx";

     mx|Button {
        upSkin:ClassReference('ButtonStylesSkin');
        downSkin:ClassReference('ButtonStylesSkin');
        overSkin:ClassReference('ButtonStylesSkin');
        disabledSkin:ClassReference('ButtonStylesSkin');
        lineThickness:4;
        backgroundFillColor:#CCCCCC;
     }
  </fx:Style>
  <fx:Script><![CDATA[
     public function changeLineThickness(e:Event):void {
        var t:int = Number(b1.getStyle("lineThickness"));
        if (t == 4) {
         styleManager.getStyleDeclaration("mx.controls.Button").setStyle("lineThickness", 1);
        } else {
         styleManager.getStyleDeclaration("mx.controls.Button").setStyle("lineThickness", 4);
        }
     }
  ]]></fx:Script>
  <mx:Button id="b1" label="Change Line Thickness" click="changeLineThickness(event)"/>

</s:Application>
```

If you do not set the values of these properties using either CSS or the `setStyle()` method, Flex uses the default values of the properties that you set in the skin's constructor.

To get the value of an existing style property, such as `color` or `fontSize`, you do not have to wrap the call to the `getStyle()` method in a check for the property's existence. This is because Flex creates a CSSStyleDeclaration that defines the default values of all of a component's styles. Preexisting style properties are never undefined. Style properties that you add to a custom skin are not added to this CSSStyleDeclaration because the component does not know that the property is a style property.

Custom skin properties that you define as styleable are noninheritable. So, subclasses or children of that component do not inherit the value of that property.

Embedding assets

Many applications built in Adobe® Flex™ use external assets like images, sounds, and fonts. Although you can reference and load assets at run time, you often compile these assets into your applications. The process of compiling an asset into your application is called *embeddingthe asset*. Flex lets you embed image files, movie files, MP3 files, and TrueType fonts into your applications.

For information on embedding fonts, see "Fonts" on page 1568.

About embedding assets

When you embed an asset, you compile it into your application's SWF file. The advantage of embedding an asset is that it is included in the SWF file, and can be accessed faster than it can if the application has to load it from a remote location at run time. The disadvantage of embedding an asset is that your SWF file is larger than if you load the asset at run time.

You should use the Image tag when embedding a general purpose image file in an application. The Spark component set also includes a BitmapImage class, but that class should be used only for embedding images in skins and FXG components. For more information, see "Image control" on page 676.

Examples of embedding assets

One of the most common uses of the embed mechanism is to import an image for a Flex control by using the `@Embed()` directive in an MXML tag definition. For example, many controls support icons or skins that you can embed in the application. The Button control lets you specify label text, as well as an optional icon image, as the following example shows:

```
<?xml version="1.0"?>
<!-- embed\ButtonIcon.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:Button label="Icon Button"
        height="30"
        icon="@Embed(source='logo.gif')"/>
</s:Application>
```

Another option for embedding is to associate the embedded image with a variable by using the `[Embed]` metadata tag. In this way, you can reference the embedded image from multiple locations in your application, as the following example shows:

```
<?xml version="1.0"?>
<!-- embed\ButtonIconClass.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <fx:Script>
        <![CDATA[
            [Embed(source="logo.gif")]
            [Bindable]
            public var imgCls:Class;
        ]]>
    </fx:Script>
    <s:Button label="Icon Button 1"
        height="30"
        icon="{imgCls}"/>
    <s:Button label="Icon Button 2"
        height="30"
        icon="{imgCls}"/>
</s:Application>
```

For style properties, you can embed an asset as part of a style sheet definition by using the `Embed()` directive, as the following example shows:

```
<?xml version="1.0"?>
<!-- embed\ButtonIconCSS.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Style>
        .myCustomButton {
            icon:Embed(source="logo.gif");
        }
    </fx:Style>
    <s:Button label="Icon Button Style Def"
        styleName="myCustomButton"/>
</s:Application>
```

Note: *The equal sign (=) in the style sheet is a Flex extension that may not be supported by all CSS processors. If you find that it is not supported, you can use the* `Embed(filename)` *syntax.*

Accessing assets at run time

The alternative to embedding an asset is to load the asset at run time. You can load an asset from the local file system in which the SWF file runs, or you can access a remote asset, typically through an HTTP request over a network.

Embedded assets load immediately, because they are already part of the Flex SWF file. However, they add to the size of your application and slow down the application initialization process. Embedded assets also require you to recompile your applications whenever your asset changes.

Assets loaded at run time exist as separate, independent files on your web server (or elsewhere) and are not compiled into your Flex applications. The referenced assets add no overhead to an application's initial load time. However, you might experience a delay when you use the asset and load it in Adobe® Flash® Player or Adobe® AIR™. These assets are independent of your Flex application, so you can change them without causing a recompile operation, as long as the names of the modified assets remain the same.

For examples that load an asset at run time, see "Image control" on page 676and "SWFLoader control" on page 715.

For security, by default Flash Player does not allow an application to access some types of remote data (such as SWF files) at run time from a domain other than the domain from which the application was served. Therefore, a server that hosts data must be in the same domain as the server hosting your application, or the server must define a crossdomain.xml file. A crossdomain.xml file is an XML file that provides a way for a server to indicate that its data and documents are available to SWF files served from specific domains, or from all domains. For more information on application security, see "Security" on page 117.

Supported file types

You can embed the following types of files in a Flex application.

File Type	File Format	MIME Type	Description and Examples
Images	GIF	image/gif	Embedding JPEG, GIF, and PNG images
Images	.JPG, .JPEG	image/jpeg	Embedding JPEG, GIF, and PNG images
Images	PNG	image/png	Embedding JPEG, GIF, and PNG images
Images	SVG	image/svg image/svg-xml	Embedding SVG images
Flash	SWF	application/x-shockwave-flash	Embedding SWF files

File Type	File Format	MIME Type	Description and Examples
Flash	Symbols stored in a SWF file	application/x-shockwave-flash	Embedding SWF files
Audio	MP3	audio/mpeg	Embedding sounds
Font	TTF (TrueType)	application/x-font-truetype	
Font	FON (System font)	application/x-font	
All other types		application/octet-stream	Embedding all other file types

Syntax for embedding assets

The syntax that you use for embedding assets depends on where in your application you embed the asset. Flex supports the following syntaxes:

- `[Embed(`*parameter1, paramater2, ...*`)]` metadata tag

  You use this syntax to embed an asset in an ActionScript file, or in an `<fx:Script>` block in an MXML file. For more information, see "Using the [Embed] metadata tag" on page 1705.

- `@Embed(`*parameter1, paramater2, ...*`)` directive

  You use this syntax in an MXML tag definition to embed an asset. For more information, see "Using the @Embed() directive in MXML" on page 1705.

- `Embed(`*parameter1, paramater2, ...*`)` directive

  You use this syntax in an `<fx:Style>` block in an MXML file to embed an asset. For more information, see "Embedding assets in style sheets" on page 1706.

All three varieties of the embed syntax let you access the same assets; the only difference is where you use them in your application.

Escaping the @ character

You can use the slash character (\) to escape the at sign character (@) when you want to use a literal @ character. For example, the string "\@Embed(foo)" means the literal string "@Embed(foo)"). You use two slash characters (\\) to escape a single backslash character. For example, use the character string "\@" to specify the literal strings "\@".

Embed parameters

Each form of the embed syntax takes one or more optional parameters. The exact syntax that you use to embed assets depends on where they are embedded. Some of these parameters are available regardless of what type of asset you are embedding, and others are specific to a particular type of media. For example, you can use the `source` and `mimeType` parameters with any type of media, but the `scaleGridRight` parameter applies only to images.

The following table describes the parameters that are available for any type of embedded asset. For more information, see "About the source parameter" on page 1703 and "About the MIME type" on page 1704.

Parameter	Description
`source=`*`asset`*	Specifies the name and path of the asset to embed; either an absolute path or a path relative to the file containing the embed statement. The embedded asset must be a locally stored asset. Therefore you cannot specify a URL for an asset to embed. For more information on setting the path, see “About setting the path to the embedded asset” on page 1704.
`mimeType=`*`type`*	Specifies the mime type of the asset. For more information, see “About the MIME type” on page 1704.
`smoothing=true|false`	Specifies whether the bitmap is smoothed when scaled. If `true`, the bitmap is smoothed when scaled. If `false`, the bitmap is not smoothed when scaled. This property can be used with any image format.
`compression=true|false`	For lossless images only (GIF and PNG) specifies to compress the embedded image in the generated SWF file.
`quality=`***`val`***	If you specify `compression=true`, specifies a percentage value, between 0 and 100, to control the compression algorithm. The lower the value, the higher the amount of compression.

The following table describes the parameters that are specific for images and Sprite objects. For more information, see “Using 9-slice scaling with embedded images” on page 1711.

Parameter	Description
`scaleGridTop`	Specifies the distance in pixels of the upper dividing line from the top of the image in a 9-slice scaling formatting system. The distance is relative to the original, unscaled size of the image.
`scaleGridBottom`	Specifies the distance in pixels of the lower dividing line from the top of the image in a 9-slice scaling formatting system. The distance is relative to the original, unscaled size of the image.
`scaleGridLeft`	Specifies the distance in pixels of the left dividing line from the left side of the image in a 9-slice scaling formatting system. The distance is relative to the original, unscaled size of the image.
`scaleGridRight`	Specifies the distance in pixels of the right dividing line from the left side of the image in a 9-slice scaling formatting system. The distance is relative to the original, unscaled size of the image.

The following table describes the parameter that is specific to SWF files. For more information, see “Embedding SWF files” on page 1709.

Parameter	Description
`symbol`	Specifies the symbol in a SWF file to embed, for use with Adobe Flash Player 8 and earlier, and for Flash Player 9 static assets. Use static assets for simple artwork or skins that do not contain any ActionScript 3.0 code.

About the source parameter

In almost all cases, you must specify the `source` parameter, or nothing is embedded.

The `source` parameter is the default parameter of the `[Embed]` metadata tag; therefore, if you are not specifying any other parameters, you can just supply its value without explicitly including the parameter name or assigning it the desired value, as the following example shows:

```
<fx:Style>
    .myCustomButton1 {
        icon:Embed("logo.gif");
    }
    .myCustomButton2 {
        icon:Embed(source="logo.gif");
    }
</fx:Style>
```

About setting the path to the embedded asset

You can specify a fully qualified path to the image, as the following examples show:

```
<s:Button label="Icon Button"
    icon="@Embed(source='c:/myapp/assets/logo.gif')"/>
```

Note: *Do not use the backslash character (\) as a separator in the path.*

If the path does not start with a slash character, Flex first searches for the file relative to the file that contains the `[Embed]` metadata tag. For example, the MXML file testEmbed.mxml includes the following code:

```
<s:Button label="Icon Button" icon="@Embed(source='assets/logo.gif')"/>
```

In this example, Flex searches the subdirectory named assets in the directory that contains the testEmbed.mxml file. If the image is not found, Flex then searches for the image in the SWC files associated with the application.

If the path starts with a slash character, Flex first searches the directory of the MXML file for the asset, and then it searches the source path. You specify the source path to the Flex compiler by using the `source-path` compiler option. For example, you set the `source-path` option as the following code shows:

```
-source-path=a1,a2,a3
```

The MXML file a1/testEmbed.mxml then uses the following code:

```
<s:Button label="Icon Button" icon="@Embed(source='/assets/logo.gif')"/>
```

Flex first searches for the file in a1/assets, then in a2/assets, and then in a3/assets. If the image is not found, Flex searches for the image in the SWC files associated with the application.

If the MXML file is in the a2 directory, as in a2/testEmbed.mxml, Flex first searches the a2 directory and then the directories specified by the `source-path` option.

About the MIME type

You can optionally specify a MIME type for the imported asset by using the `mimeType` parameter. If you do not specify a `mimeType` parameter, Flex makes a best guess about the type of the imported file based on the file extension. If you do specify it, the `mimeType` parameter overrides the default guess of the asset type.

Flex supports the following MIME types.

- application/octet-stream
- application/x-font
- application/x-font-truetype
- application/x-shockwave-flash
- audio/mpeg
- image/gif
- image/jpeg

- image/png
- image/svg
- image/svg-xml

Using the [Embed] metadata tag

You can use the `[Embed]` metadata tag to import JPEG, GIF, PNG, SVG, SWF, TTF, and MP3 files.

You must use the `[Embed]` metadata tag before a variable definition, where the variable is of type Class. The following example loads an image file, assigns it to the `imgCls` variable, and then uses that variable to set the value of the `source` property of an Image control:

```
<?xml version="1.0"?>
<!-- embed\ImageClass.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    width="100" height="80">

    <fx:Script>
        <![CDATA[
            [Embed(source="logo.gif")]
            [Bindable]
            public var imgCls:Class;
        ]]>
    </fx:Script>
    <s:Image source="{imgCls}"/>
</s:Application>
```

Notice that Flex uses data binding to tie the `imgCls` variable to the `source` property. If you omit the `[Bindable]` metadata tag preceding the `imgCls` variable definition, Flex can perform the data binding operation only once, at application startup. When you include the `[Bindable]` metadata tag, Flex recognizes any changes to the `imgCls` variable and updates any components that use that variable when a change to it occurs.

Generally, this method of embedding assets provides more flexibility than other methods because you can import an asset once and then use it in multiple places in your application, and because you can update the asset and have the data binding mechanism propagate that update throughout your application.

Using the @Embed() directive in MXML

Many Flex components, such as Button and TabNavigator, take an `icon` property or other property that lets you specify an image to the control. You can embed the image asset by specifying the property value by using the `@Embed()` directive in MXML. You can use any supported graphic file with the `@Embed()` directive, including SWF files and assets inside SWF files.

You can use the `@Embed()` directive to set an MXML tag property, or to set a property value by using a child tag. The `@Embed()` directive returns a value of type Class or String. If the component's property is of type String, the `@Embed()` directive returns a String. If the component's property is of type Class, the `@Embed()` directive returns a Class. Using the `@Embed()` directive with a property that requires a value of any other data type results in an error.

The following example creates a Button control and sets its `icon` property by using the `@Embed()` directive:

```
<?xml version="1.0"?>
<!-- embed\ButtonAtEmbed.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:Button label="Icon Button"
        height="30"
        icon="@Embed(source='logo.gif')"/>

</s:Application>
```

Embedding assets in style sheets

Many style properties of Flex components support imported assets. The following examples show different ways to embed assets in style sheets:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- embed/EmbedWithStyleSheet.mxml -->
<s:Application name="Spark_Button_icon_test"
        xmlns:fx="http://ns.adobe.com/mxml/2009"
        xmlns:s="library://ns.adobe.com/flex/spark"
        xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout horizontalAlign="center" verticalAlign="middle"/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            [Embed("logo.gif")]
            protected const ICON:Class;
        ]]>
    </fx:Script>

    <fx:Style>
        @namespace s "library://ns.adobe.com/flex/spark";
        @namespace mx "library://ns.adobe.com/flex/mx";

        s|Button#btn1 {
            icon: "logo.gif";
        }

        s|Button#btn2 {
            icon: Embed("logo.gif");
        }

        s|Button#btn3 {
            icon: PropertyReference("ICON");
        }
    </fx:Style>

    <s:Button id="btn1" label="Spark Button with dynamic icon"/>
    <s:Button id="btn2" label="Spark Button with inline embedded icon"/>
    <s:Button id="btn3" label="Spark Button with metadata [Embed] icon"/>

</s:Application>
```

This example is used with permission by http://blog.flexexamples.com.

You can also use these style properties to set the skins for a component. *Skinning* is the process of changing the appearance of a component by modifying or replacing its visual elements. These elements can be made up of images, SWF files, or class files that contain drawing API methods.

For more information on skinning and on embedding assets by using style sheets, see “Skinning MX components” on page 1655.

Embedding asset types

You can import various types of media, including images, SWF files, and sound files.

Embedding JPEG, GIF, and PNG images

Flex supports embedding JPEG, GIF, and PNG files. You can use these images for icons, skins, and other types of application assets.

You might want to manipulate an embedded image at run time. To manipulate it, you determine the data type of the object representing the image and then use the appropriate ActionScript methods and properties of the object.

For example, you use the `[Embed]` metadata tag in ActionScript to embed a GIF image, as the following code shows:

```
[Embed(source="logo.gif")]
[Bindable]
public var imgCls:Class;
```

In this example, you define a class named imgCls that represents the embedded image. When embedding JPEG, GIF, and PNG files, Flex defines imgCls as a reference to a subclass of the mx.core.BitmapAsset class, which is a subclass of the flash.display.Bitmap class.

In ActionScript, you can create and manipulate an object that represents the embedded image before passing it to a control. To do so, you create an object with the type of the embedded class, manipulate it, and then pass the object to the control, as the following example shows:

```
<?xml version="1.0"?>
<!-- embed/EmbedAccessClassObject.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">

    <fx:Script>
        <![CDATA[
            import mx.core.BitmapAsset;

            [Embed(source="logo.gif")]
            [Bindable]
            public var imgCls:Class;
            private function modImage():void {
                // Create an object from the embed class.
                // Since the embedded image is a GIF file,
                // the data type is BitmapAsset.
                var imgObj:BitmapAsset = new imgCls() as BitmapAsset;

                // Modify the object.
                imgObj.bitmapData.noise(4);
                // Write the modified object to the Image control.
                myImage.source=imgObj;
            }
        ]]>
    </fx:Script>

    <s:HGroup>
        <s:Image id="myImageRaw" source="{imgCls}"/>
        <s:Image id="myImage" creationComplete="modImage();"/>
    </s:HGroup>
</s:Application>
```

In this example, the first Image control displays the unaltered image and the second Image control displays the modified image. You use the `bitmapData` property of the mx.core.BitmapAsset class to modify the object. The `bitmapData` property is of type flash.display.BitmapData; therefore you can use all of the methods and properties of the BitmapData class to manipulate the object.

Embedding SVG images

Flex supports importing Scalable Vector Graphics (SVG) images, or a GZip compressed SVG image in a SVGZ file, into an application. This lets you import SVG images and use SVG images as icons for Flex controls.

Flex supports a subset of the SVG 1.1 specification to let you import static, two-dimensional scalable vector graphics. This includes support for basic SVG document structure, Cascading Style Sheets (CSS) styling, transformations, paths, basic shapes, colors, and a subset of text, painting, gradients, and fonts. Flex does not support SVG animation, scripting, or interactivity with the imported SVG image.

For example, you use the `[Embed]` metadata tag in ActionScript to embed an SVG image, as the following code shows:

```
[Embed(source="logo.svg")]
[Bindable]
public var imgCls:Class;
```

In this example, you define a class named imgCls that represents the embedded image. When embedding an SVG image, Flex defines imgCls as a reference to a subclass of the mx.core.SpriteAsset class, which is a subclass of the flash.display.Sprite class. Therefore, you can manipulate the image by using the methods and properties of the SpriteAsset class. For an example that manipulates an imported image, see "Embedding JPEG, GIF, and PNG images" on page 1707.

Embedding sounds

Flex supports embedding MP3 sound files for later playback. The following example creates a simple media player with Play and Stop buttons:

```
<?xml version="1.0"?>
<!-- embed/EmbedSound.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <fx:Script>
        <![CDATA[

            import flash.media.*;

            [Embed(source="sample.mp3")]
            [Bindable]
            public var sndCls:Class;

            public var snd:Sound = new sndCls() as Sound;
            public var sndChannel:SoundChannel;

            public function playSound():void {
                sndChannel=snd.play();
            }

            public function stopSound():void {
                sndChannel.stop();
            }
        ]]>
    </fx:Script>
    <s:HGroup>
        <s:Button label="play" click="playSound();"/>
        <s:Button label="stop" click="stopSound();"/>
    </s:HGroup>
</s:Application>
```

In this example, you define a class named sndCls that represents the embedded MP3 file. When embedding MP3 files, Flex defines sndCls as a reference to a subclass of the mx.core.SoundAsset, which is a subclass of the flash.media.Sound class.

Flex can handle any legal filename, including filenames that contain spaces and punctuation marks. If the MP3 filename includes regular quotation marks, be sure to use single quotation marks around the filename.

You do not have to embed the sound file to use it with Flex. You can also use the Sound class to load a sound file at run time. For more information, see the Sound class in the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

Embedding SWF files

Flex fully supports embedding Flash SWF files. You can embed different types of SWF files.

Embedding SWF files for Flash Player 8 and earlier, and for static Flash Player 9 or later assets

You can embed SWF files created for Flash Player 8 and earlier and for Flash Player 9 or later static assets. Use static assets for simple artwork or skins that do not contain any ActionScript 3.0 code. When embedded, your Flex application cannot interact with the embedded SWF file. That is, you cannot use ActionScript in a Flex application to access the properties or methods of a SWF file created for Flash Player 8 or earlier or for static Flash Player 9 or later assets.

***Note:** You can use the flash.net.LocalConnection class to communicate between a Flex application and a SWF file.*

For example, you use the `[Embed]` metadata tag in ActionScript to embed a SWF file, as the following code shows:

```
[Embed(source="icon.swf")]
[Bindable]
public var imgCls:Class;
```

In this example, you define a class named imgCls that represents the embedded SWF file. Flex defines imgCls as a reference to a subclass of the mx.core.MovieClipAsset class, which is a subclass of the flash.display.MovieClip class. Therefore you can manipulate the image by using the methods and properties of the MovieClipAsset class.

Embedding SWF symbols

Flex lets you reference exported symbols in an embedded SWF file. If the symbol has dependencies, Flex embeds them also; otherwise, Flex embeds only the specified symbol from the SWF file. To reference a symbol, you specify the `symbol` parameter:

```
[Embed(source='SWFFileName.swf', symbol='symbolName')]
```

***Note:** Flash defines three types of symbols: Button, MovieClip, and Graphic. You can embed Button and MovieClip symbols in a Flex application, but you cannot embed a Graphic symbol because it cannot be exported for ActionScript.*

This capability is useful when you have a SWF file that contains multiple exported symbols, but you want to load only some of them into your Flex application. Loading only the symbols that your application requires makes the resulting Flex SWF file smaller than if you imported the entire SWF file.

A Flex application can import any number of SWF files. However, if two SWF files have the same filename and the exported symbol names are the same, you cannot reference the duplicate symbols, even if the SWF files are in separate directories.

If the SWF file contains any ActionScript code, Flex prints a warning during compilation and then strips out the ActionScript from the embed symbol. This means that you can only embed the symbol itself.

The following example imports a green square from a SWF file that contains a library of different shapes:

```
<?xml version="1.0"?>
<!-- embed\EmbedSWFSymbol.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx" >
    <s:Image id="image0"
        source="@Embed(source='circleSquare.swf', symbol='greenSquare')"/>
</s:Application>
```

If you use the `[Embed]` metadata tag in ActionScript to embed the symbol, you can access the object that represents the symbol, as the following code shows:

```
[Embed(source='shapes.swf', symbol='greenSquare')]
[Bindable]
public var imgCls:Class;
```

In this example, you define a class named imgCls that represents the embedded symbol. Internally, Flex defines imgCls as a reference to a subclass of either one of the following classes:

SpriteAsset For single-frame SWF files

MovieClipAsset For multiframe SWF files

Embedding SWF files that represent Flex applications

You can embed SWF files that represent Flex applications. For example, you use the `[Embed]` metadata tag in ActionScript to embed a SWF file, as the following code shows:

```
[Embed(source="flex2.swf")]
[Bindable]
public var flexAppCls:Class;
```

In this example, you define a class named flexAppCls that represents the embedded SWF file. Flex defines flexAppCls as a reference to a subclass of the mx.core.MovieClipAsset class, which is a subclass of the flash.display.MovieClip class. Therefore you can manipulate the embedded SWF file by using the methods and properties of the MovieClipAsset class.

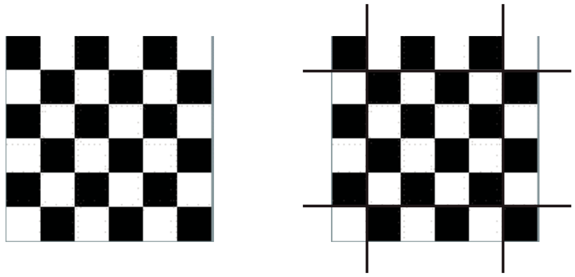
You typically embed a Flex application when you do not require the embedding application to interact with the embedded application. If the embedding application requires interactivity with the embedded application, you might consider implementing it as a custom component, rather than as a separate application.

Alternatively, if you use the SWFLoader control to load the Flex application at run time, the embedding application can interact with the loaded application to access its properties and methods. For more information and examples, see "Interacting with a loaded Flex application" on page 717.

Using 9-slice scaling with embedded images

Flex supports the 9-slice scaling of embedded images. This feature lets you define nine sections of an image that scale independently. The nine regions are defined by two horizontal lines and two vertical lines running through the image, which form the inside edges of a 3 by 3 grid. For images with borders or fancy corners, 9-slice scaling provides more flexibility than full-graphic scaling.

The following example show an image, and the same image with the regions defined by the 9-slice scaling borders:



When you scale an embedded image that uses 9-slice scaling, all text and gradients are scaled normally. However, for other types of objects the following rules apply:

- Content in the center region is scaled normally.
- Content in the corners is not scaled.
- Content in the top and bottom regions is scaled only horizontally. Content in the left and right regions is scaled only vertically.
- All fills (including bitmaps, video, and gradients) are stretched to fit their shapes.

If you rotate the image, all subsequent scaling is normal, as if you did not define any 9-slice scaling.

To use 9-slice scaling, define the following four parameters in your embed statement: `scaleGridTop`, `scaleGridBottom`, `scaleGridLeft`, and `scaleGridRight`. For more information on these parameters, see “Embed parameters” on page 1702.

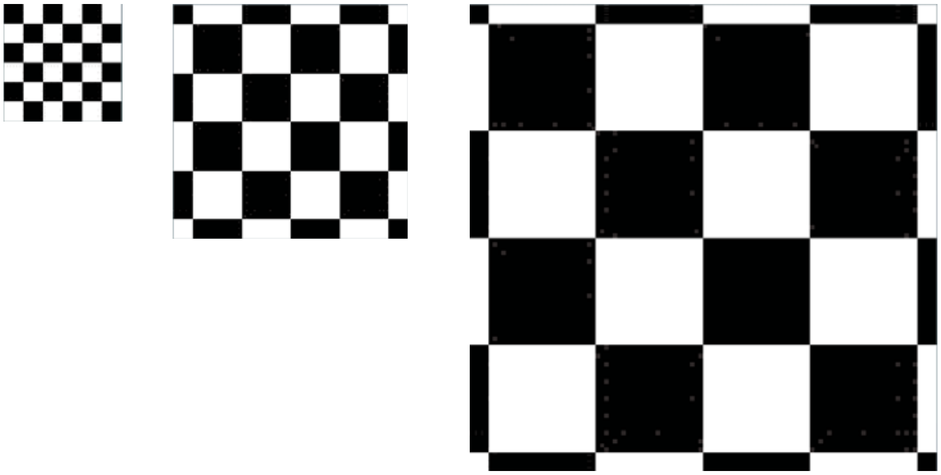
An embedded SWF file may already contain 9-slice scaling information specified by using Adobe Flash Professional. In that case, the SWF file ignores any 9-slice scaling parameters that you specify in the embed statement.

The following example uses 9-slice scaling to maintain a set border, regardless of how the image itself is resized.

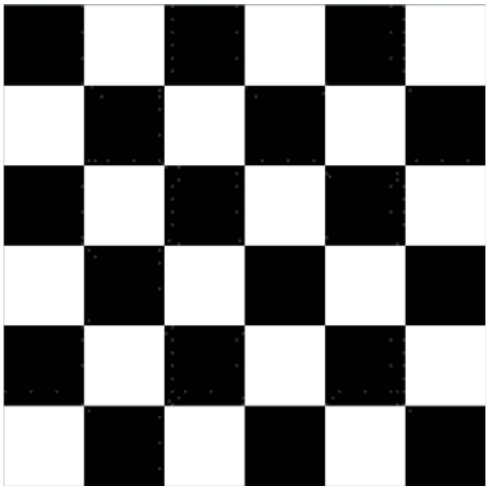
```
<?xml version="1.0"?>
<!-- embed\Embed9slice.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    height="1200" width="600">
    <fx:Script>
        <![CDATA[
            [Embed(source="slice_9_grid.gif",
                scaleGridTop="25", scaleGridBottom="125",
                scaleGridLeft="25", scaleGridRight="125")]
            [Bindable]
            public var imgCls:Class;
        ]]>
    </fx:Script>

    <s:VGroup>
        <s:Image source="{imgCls}"/>
        <s:Image source="{imgCls}" width="300" height="300"/>
        <s:Image source="{imgCls}" width="450" height="450"/>
    </s:VGroup>
</s:Application>
```

The original image is 30 by 30 pixels. The preceding code produces a resizable image that maintains a 5-pixel border:



If you had omitted the 9-slice scaling, the scaled image would have appeared exactly like the unscaled image, as the following image shows:



In this example, you define a class named imgCls that represents the embedded image. If the image is a SWF file that uses 9-slice scaling, Flex defines imgCls as a subclass of the mx.core.SpriteAsset class, which is a subclass of the flash.display.Sprite class. Therefore you can use all of the methods and properties of the SpriteAsset class to manipulate the object.

Embedding all other file types

You can embed any file type in a Flex application as a bit map array. However, Flex does not recognize or process files other than those described previously. If you embed any other file type, you must provide the transcode logic to properly present it to the application user.

To load a file type that is not specifically supported by Flex, use the `[Embed]` metadata tag to define the source file and MIME type "application/octet-stream". Then define a new class variable for the embedded file. The embedded object is a ByteArrayAsset type object.

The following code embeds a bitmap (.bmp) file and displays properties of the embedded object when you click the Show Properties button. To display or use the object in any other way, you must provide code to create a supported object type.

```
<?xml version="1.0"?>
<!-- embed\EmbedOtherFileTypes.mxml -->
<s:Application xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:mx="library://ns.adobe.com/flex/mx">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

    <fx:Script>
        <![CDATA[
            import mx.core.UIComponent;
            import mx.core.BitmapAsset;

            [Embed(source="logo.bmp",mimeType="application/octet-stream")]
            private var FileClass : Class;

            private function captureEmbeddedImage():void {
                var fileByteArray:Object = new FileClass();
                myTA.text+= "File length:  " + String(fileByteArray.length) + "\n";
                myTA.text+="File type:  " +
                    String(getQualifiedSuperclassName(fileByteArray)) + "\n";
            }
        ]]>
    </fx:Script>

    <s:Button
        id="showProperties"
        label="Show Properties"
        click="captureEmbeddedImage();"/>

    <s:TextArea id="myTA"
        width="75%"
        height="100"/>
</s:Application>
```

FXG and MXML graphics

Adding graphics to your applications can make them more attractive and usable. In many cases, you might want to add graphics that are vector-based, and not import images that don’t scale well. You can create vector based graphics in Flex by using one of the following APIs:

- FXG
- MXML graphics

FXG is a declarative syntax for defining static graphics. You typically use a graphics tool such as Adobe Illustrator to export an FXG document, and then use the FXG document as an optimized component in your application. FXG graphics are used by the mobile skin classes because they are so lightweight.

MXML graphics, on the other hand, are a collection of classes that you use to define interactive graphics. You typically write MXML graphics code in Flash Builder. You can add interactivity to MXML graphics code because they use classes in the Flex SDK that are subclasses of GraphicElement. The result is not as optimized as FXG.

FXG and MXML graphics define the following:

- Graphics and text primitives
- Fills, strokes, gradients, and bitmaps
- Support for effects such as filters, masks, alphas, transforms, and blend modes

FXG and MXML graphics share very similar syntax. For example, in FXG, you can define a rectangle with the `<Rect>` tag. In MXML graphics, you use the `<s:Rect>` tag. Most FXG elements have MXML graphics equivalents, although the attributes supported on FXG elements are only a subset of those supported on MXML graphics tags.

The amount of interactivity when using FXG and MXML graphics is different. If you use MXML graphics, the tags are mapped to their backing ActionScript implementations during compilation. You can reference the MXML graphic elements and have greater control over them in your code. If you use FXG, then you cannot reference instances of objects within the FXG document from the application or other components. In addition, you cannot add MXML code to it, nor can you add ActionScript.

FXG and MXML graphics do not share the same namespace. MXML graphics use the MXML namespace of the containing document. In most cases, this is the Spark namespace. An FXG document uses its own namespace.

You cannot use fragments of FXG syntax in an MXML file. You must either use the FXG document as a separate component or convert the code to MXML graphics syntax.

You can also draw with the ActionScript drawing APIs, described in Using the drawing API.

Chapter 4 "Graphics" in Flex 4 Cookbook

Graphics classes and elements

FXG and MXML graphics share a very similar syntax. The FXG language includes a set of elements that are defined in the FXG 2.0 specification. MXML graphics include tags that are defined in the MXML language. FXG can be thought of as a subset of the MXML graphics tags.

MXML graphics tags are converted to their backing ActionScript implementations by the MXML compiler. Most FXG tags, on the other hand, are converted to low-level Flash Player instructions when compiled. It is this difference that make FXG components much more highly optimized than MXML graphics.

Most FXG elements are roughly equivalent to an MXML graphics class of the same name. But, they do not support all the properties of the MXML graphics class, nor are they backed by ActionScript classes. The following table shows the FXG 2.0 elements and their supported attributes and children. In addition, it lists the equivalent MXML graphics tag:

FXG tag	**Equivalent MXML tag and ActionScript class**	**FXG-supported attributes**	**FXG children**

`<BitmapFill>`	`<s:BitmapFill>`
	mx.graphics.BitmapFill

	mx.geom.Transform
		None.	`<colorTransform>`
			`<matrix>`

For complete descriptions of the FXG elements and their supported attributes, see the FXG 2.0 specification.

FXG

FXG is a declarative XML syntax for defining vector graphics in applications built with Flex. FXG can also be used as an interchange format with other Adobe tools such as Illustrator or Photoshop. FXG closely follows the Flash Player 10 rendering model.

Designers can create vector images using tools such as Photoshop, Illustrator and Fireworks and export them as an FXG document. You can then use that FXG document as a component in your applications.

The following example is an FXG document that draws a filled rectangle:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/comps/GraphicComp.fxg -->
<Graphic xmlns="http://ns.adobe.com/fxg/2008" version="2">
     <Rect id="rect1" width="200" height="200">
          <fill>
             <SolidColor color="#FFFFCC"/>
          </fill>
          <stroke>
             <SolidColorStroke color="#660099" weight="2"/>
          </stroke>
     </Rect>
</Graphic>
```

When using FXG documents as components, you specify the tag to be the name of the FXG file, just as you would do with an ActionScript or MXML component.

The following application uses the GraphicComp.fxg file as a component:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/GraphicCompMain.mxml -->
<s:Application backgroundColor="0xFFFFFF"
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:comps="comps.*">
     <comps:GraphicComp id="graphic1"/>
</s:Application>
```

FXG documents encapsulate nearly all of their functionality in a single document. FXG documents cannot reference other FXG documents or MXML documents. However, they can reference the following external resources:

- External bitmap files. For an example that embeds an external image, see “Bitmap graphics in FXG and MXML graphics” on page 1772.
- Platform fonts by family name and style name.

Like MXML graphics, FXG tags have an implicit depth order. The order in which elements are defined defines their depth. Each tag is effectively drawn above its previous sibling. Children are drawn on top of their parents.

Adobe Creative Suite tools can be used to convert SVG to FXG. To do this, open the SVG file in the tool and export it as an FXG file.

FXG syntax

The root of an FXG document file is a `<Graphic>` tag. An FXG document can include zero or more containers (such as Group) and graphic elements, as well as a single library that can include any number of definitions.

The `<Graphic>` tag can only appear once in an FXG document. While the document cannot contain other `<Graphic>` elements, it can contain other elements such as `<Rect>`, `<Ellipse>`, `<Path>`, and `<BitmapImage>`. The `<Graphic>` tag can also optionally contain a single child `<Library>` tag and/or a single `<mask>` tag. These elements must appear before any other tag. If both are present, then the `<Library>` tag must come first.

You cannot specify an ID for the root `<Graphic>` tag in an FXG document.

FXG documents use the following language namespace:

```
http://ns.adobe.com/fxg/2008
```

When you create an FXG document, you must also add the `version` attribute to the `<Graphic>` root tag. The currently supported version is 2. For example:

```
:Graphic xmlns="http://ns.adobe.com/fxg/2008" version="2">
```

To use an FXG document in an application, you treat is as any other component. In your application, you define a namespace that matches the location of the FXG document. This namespace definition includes a prefix. For example:

```
<s:Application
    ...
    xmlns:comps="comps.*">
```

You then use that prefix to reference the FXG document as a component; for example:

```
<comps:MyGraphicComp id="graphic1"/>
```

FXG data types

The following table describes the basic data types that you can use in an FXG document:

Data Type	Description
angle	An arbitrary number specified as degrees. Angles are clockwise.
color	A numerical RGB specification in hexadecimal notation. You specify a color by using a pound sign (#) immediately followed by six hexadecimal characters. You cannot use the 0x notation that is supported in MXML graphics.
coordinate	Represents a length in the local coordinate system that is the given distance from the origin of the local coordinate system along the relevant axis (the x-axis for x coordinates, the y-axis for y coordinates).
identifier	A text string that matches the regular expression [A-Za-z][A-Za-z0-9_]*.
integer	An optional sign character (+ or -) followed by one or more digits 0 through 9. If the sign character is not present, the number is non-negative. Unless stated otherwise for a particular attribute or property, the range for an integer ranges from -2147483648 to 2147483647.
length	A distance measurement. The format of a length is a number.
number	Specified either in decimal notation, or in scientific notation. Decimal notation consists of either an integer or an optional sign character, followed by zero or more digits, followed by a dot (.), followed by one or more digits. Scientific notation consists of a decimal-number immediately followed by the letter "e" or "E" immediately followed by an integer. Unless stated otherwise for a particular attribute or property, a number has the capacity for at least a single-precision floating point number and has a range of -3.4e+38F to +3.4e+38F.
percentage	A number immediately followed by a percentage sign (%). Percentage values are always relative to another value; for example, a length. Attributes or properties that allow percentage values also define the reference distance measurement to which the percentage refers.

Tags not supported by FXG

While FXG is syntactically very similar to MXML, FXG does not define equivalents for all the MXML language tags. It does, however, include the `<Definition>`, `<Library>` and `<Private>` elements, which are equivalent to the MXML language tags of the same names. FXG does not define any other MXML language tags. The MXML language tags not defined by FXG include the following tags:

- `<fx:Binding>`
- `<fx:Component>`
- `<fx:Declaration>`
- `<fx:Metadata>`
- `<fx:Model>`
- `<fx:Reparent>`
- `<fx:Repeater>`
- `<fx:Script>`
- `<fx:State>`
- `<fx:states>`
- `<fx:Style>`

FXG syntax also does not include any ActionScript 3.0 built-in primitive tags. The list of built-in tags that are not defined by FXG includes the following:

- `<fx:Array>`
- `<fx:Boolean>`

- `<fx:Class>`
- `<fx:Date>`
- `<fx:Function>`
- `<fx:int>`
- `<fx:Number>`
- `<fx:Object>`
- `<fx:String>`
- `<fx:uint>`
- `<fx:XML>`
- `<fx:XMLList>`

FXG does not support data binding. If you try to use the data binding short-hand syntax in an FXG document, the compiler treats it as a literal String value.

Using FXG in applications built with Flex

When you use an FXG document as a component in your application, the compiler optimizes the document into a subclass of the spark.core.SpriteVisualElement class. Specifically, the compiler maps the FXG elements to SWF graphics primitive tags and links only a light-weight, Sprite-based class into your application.

The SpriteVisualElement class extends the Sprite class. It adds support for sizing, positioning, and alpha when used in an application built with Flex.

To use FXG as a component in your applications:

1 Store the FXG document in a location where the compiler can find it. This can be in the same directory as the application, or in a separate location. If you store the FXG document in a separate location, you must add the location to the compiler's source path.

2 Declare a namespace for the component. For example, if the FXG file is in the same directory as the main application that uses it, you can declare a namespace of "*". If the FXG file is in a directory called comps, you can declare a namespace of "comps.*".

3 Add a tag in your application that declares the component inside a Spark container. (You cannot use a MX container as a direct parent of an FXG component.) You can set DisplayObject properties on the tag, such as `x` and `y`, `alpha`, `height` and `width`. You can also add event handlers that are supported by the SpriteVisualElement class on the tag.

The following example creates multiple instances of the star.fxg component, and sets properties on each of those instances:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/OptimizedFXGExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:comps="*"
    width="500" height="300">
    <s:Group>
        <comps:star height="100" width="100" x="50" y="50"/>
        <comps:star rotationX="20" height="70" width="70" x="150" y="50" alpha=".75"/>
        <comps:star rotationX="40" height="50" width="50" x="220" y="50" alpha=".5"/>
        <comps:star rotationX="60" height="30" width="30" x="270" y="50" alpha=".3"/>
        <comps:star rotationX="80" height="10" width="10" x="300" y="50" alpha=".1"/>
    </s:Group>
</s:Application>
```

The following is the FXG component that is used by the previous example:

```
<?xml version='1.0' encoding='UTF-8'?>
<!-- fxg/star.fxg -->
<fxg:Graphic xmlns:fxg="http://ns.adobe.com/fxg/2008" version="2">
    <fxg:Path x="9.399" y="10.049" data="M 82.016 78.257 L 51.895 69.533 L 27.617 89.351 L 
26.621 58.058 L 0.231 41.132 L 29.749 30.52 L 37.714 0.241 L 56.944 24.978 L 88.261 23.181 L 
70.631 49.083 Z">
        <fxg:fill>
            <fxg:SolidColor color="#FFFFFF"/>
        </fxg:fill>
        <fxg:stroke>
            <fxg:SolidColorStroke 
                caps="none" 
                color="#4769C4" 
                joints="miter" 
                miterLimit="4" 
                weight="20"/>
        </fxg:stroke>
    </fxg:Path>
</fxg:Graphic>
```

FXG documents use only the *.fxg filename suffix. You cannot have another file of the same name with an *.mxml or *.as suffix in the same directory.

You can use ActionScript to instantiate an FXG component. When you do this, you declare the FXG tag to be of type SpriteVisualElement. You then add the component to the display list by calling the `addElement()` method, as the following example shows:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/OptimizedFXGActionScriptExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    width="500" height="300"
    creationComplete="drawStar()">
    <fx:Script>
        <![CDATA[
        import spark.core.SpriteVisualElement;
        private var myStar:SpriteVisualElement;
        private function drawStar():void {
            // Create new instances of star.fxg as if it were a local component.
            for (var i:int = 0; i<4; i++) {
                myStar = new star();
                myStar.x = 50 + (i*75);
                myStar.y = 50;
                myStar.height = 100 - (i*30);
                myStar.width = 100 - (i*30);
                myStar.alpha = 1 - (i*.2);
                myStar.rotationX = 20 + (i*20);
                addElement(myStar);
            }
        }
        ]]>
    </fx:Script>
</s:Application>
```

Generating FXG

When you export a graphic file from a tool such as Adobe Illustrator in the FXG format, the tool writes a *.fxg file with a `<Graphic>` root tag.

If you are given the option to select a version of FXG, select version 2.

You can ignore the information in the `<Private>` code block, as long as you also leave the its namespace declaration. The contents of the `<Private>` block must be well-formed and valid XML but is not rendered.

You can optionally remove the `<Private>` tag and its contents from the FXG document. Some tools export FXG with additional syntax so that the file can be re-edited. An FXG document exported from Illustrator, for example, includes a `<Private>` block of code that is used by Illustrator if you want to edit the file again. If you do not expect to edit the file in Illustrator again, then you can remove the `<Private>` block.

Converting FXG elements to MXML graphics

In general, you should use an FXG document as a standalone component in your applications. This gives you the greatest amount of memory optimization, and lets you reuse your FXG files in other parts of the same application, or in other applications. In addition, by keeping the FXG document separate from the application, you can edit and export the FXG again from a graphics tool.

One disadvantage to using an FXG file as a standalone component is that you cannot get a reference to individual elements in it. The FXG component itself is a “black box”; you cannot interact with individual elements from your application or other components. You can, however, still apply effects, resize, position, and trigger events from interaction with the FXG component itself.

In some cases, you might want to add the FXG output directly into your application. You can do this, but you must convert the FXG syntax to MXML graphics.

After converting FXG elements to MXML graphics, you can get a reference to the various graphic elements, just as you can with any other MXML tags. This is useful if you want to apply special effects or events to what were previously FXG elements. After you convert the FXG file to MXML graphics, you cannot re-edit the FXG file in a graphics tool. It is now part of MXML.

To convert an FXG document to MXML graphics:

1 Start by copying and pasting the FXG code into your MXML document.

2 Update the namespaces:

   1 Change the FXG namespace (http://ns.adobe.com/fxg/2008) to the Spark component namespace (library://ns.adobe.com/flex/spark). There can be only one language namespace per document.

   2 If the FXG fragment uses additional tool specific namespaces, you can add these to the root of the MXML file. For example, FXG exported from Adobe Illustrator typically includes the following namespace declarations:

   ```
   xmlns:ai="http://ns.adobe.com/ai/2008"
   xmlns:d="http://ns.adobe.com/fxg/2008/dt"
   ```

   These namespaces do not impact the rendering of the document, but must be retained to keep the XML document valid as tool-specific private attributes will be prefixed in these namespaces.

3 Change or remove any namespace prefixes on the `<Library>`, `<Definition>`, and `<Private>` elements. They must use the MXML 2009 language namespace (http://ns.adobe.com/mxml/2009). If you remove a namespace prefix on the tag, you can usually just add the "fx:" prefix to each of these elements.

4 Move the `<Library>` tag and any `<Definition>` elements it contains to the top of the MXML document. If there is already a `<fx:Library>` tag in the MXML document, move just the `<Definition>` elements into it and remove the FXG `<Library>` tag.

5 For library definitions, add the "fx:" prefix to their tags in the body of the MXML file. In MXML 2009 documents, library definitions are actually in the language namespace. For example, the `<fx:Definition name="BlueCircle">` tag references to a definition that must also be in the "fx" namespace; for example, `<fx:BlueCircle>`.

6 Move the `<Private>` tag to the end of the MXML document or remove it. You do not need to include the `<Private>` tag at all, but it can contain useful information about the tool that generated the FXG.

7 Update the namespace prefix of the FXG elements. There is likely to be an "s:" prefix already mapped to the Spark component namespace on the MXML document's root tag (xmlns:s="library://ns.adobe.com/flex/spark"). Add the "s:" prefix to all of the FXG graphical elements. For example, change `<Graphic>` to `<s:Graphic>`.

8 For FXG 1.0 documents only:

   a Convert `<TextGraphic>` elements to `<s:RichText>`. This does not apply to FXG 2.0 documents, which use the `<RichText>` tag. In that case, you just add the "s:" prefix to the `<RichText>` tag to make it conform to MXML syntax.

   b Convert `<BitmapGraphic>` elements to `<s:BitmapImage>`. This does not apply to FXG 2.0 documents, which use the `<BitmapImage>` tag. In that case, you just add the "s:" prefix to the `<BitmapImage>` tag to make it conform to MXML syntax.

The following file, exported in FXG format from Adobe Illustrator, includes the private information as well as the `<Graphic>` root tag. The contents of this *.fxg file are being shown so that you can then see in a subsequent example how the contents are converted to MXML graphics.

```
<?xml version="1.0" encoding="utf-8" ?>
<!-- assets/skins/SimpleBox.fxg -->
<Graphic version="1.0"
    viewHeight="30"
    viewWidth="100"
    ai:appVersion="14.0.0.367"
    d:id="1"
    xmlns="http://ns.adobe.com/fxg/2008"
    xmlns:ai="http://ns.adobe.com/ai/2008"
    xmlns:d="http://ns.adobe.com/fxg/2008/dt">
  <Library/>
  <Group
    x="-0.296875"
    y="-0.5" d:id="2"
    d:type="layer"
    d:userLabel="Layer 1">
    <Group d:id="3">
      <Rect x="0.5" y="0.5" width="100" height="30" ai:knockout="0">
        <fill>
          <LinearGradient x="0.5" y="15.5" scaleX="100" rotation="-0">
            <GradientEntry color="#ffffff" ratio="0"/>
            <GradientEntry ratio="1"/>
          </LinearGradient>
        </fill>
        <stroke>
          <SolidColorStroke
            color="#0000ff"
            caps="none"
            weight="1"
            joints="miter"
            miterLimit="4"/>
        </stroke>
      </Rect>
    </Group>
  </Group>
  <Private>
    <ai:PrivateElement d:ref="#1">
      <ai:SaveOptions>
        <ai:Dictionary>
          <ai:DictEntry name="preserveGradientPolicy" value="3" valueType="Integer"/>
          <ai:DictEntry name="rasterizeResolution" value="72" valueType="Integer"/>

          <ai:DictEntry name="preserveTextPolicy" value="3" valueType="Integer"/>
          <ai:DictEntry name="writeImages" value="1" valueType="Boolean"/>
          <ai:DictEntry name="includeXMP" value="0" valueType="Boolean"/>
          <ai:DictEntry name="aiEditCap" value="1" valueType="Boolean"/>
          <ai:DictEntry name="versionKey" value="1" valueType="Integer"/>
          <ai:DictEntry name="includeSymbol" value="0" valueType="Boolean"/>
        </ai:Dictionary>
      </ai:SaveOptions>
      <ai:DocData base="SimpleBox.assets/images"/>
      <ai:Artboards
        originOffsetH="0"
        originOffsetV="30"
        rulerCanvasDiffH="50.5"
        rulerCanvasDiffV="-14.5"
        zoom="17.17">
        <ai:Artboard active="1" index="0" right="100" top="30"/>
        <ai:ArtboardsParam all="0" range="" type="0"/>
      </ai:Artboards>
    </ai:PrivateElement>
    <ai:PrivateElement d:ref="#2">
      <ai:LayerOptions colorType="ThreeColor">
        <ai:ThreeColor blue="257" green="128.502" red="79.31"/>
      </ai:LayerOptions>
    </ai:PrivateElement>
    <ai:PrivateElement
        ai:hashcode="769d7bac08ad6bdcf80f40fca11df6c0"
        d:ref="#3">
      <ai:Rect height="30" knockout="0" width="100" x="0.5" y="0.5">
        <ai:Stroke colorType="ThreeColor" miterLimit="4" weight="1">
          <ai:ThreeColor blue="1"/>
        </ai:Stroke>
        <ai:Fill colorType="Gradient">
          <ai:Gradient
            gradientType="linear"
            length="100" originX="0.5"
            originY="15.5">
            <ai:GradientStops>
              <ai:GradientStop colorType="GrayColor" rampPoint="0">
                <ai:GrayColor/>
              </ai:GradientStop>
              <ai:GradientStop colorType="GrayColor" rampPoint="100">
                <ai:GrayColor gray="1"/>
              </ai:GradientStop>
            </ai:GradientStops>
          </ai:Gradient>
        </ai:Fill>
        <ai:ArtStyle/>
      </ai:Rect>
    </ai:PrivateElement>
  </Private>
</Graphic>
```

To convert this example to MXML graphics:

- Remove the `<Library/>` tag. This example does not contain any `<Definition>` elements.
- Remove the `<Private>` block.
- Move the two Illustrator-specific namespaces to the application's root tag:

  ```
  xmlns:ai="http://ns.adobe.com/ai/2008"
  xmlns:d="http://ns.adobe.com/fxg/2008/dt"
  ```

- Remove the FXG-specific namespace:

  ```
  "http://ns.adobe.com/fxg/2008"
  ```

- Add the "s:" prefix to all elements.
- Because the "d" and "ai" namespace definitions are intact, you do not have to remove the attributes specific to these namespaces. The attributes `type` and `userLabel`, for example, appear on the `<Group>` tag from the original FXG file. To further simplify this example, though, you could remove them because Flex ignores anything in those namespaces.

For example, this:

```
<s:Group x="-0.296875" y="-0.5" d:id="2" d:type="layer" d:userLabel="Layer 1">
```

Becomes this:

```
<s:Group x="-0.296875" y="-0.5">
```

The following example application contains the converted FXG from the previous example:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/ResultsMXMLGraphicsApp.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:ai="http://ns.adobe.com/ai/2008"
    xmlns:d="http://ns.adobe.com/fxg/2008/dt">

    <s:Graphic version="1.0"
        viewHeight="30"
        viewWidth="100"
        ai:appVersion="14.0.0.367"
        d:id="1">
      <s:Group x="-0.296875" y="-0.5" d:id="2" d:type="layer" d:userLabel="Layer 1">
        <s:Group d:id="3">
          <s:Rect x="0.5" y="0.5" width="100" height="30" ai:knockout="0">
            <s:fill>
              <s:LinearGradient x="0.5" y="15.5" scaleX="100" rotation="-0">
                <s:GradientEntry color="#ffffff" ratio="0"/>
                <s:GradientEntry ratio="1"/>
              </s:LinearGradient>
            </s:fill>
            <s:stroke>
              <s:SolidColorStroke
                color="#0000ff"
                caps="none"
                weight="1"
                joints="miter"
                miterLimit="4"/>
            </s:stroke>
          </s:Rect>
        </s:Group>
      </s:Group>
    </s:Graphic>
</s:Application>
```

Coordinate systems

FXG defines two coordinate system concepts: the document coordinate system, and the user coordinate system.

The *document coordinate system* refers to the coordinate system of the root tag. By default, its origin sits at the top left of the document, and extends downward along the positive y axis, and to the right along the positive x axis. 1 unit corresponds to 1 pixel on the screen.

The *user coordinate system* refers to the coordinate system defined on any individual tag in the document. In FXG, the user coordinate system at the root `<Graphic>` tag is identical to the document coordinate system.

By default, each grouping instance element and graphic element defines its user coordinate system to be identical to that of its parent. Any geometry transform defined on the tag (through attributes or child transform elements) transforms its parent's user coordinate system into a new system.

All attributes of elements are defined in units of the current user coordinate system. As a result, the coordinates of the segments of a path are relative to its coordinate system. To determine the position of the path segments in document coordinates, you would multiply its x and y by the geometry transform of the path and each of its parent elements until you reached the root graphic tag.

Some fills and strokes have their own user coordinate system. As with Groups, the default coordinate system is aligned with the coordinate system of their most immediate parent instance. As appropriate, fills and strokes support geometry transforms that can modify their coordinate space.

Sizing FXG components

FXG elements use their `height` and `width` properties to determine the size of the graphic. The graphic tag scales to the values of the `height` and `width` properties. The `viewWidth` and `viewHeight` properties define the space that the graphic takes up. When you set these values, the content is not scaled.

If you specify a `viewWidth` and `viewHeight` that is larger than the natural size of the content, the graphic takes up more space than its visual size. The result is a boundary around the graphic.

You can also specify a `viewWidth` and `viewHeight` that is smaller than the natural size of the content. You might do this if your graphic has chrome such as a border that extends past the edges of the graphic. In this case, be sure to turn off clipping in your layout.

Optimizing FXG

Use the techniques described in this section when working with FXG.

Composite path versus rounded rectangle

Composite paths create a cleaner look because there are no extra pixels inside the corners. Rounded rectangles, on the other hand, have extra pixels due to anti-aliasing. Rounded rectangles convert to a `<Rect>` element in FXG, which is preferable because a `<Rect>` element is easier to manipulate than a compex path.

Move alpha values from the element to the fill or stroke

When exporting FXG files from a graphics editor, the `alpha` property is sometimes placed on the graphic element tag. If you convert the FXG to MXML, this element uses its own DisplayObject, which can be computationally expensive. To avoid this, move any `alpha` properties from the element tag down to the stroke or fill. If both the stroke/fill and the element have `alpha` values, multiply the stroke and fill `alpha` values by the element's `alpha` value. For example, if the stroke and element `alpha` values are both .5, then remove the element's `alpha` property and set the stroke's `alpha` to .25 (.5 x .5).

Round alpha values to 2 decimal places

Exported FXG files sometimes use percentage values for `alpha` values. The visual difference between an `alpha` value with two decimal places and a rounded `alpha` value is negligible. To make your code more readable, round off `alpha` values to 2 decimal places. For example, round an `alpha` value of 0.05882352941176471 to 0.06.

Remove blendMode="normal"

By default on graphic elements, the `blendMode` is "auto". When the `blendMode` property is "auto", Flash Player correctly determines whether the element needs to use the "layer" `blendMode` based on the `alpha` value.

Identifying elements of an FXG file

Sometimes it can be hard to look at FXG tags and determine what that element looks like. An easy way to do this is to copy your FXG into a `<s:Group>` tag in an MXML application. Then, change the x values of each element so that they no longer overlap. For example, if your skin is 45 pixels wide and is comprised of three `<Rect>` elements, increase the `x` value of the second `<Rect>` by 50 and the third `<Rect>` by 100. When you compile and run the application, you can see each layer spread separately.

An alternative is to toggle the `visible` property of different elements so that you can isolate a particular element.

Placing shapes with odd stroke weights (mobile applications only)

For a given shape, strokes straddle the shape edges as opposed to being on the inside or outside of an edge. For example, take a vertical line starting from 0,0 to 0,100 with a 1-pixel wide stroke. That stroke stretches in the x-axis from -.5 to .5. However, because you cannot draw an element at a fractional pixel, Flash Player draws an anti-aliased line 2 pixels wide to approximate the fractional position.

This is true only on mobile applications. For desktop applications, Flash Player pixel-snaps stroke segments.

To counteract this anti-aliasing, place your shapes with odd numbered stroke weights on a half pixel boundary. For example, place a `<Rect>` with a `<SolidColorStroke>` of weight 1 at 10,10 at 10.5,10.5 instead.

An alternative is to leave all of your stroked shapes at integer pixels and shift the entire FXG component by .5 in the x and y positions. If possible, use filled `<Rect>` elements in place of stroked `<Rect>` or `<Line>` elements. If you have a `<Rect>` element with a fill and a stroke, try to split it into two filled `<Rect>` elements This technique works only if the fill is completely opaque. If you have a `<Line>` element, try using a filled `<Rect>` element instead. For example, if you have a horizontal `<Line>` element, create a filled `<Rect>` element with a height equal to the `<Line>` element's stroke weight.

Reduce anti-aliasing due to stage quality

Mobile applications built in Flex are currently limited to using `StageQuality.MEDIUM`. When designing skins using FXG and/or programmatic graphics, watch for anti-aliasing artifacts in rounded corners. The mobile skins mitigate this issue by using FXG Path data with fills instead strokes to draw curves.

To create the appearance of a rounded rectangle at a 1px stroke in Fireworks:

1 Draw a filled rounded rectangle.

2 Copy the rectangle, position it 1px down and to the left of the original rectangle and reduce its width and height by 2px.

3 Select both rectangles, right click and choose Combine Path > Punch.

Use 45 degree angles

Try to keep all angles at 45 degrees. This helps to reduce the visual artifacts from anti-aliasing.

MXML graphics

MXML graphics are a collection of classes that define graphic elements in an application. MXML graphics tags support interactivity. They can be children of any container or group, can be declared as children of the root Application tag, and can be added to the application's display list.

Most MXML graphics classes are in the mx.graphics and spark.primitives packages. These classes include shapes, strokes, colors, fills, and gradients.

MXML graphics tags have an implicit depth order. The order in which elements are defined defines their depth. Each tag is effectively drawn above its previous sibling. Children are drawn above their parents.

The following example uses MXML graphics to draw a filled rectangle:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/GraphicCompMainMXML.mxml -->
<s:Application backgroundColor="0xFFFFFF"
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:Graphic>
         <s:Rect id="rect1" width="200" height="200">
              <s:fill>
                 <s:SolidColor color="0xFFFFCC"/>
              </s:fill>
              <s:stroke>
                 <s:SolidColorStroke color="0x660099" weight="2"/>
              </s:stroke>
         </s:Rect>
    </s:Graphic>
</s:Application>
```

Because the classes that make up MXML graphics are part of the Flex SDK, you can reference them from within ActionScript or from other components. The following example changes the rectangle's color when you click the button:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/ReferenceGraphics.mxml -->
<s:Application backgroundColor="0xFFFFFF"
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>
    <s:Graphic>
         <s:Rect id="rect1" width="200" height="200">
              <s:fill>
                 <s:SolidColor id="sc1" color="0xFFFFCC"/>
              </s:fill>
              <s:stroke>
                 <s:SolidColorStroke color="0x660099" weight="2"/>
              </s:stroke>
         </s:Rect>
    </s:Graphic>

    <s:Button label="Change Color" click="sc1.color=0xCCFFFF"/>
</s:Application>
```

All MXML graphics classes have backing ActionScript implementations. This means that every MXML tag has a corresponding ActionScript class that the compiler maps the tag to during compilation. The table in "Graphics classes and elements" on page 1715 lists the tags and their backing ActionScript classes. You can use the classes in ActionScript directly in your `<fx:Script>` blocks to draw vector based graphics instead of the MXML tags. For more information, see Using the drawing API.

Paths in FXG and MXML graphics

Paths define a filled graphic tag that draws a series of path segments. In vector graphics, a path is a series of points connected by straight or curved line segments. Together the lines form an image.

In FXG, you use a `<Path>` tag to define a vector shape constructed from a set of line segments. The MXML graphics equivalent of the FXG `<Path>` tag is the Path class. In MXML, you use the `<s:Path>` tag.

There are several different types of path segments you can use: line, cubic bezier, and quadratic bezier. Typically, the first tag of a path definition moves the pen to the starting position of the graphic. You then use the segments to draw the lines of the graphic.

To define a series of segments in a path, you use the path's `data` property. You pass this property a series of instructions using shorthand syntax. Each value is preceded by a letter that acts as a segment identifier. The segment identifier indicates which type of segment to draw with the numeric values that follow it.

The following table describes the shorthand syntax used by the Path tag's `data` property:

Segment Type	**Segment Identifier**	**Parameters**	**Example**
Close path	`Z/z`	n/a	`Z` Closes off the path.
Cubic Bezier	`C/c`	`c1X c1Y c2X c2Y x y`	`C 45 50 20 30 10 20` Curve to (10, 20), with the first control point at (45, 50) and the second control point at (20, 30).
Cubic Bezier (without control points)	`S/s`	`c2X c2Y x y`	S 20 30 10 20 Curve to (10, 20), with the second control point at (20, 30). The first control point is assumed to be the reflection of the second control point on the previous command relative to the current point.
Horizontal line	`H/h`	`x`	`H 100` Horizontal line to 100.
Line	`L/l`	`x y`	`L 50 30` Line to (50, 30).
Move	`M/m`	`x y`	`M 10 20` Move pen position to (10, 20).
Quadratic Bezier	`Q/q`	`cX cY x y`	`Q 110 45 90 30` Curve to (90, 30) with the control point at (110, 45).
Quadratic Bezier (without control points)	T/t	x y	T 90 30 Curve to (90, 30). The control point is the reflection of the control point on the previous command relative to the current point.
Vertical line	`V/v`	`y`	`V 100` Vertical line to 100.

You can use an uppercase or lowercase letter for the segment identifiers. If you specify a segment identifier using the uppercase letter, then the positioning is absolute. If you specify a segment identifier using the lowercase letter, then the positioning is relative.

When using segments, you do not need to specify the starting position of the pen; the x and y coordinate of the starting point is defined by the current pen position.

After drawing a line segment, the current pen position becomes the x and y coordinates of the end point of the line. You can use the Move segment type to reposition the pen without drawing a line.

The Path syntax is nearly identical to the SVG path syntax. This makes it easy to convert SVG paths to FXG or MXML graphics. There is one exception: FXG and MXML graphics do not support an “A” or Arc segment. To create an arc (elliptical, parabolic, or otherwise), use the the cubic Bezier and quadratic Bezier control points to achieve any sort of arc.

Paths can contain effects such as transforms, filters, blend modes, and masks.

FXG examples

The following example uses the `<Path>` tag to draw a rectangle in FXG:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/SimplePathShorthandExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:comps="comps.*">
     <s:Panel title="Rectangle Example" height="75%" width="75%">
           <comps:SimplePathComp x="10" y="10"/>
     </s:Panel>
</s:Application>
```

The following is the FXG component that is used by the previous example:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/comps/SimplePathComp.fxg -->
<fx:Graphic xmlns:fx="http://ns.adobe.com/fxg/2008" version="2">
    <!-- Use shorthand syntax to draw the rectangle. -->
    <fx:Path data="M 0 0 L 0 100 L 100 100 L 100 0 L 0 0">
         <!-- Define the border color of the rectangle. -->
         <fx:stroke>
              <fx:SolidColorStroke color="#888888"/>
         </fx:stroke>
    </fx:Path>
</fx:Graphic>
```

The following example draws two arrows in FXG, one in relative coordinates and one in absolute coordinates.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/ArrowExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:comps="comps.*">

     <mx:Panel title="Arrow Graphic Example"
        height="75%" width="75%" layout="horizontal"
        paddingTop="10" paddingBottom="10" paddingLeft="10" paddingRight="10">
          <s:HGroup>
              <!-- Use the ArrowAbsolute FXG component which uses absolute coordinates. -->
               <comps:ArrowAbsolute/>

              <!-- Use the ArrowRelative FXG component which uses relative coordinates. -->
               <comps:ArrowRelative/>
          </s:HGroup>
     </mx:Panel>
</s:Application>
```

The following file defines an arrow graphic as an FXG graphic using absolute coordinates:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/comps/ArrowAbsolute.fxg -->
<Graphic xmlns="http://ns.adobe.com/fxg/2008" version="2">
    <!-- Use Use compact syntax with absolute coordinates. -->
    <Path data="
         M 20 0
         C 50 0 50 35 20 35
         L 15 35
         L 15 45
         L 0 32
         L 15 19
         L 15 29
         L 20 29
         C 44 29 44 6 20 6">
         <!-- Define the border color of the arrow. -->
         <stroke>
              <SolidColorStroke color="#888888"/>
         </stroke>
         <!-- Define the fill for the arrow. -->
         <fill>
              <LinearGradient rotation="90">
                   <GradientEntry color="#000000" alpha="0.8"/>
                   <GradientEntry color="#FFFFFF" alpha="0.8"/>
              </LinearGradient>
         </fill>
    </Path>
</Graphic>
```

The following file defines an arrow graphic as an FXG graphic using relative coordinates:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/comps/ArrowRelative.fxg -->
<Graphic xmlns="http://ns.adobe.com/fxg/2008" version="2">
    <!-- Use compact syntax with relative coordinates. -->
    <Path data="
              m 20 0
              c 30 0 30 35 0 35
              l -5 0
              l 0 10
              l -15 -13
              l 15 -13
              l 0 10
              l 5 0
              c 24 0 24 -23 0 -23">
         <!-- Define the border color of the arrow. -->
         <stroke>
              <SolidColorStroke color="#888888"/>
         </stroke>
         <!-- Define the fill for the arrow. -->
         <fill>
              <LinearGradient rotation="90">
                   <GradientEntry color="#000000" alpha="0.8"/>
                   <GradientEntry color="#FFFFFF" alpha="0.8"/>
              </LinearGradient>
         </fill>
    </Path>
</Graphic>
```

MXML graphics examples

The following MXML graphics example uses the `<s:Path>` tag to draw a rectangle:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/SimplePathShorthandExampleMXML.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark">
     <s:Panel title="Rectangle MXML Graphics Example" height="75%" width="75%">
        <s:Path x="10" y="10" data="M 0 0 L 0 100 L 100 100 L 100 0 L 0 0">
             <!-- Define the border color of the rectangle. -->
             <s:stroke>
                  <s:SolidColorStroke color="0x888888"/>
             </s:stroke>
        </s:Path>
     </s:Panel>
</s:Application>
```

The following MXML graphics example defines two arrows, one with relative and the other with absolute positioning:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/ArrowExampleMXML.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:comps="comps.*">

     <mx:Panel title="Arrow MXML Graphics Example"
        height="75%" width="75%" layout="horizontal"
        paddingTop="10" paddingBottom="10" paddingLeft="10" paddingRight="10">
          <s:HGroup>
              <!-- Use absolute coordinates. -->
                <s:Graphic>
                    <!-- Use Use compact syntax with absolute coordinates. -->
                    <s:Path data="
                         M 20 0
                         C 50 0 50 35 20 35
                         L 15 35
                         L 15 45
                         L 0 32
                         L 15 19
                         L 15 29
                         L 20 29
                         C 44 29 44 6 20 6">
                         <!-- Define the border color of the arrow. -->
                         <s:stroke>
                              <s:SolidColorStroke color="0x888888"/>
                         </s:stroke>
                         <!-- Define the fill for the arrow. -->
                         <s:fill>
                              <s:LinearGradient rotation="90">
                                   <s:GradientEntry color="0x000000" alpha="0.8"/>
                                   <s:GradientEntry color="0xFFFFFF" alpha="0.8"/>
                              </s:LinearGradient>
                         </s:fill>
                    </s:Path>
                </s:Graphic>
              <!-- Use relative coordinates. -->
                <s:Graphic>
                    <!-- Use compact syntax with relative coordinates. -->
                    <s:Path data="
                              m 20 0
                              c 30 0 30 35 0 35
                              l -5 0
                              l 0 10
                              l -15 -13
```

```
                                        l 15 -13
                                        l 0 10
                                        l 5 0
                                        c 24 0 24 -23 0 -23">
                                   <!-- Define the border color of the arrow. -->
                                   <s:stroke>
                                        <s:SolidColorStroke color="0x888888"/>
                                   </s:stroke>
                                   <!-- Define the fill for the arrow. -->
                                   <s:fill>
                                        <s:LinearGradient rotation="90">
                                             <s:GradientEntry color="0x000000" alpha="0.8"/>
                                             <s:GradientEntry color="0xFFFFFF" alpha="0.8"/>
                                        </s:LinearGradient>
                                   </s:fill>
                              </s:Path>
                         </s:Graphic>
                   </s:HGroup>
     </mx:Panel>
</s:Application>
```

Libraries and symbols in FXG and MXML graphics

A symbol is a named grouping tag that can be made up of other symbols and graphic elements. You can define a symbol once and reuse it any number of times in an FXG document by using the `<Library>` and `<Definition>` elements. In MXML graphics, you use the MXML file's `<fx:Library>` and `<fx:Definition>` tags.

In FXG, the `<Library>` tag contains `<Definition>` elements. The `<Library>` tag can only be placed as a child of the root tag of an FXG document, just as the `<fx:Library>` tag can only be a child of the root tag in an MXML file. Symbols defined in a library can be referenced by name anywhere in the document.

In FXG, the `<Library>` tag must be the first child of the root tag.

The FXG `<Definition>` tag and the MXML `<fx:Definition>` tag can contain only a Group or other symbols. You cannot nest definitions, as the following example shows:

```
<!-- This is illegal. -->
<Library>
    <Definition name="A">
        <Definition name="B"/>
    </Definition>
</Library>
```

You can, however, reference symbols inside definitions. Symbols can be used anywhere a Group can be used, as the following example shows:

```
<!-- This is OK. -->
<Library>
    <Definition name="A/>
    <Definition name="B">
        <A/>
    </Definition>
</Library>
```

All attributes that are legal on an instance group are also legal on a symbol.

Libraries can have any number of definitions. Each definition defines a named symbol that you can reuse in that document. For example, you can define a rectangle shape in your library, and then use that rectangle shape any number of times in the document. The named symbol can optionally contain effects such as color transforms, filters, blend modes, or masks. These elements can appear in any order in FXG.

For more information about using the `<fx:Library>` and `<fx:Definition>` language tags in MXML, see *ActionScript 3.0 Reference for the Adobe Flash Platform*.

FXG examples

The following example uses three FXG components. Each component includes a library definition of an object, and uses that tag multiple times to make up its shape.

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/LibraryExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:comps="comps.*">
     <mx:Panel title="Library Example"
        height="75%" width="75%" layout="horizontal"
        paddingTop="10" paddingBottom="10" paddingLeft="10" paddingRight="10">
          <s:VGroup>
            <comps:YellowShape/>
            <comps:BlueShape/>
            <comps:RedShape/>
          </s:VGroup>
     </mx:Panel>
</s:Application>
```

The following file defines the YellowShape FXG component used in the previous example:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/comps/YellowShape.fxg -->
<Graphic xmlns="http://ns.adobe.com/fxg/2008" version="2">
     <Library>
          <Definition name="YellowRect">
               <Group>
                   <Rect height="10" width="10">
                         <stroke>
                              <SolidColorStroke color="#000000" weight=".5"/>
                         </stroke>
                         <fill>
                              <SolidColor color="#FFFF00"/>
                         </fill>
                   </Rect>
                </Group>
          </Definition>
     </Library>
     <YellowRect x="0" y="0"/>
     <YellowRect x="0" y="12"/>
     <YellowRect x="12" y="0"/>
     <YellowRect x="12" y="12"/>
</Graphic>
```

The following file defines the BlueShape FXG component used in the previous example:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/comps/BlueShape.fxg -->
<Graphic xmlns="http://ns.adobe.com/fxg/2008" version="2">
     <Library>
          <Definition name="BlueRect">
               <Group>
                   <Rect height="10" width="10">
                         <stroke>
                              <SolidColorStroke color="#000000" weight=".5"/>
                         </stroke>
                         <fill>
                              <SolidColor color="#66CCFF"/>
                         </fill>
                   </Rect>
                </Group>
          </Definition>
     </Library>
     <BlueRect x="0" y="0"/>
     <BlueRect x="12" y="0"/>
     <BlueRect x="24" y="0"/>
     <BlueRect x="36" y="0"/>
</Graphic>
```

The following file defines the RedShape FXG component used in the previous example:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/comps/RedShape.fxg -->
<Graphic xmlns="http://ns.adobe.com/fxg/2008" version="2">
     <Library>
          <Definition name="RedRect">
               <Group>
                   <Rect height="10" width="10">
                         <stroke>
                              <SolidColorStroke color="#000000" weight=".5"/>
                         </stroke>
                         <fill>
                              <SolidColor color="#FF3333"/>
                         </fill>
                   </Rect>
                </Group>
          </Definition>
     </Library>
     <RedRect x="0" y="0"/>
     <RedRect x="12" y="0"/>
     <RedRect x="12" y="12"/>
     <RedRect x="24" y="12"/>
</Graphic>
```

MXML graphics examples

The following example draws three groups of shapes using MXML graphics that are defined in the library:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/LibraryExampleMXML.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:comps="comps.*">
     <fx:Library>
          <fx:Definition name="YellowRect">
               <s:Group>
                   <s:Rect height="10" width="10">
                         <s:stroke>
                              <s:SolidColorStroke color="#000000" weight=".5"/>
                         </s:stroke>
                         <s:fill>
                              <s:SolidColor color="#FFFF00"/>
                         </s:fill>
                   </s:Rect>
                </s:Group>
          </fx:Definition>
          <fx:Definition name="BlueRect">
               <s:Group>
                   <s:Rect height="10" width="10">
                         <s:stroke>
                              <s:SolidColorStroke color="#000000" weight=".5"/>
                         </s:stroke>
                         <s:fill>
                              <s:SolidColor color="#66CCFF"/>
                         </s:fill>
                   </s:Rect>
                </s:Group>
          </fx:Definition>
          <fx:Definition name="RedRect">
               <s:Group>
                   <s:Rect height="10" width="10">
                         <s:stroke>
                              <s:SolidColorStroke color="#000000" weight=".5"/>
                         </s:stroke>
                         <s:fill>
                              <s:SolidColor color="#FF3333"/>
                         </s:fill>
                   </s:Rect>
                </s:Group>
          </fx:Definition>
     </fx:Library>
     <mx:Panel title="Library MXML Graphic Example"
        height="75%" width="75%" layout="horizontal"
        paddingTop="10" paddingBottom="10" paddingLeft="10" paddingRight="10">
          <s:VGroup>
            <s:Graphic>
             <fx:YellowRect x="0" y="0"/>
             <fx:YellowRect x="0" y="12"/>
             <fx:YellowRect x="12" y="0"/>
             <fx:YellowRect x="12" y="12"/>
            </s:Graphic>
            <s:Graphic>
             <fx:BlueRect x="0" y="0"/>
             <fx:BlueRect x="12" y="0"/>
             <fx:BlueRect x="24" y="0"/>
             <fx:BlueRect x="36" y="0"/>
            </s:Graphic>

            <s:Graphic>
             <fx:RedRect x="0" y="0"/>
             <fx:RedRect x="12" y="0"/>
             <fx:RedRect x="12" y="12"/>
             <fx:RedRect x="24" y="12"/>
            </s:Graphic>

     </s:VGroup>
     </mx:Panel>
</s:Application>
```

Groups in FXG and MXML graphics

Groups contain content items. In MXML, these items are typically of type IGraphicElement (the base interface class for graphic elements), but can also include effects such as the `<transform>`, `<filters>`, `<mask>` elements, and other `<Group>` elements. In MXML graphics, items inside a group can be any MXML tags.

You define a group in an FXG document by using the `<Group>` tag. In MXML graphics, you use the `<s:Group>` tag, which corresponds to the Group class. This class implements the IGraphicElementContainer interface.

The order of graphical objects inside a group determines their depth order when rendered. The last object defined in a group is the top-most tag of the depth order.

A group can be inside a graphic or another group. When a group is inside a graphic or other group, it is considered an instance group. Instance groups can optionally contain features such as transforms, filters, and masks. The order that these children appear does not matter. Graphical effects such as these are rendered based on a predefined order, as described in "Effects in FXG and MXML graphics" on page 1776.

A Group can also be used inside a definition in the library section. When a group is inside a definition, it is considered a symbol definition. Groups inside libraries (symbol definition groups) cannot contain effects such as masks or transforms.

A group defines a new local coordinate space for its immediate child elements.

For more information about using the `<s:Group>` tag in MXML, see the *ActionScript 3.0 Reference for the Adobe Flash Platform*.

FXG example

The following FXG example uses the YellowShape FXG component:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/GroupCoordinateExample.mxml -->
<s:Application
    xmlns:fx="http://ns.adobe.com/mxml/2009"
    xmlns:mx="library://ns.adobe.com/flex/mx"
    xmlns:s="library://ns.adobe.com/flex/spark"
    xmlns:comps="comps.*">
    <s:layout>
        <s:VerticalLayout/>
    </s:layout>

     <mx:Panel title="Group Coordinate Example"
        height="75%" width="75%" layout="horizontal"
        paddingTop="10" paddingBottom="10" paddingLeft="10" paddingRight="10">
       <s:Group>
            <comps:YellowShape/>
       </s:Group>
     </mx:Panel>
</s:Application>
```

The following file defines the YellowShape FXG component used in the previous example. The component is defined in a `<Group>` tag inside a `<Library>`, which means it is a symbol definition group:

```
<?xml version="1.0" encoding="utf-8"?>
<!-- fxg/comps/YellowShape.fxg -->
<Graphic xmlns="http://ns.adobe.com/fxg/2008" version="2">
     <Library>
